Fig. 3 Distribution of Radial Stress σ_r, for $\frac{a}{r_0} = 0.150$

applied radial stress as is implied when one neglects that portion of the length of the shaft beyond the ring over which the applied radial stress is distributed.

The distribution of tangential stress σ_θ has been plotted in Fig. 4 for the same ratio of $\frac{a}{r_0}$ (= 0.150). Note that at the center of

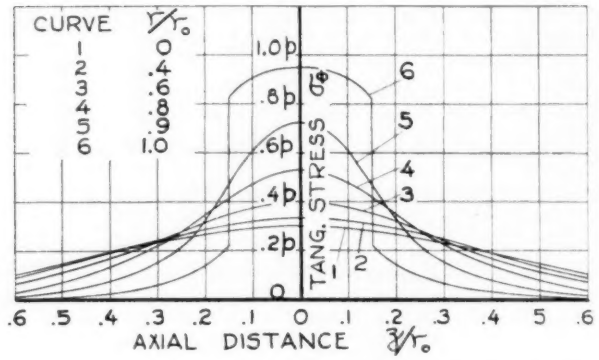

FIG. 4 DISTRIBUTION OF TANGENTIAL STRESS σ_θ, FOR $\frac{a}{r_0} = 0.150$

the shaft σ_θ is reduced to only 30 per cent of the applied radial stress; note also that on the surface of the shaft σ_θ is discontinuous at the lines of discontinuity of the applied radial stress.

The distribution of axial stress σ_z has been plotted in Fig. 5 $\left(\text{for } \frac{a}{r_0} = 0.150\right)$, and the rapidity with which σ_z changes magnitude may be seen by noting that σ_z has decreased from its maximum value (at $r = r_0$) to zero and has changed sign all within the outer 15 per cent of the shaft radius. The axial stress is actually discontinuous on the surface $r = r_0$ at the lines of discontinuity of the applied radial stress, changing from the maximum positive value to the maximum negative value at this point.

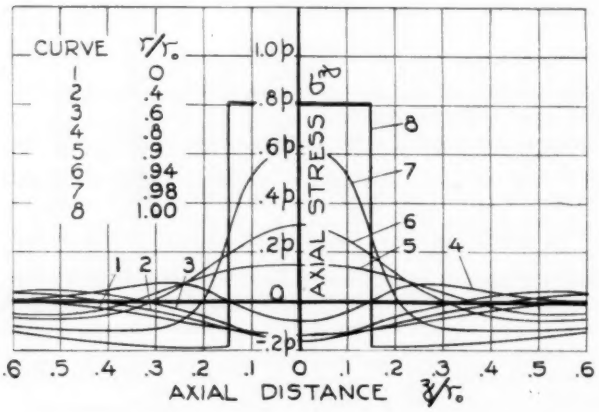

FIG. 5 DISTRIBUTION OF AXIAL STRESS σ_z, FOR $\frac{a}{r_0} = 0.150$

The distribution of shear stress τ_{rz} has been plotted in Fig. 6 for the ratio $\frac{a}{r_0} = 0.150$. It may be observed from this figure that the shear stress is zero for the center of the shaft, and is also zero at the shaft surface $r = r_0$ with the exception of the lines of discontinuity of the applied radial stress; at the latter lines, for $r = r_0$, the shear stress reaches its maximum value of $\pm \frac{p}{\pi}$. For intermediate values of r, the shear stress varies from zero, at the cross section representing the center line of the applied radial stress, to a maximum value which approaches $\frac{p}{\pi}$ as r approaches r_0, and then decreases to zero for cross sections remote from the applied radial stress. It is extremely interesting to note that this type of shear pattern, which gives a maximum shear at the surface of the shaft with zero shear at the shaft center line, is remarkably close to the shear patterns given by Timoshenko,[4] which actually apply to short beams under concentrated loads. The parabolic distribution which elementary theory gives for the shear in beams actually applies only to cross sections remote from the applied loads; near the applied loads, the shear in a beam is actually zero at the beam axial center line, and has a maximum value which approaches the outer surface of the beam as the point of application of the applied load is approached.

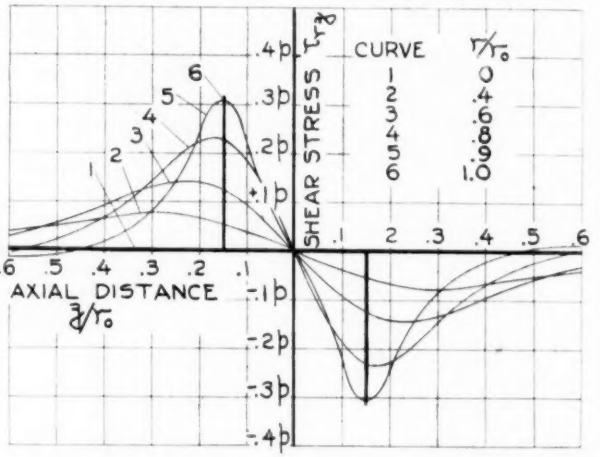

FIG. 6 DISTRIBUTION OF SHEAR STRESS τ_{rz}, FOR $\frac{a}{r_0} = 0.150$

Plotted in Fig. 7 are the stress trajectories formed by one of the principal stresses. These trajectories serve to illustrate clearly how the stress flows axially along the shaft so that the length of the latter external to the applied radial stress also tends to carry some of the load.

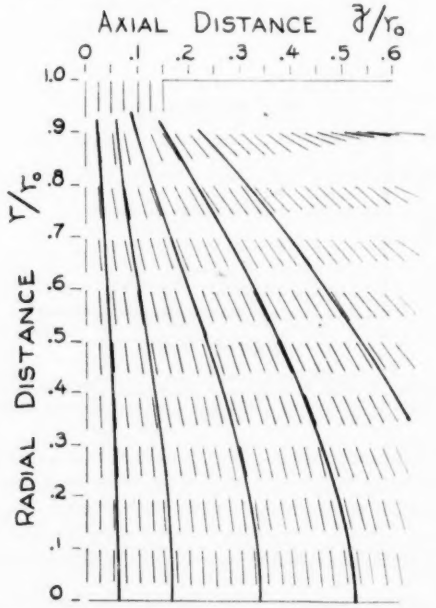

FIG. 7 DIRECTIONS OF ONE PRINCIPAL STRESS, AND STRESS TRAJECTORIES, FOR $\frac{a}{r_0} = 0.150$

[4] Bibliography, ref. (1), p. 49.

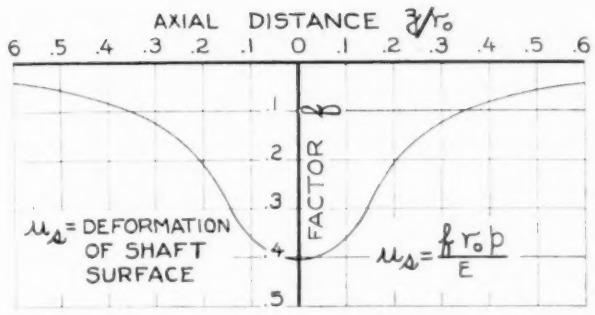

FIG. 8 DEFORMATION OF SHAFT SURFACE, FOR $\frac{a}{r_0} = 0.150$, PLOTTED AGAINST z/r_0

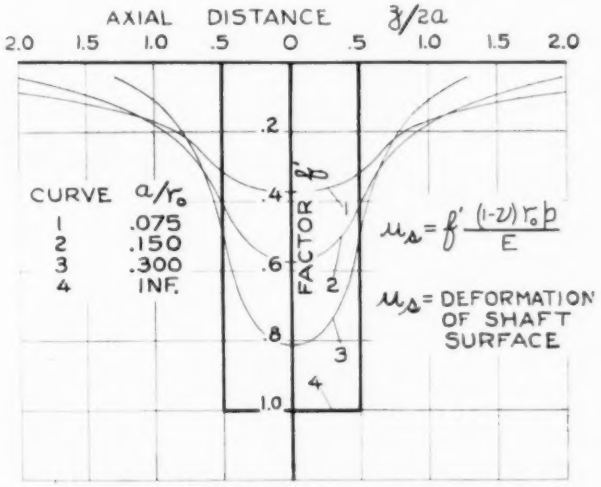

FIG. 9 DEFORMATION OF SHAFT SURFACE, FOR VARIOUS VALUES OF $\frac{a}{r_0}$, PLOTTED AGAINST $z/2a$

The radial deformation for the case of axial symmetry is given by

$$u = \frac{r}{E}\left[\sigma_\theta - \nu(\sigma_z + \sigma_r)\right] \quad \ldots\ldots\ldots\ldots\ldots [7]$$

and the deformation of the shaft surface has been plotted in Fig. 8 from this equation. Fig. 8 gives the shaft surface deformation, for the ratio $a/r_0 = 0.150$, plotted against z/r_0. In Fig. 9, the deformation of the shaft surface has been plotted for several values of a/r_0, but in this figure the plotting is against the axial distance $z/2a$.

In Figs. 10 to 13, inclusive, have been plotted the stress components whose use has been described in the section headed "Results" and whose derivation is given in the appendix. To illustrate numerically the use of these stress components, assume that σ_r is desired for the following point:

$$\frac{r}{r_0} = 0.80 \qquad \frac{a}{r_0} = 0.150 \qquad \frac{z}{r_0} = 0.20$$

then

$$m_1 = 0.15 + 0.20 = +0.35 \qquad \bar{\sigma}_r\left(\begin{matrix} m_1 = +0.35 \\ \frac{r}{r_0} = 0.80 \end{matrix}\right) = +0.48p$$

$$m_2 = 0.15 - 0.20 = -0.05 \qquad \bar{\sigma}_r\left(\begin{matrix} m_2 = -0.05 \\ \frac{r}{r_0} = 0.80 \end{matrix}\right) = -0.15p$$

$$\therefore \bar{\sigma}_r\left(\frac{r}{r_0} = 0.80;\ \frac{a}{r_0} = 0.150;\ \frac{z}{r_0} = 0.20\right) = +0.48p - 0.15p = +0.33p$$

In a similar fashion, σ_r, σ_θ, or σ_z may be plotted for any point within the cylinder. The shear-stress component $\bar{\tau}_{rz}$ is plotted in Fig. 13, and this component differs from $\bar{\sigma}_r$, $\bar{\sigma}_\theta$, and $\bar{\sigma}_z$ in that the integral contains a cosine term, and the sign of $\bar{\tau}_{rz}$ differs from the sign of τ_{rz}: since the integral contains a cosine term, the sign of $\bar{\tau}_{rz}$ is independent of the sign of m_1 or m_2. Assume τ_{rz} is desired for the following point:

$$\frac{r}{r_0} = 0.80 \qquad \frac{a}{r_0} = 0.150 \qquad \frac{z}{r_0} = 0.20$$

then

$$m_1 = 0.15 + 0.20 = +0.35 \qquad \bar{\tau}_{rz}\left(\begin{matrix} m_1 = +0.35 \\ \frac{r}{r_0} = 0.80 \end{matrix}\right) = +0.02p$$

$$m_2 = 0.15 - 0.20 = -0.05 \qquad \bar{\tau}_{rz}\left(\begin{matrix} m_2 = -0.05 \\ \frac{r}{r_0} = 0.80 \end{matrix}\right) = -0.21p$$

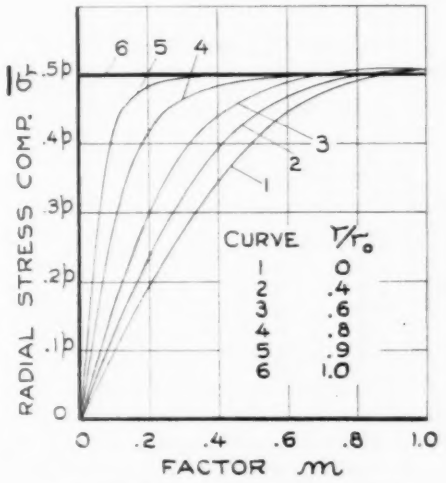

FIG. 10 RADIAL-STRESS COMPONENT $\bar{\sigma}_r$

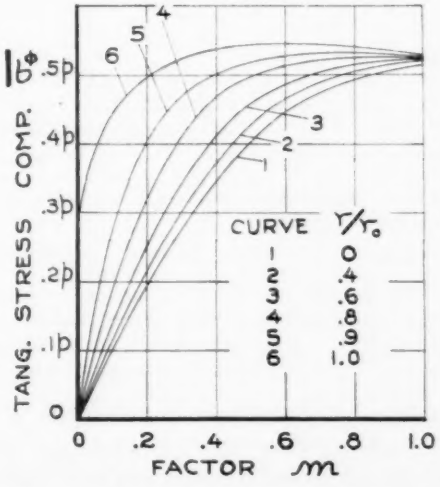

FIG. 11 TANGENTIAL-STRESS COMPONENT $\bar{\sigma}_\theta$

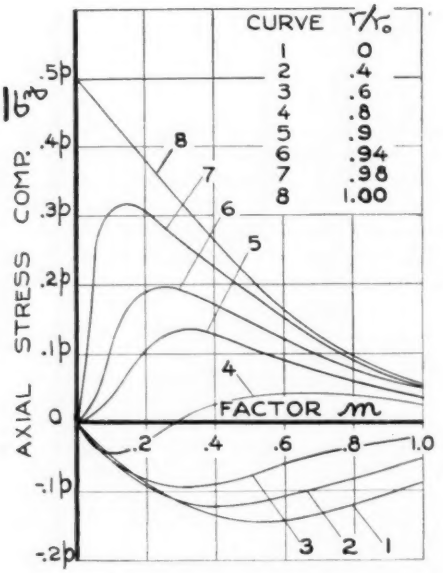

FIG. 12 AXIAL-STRESS COMPONENT $\bar{\sigma}_z$

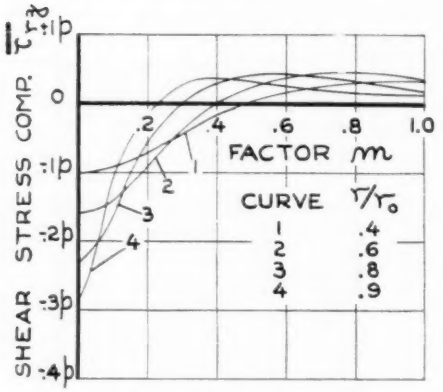

FIG. 13 SHEAR-STRESS COMPONENT $\bar{\tau}_{rz}$

(For $r = 0$, $\bar{\tau}_{rz}$ is zero for all values of m; for $r = r_0$ τ_{rz} is zero for all values of m except $m = 0$ at which point $\bar{\tau}_{rz} = -0.318p$.)

$$\therefore \tau_{rz}\left(\frac{r}{r_0} = 0.80;\ \frac{a}{r_0} = 0.15;\ \frac{z}{r_0} = 0.20\right) = -0.02p - 0.21p$$

$$= -0.23p$$

From the $\bar{\sigma}_r$ and $\bar{\sigma}_\theta$ curves, it is interesting to note than σ_r and σ_θ may both reach values exceeding the applied radial stress p. In Fig. 11, note that it is possible for the tangential stress to reach a value about 9 per cent greater than the applied radial stress p. This maximum is reached for a value of $\frac{a}{r_0} = 0.60$ and occurs at the surface $r = r_0$. For greater values of $\frac{a}{r_0}$, σ_θ decreases to its limiting value of unity, which value is approached for all points within the shaft. This limiting value is the value to be expected from the analysis of a long solid shaft subjected to an applied radial stress over its entire surface. It might also be noted that for large ratios of $\frac{a}{r_0}$ or for points on the shaft remote from the applied stress, the tangential stress can change sign and become negative; this may be seen by noting that the $\bar{\sigma}_r$ curves have a maximum value at the point $m = 0.6$. This reversal of tangential stress is similar to the reversals of stress which may be noted when subjecting a beam on an elastic foundation to a concentrated load.

From the $\bar{\sigma}_r$ curves (Fig. 10), it may be seen that it is possible for σ_r to exceed the applied radial stress p; the excess, however, is small and occurs at some point below the shaft surface.

It will be noted that all the stress-component curves are plotted only to the value $m = 1.0$. Beyond this value of m, however, the stress components are sufficiently close to their limiting values so that the latter may be used. These curves are consequently approximately valid for all values of the ratio $\frac{a}{r_0}$, but if the stresses are desired only on the shaft cross section at the center of the applied radial stress, the stress-component curves indicate that the analysis of a long solid cylinder with an applied radial stress over the entire surface may be used if $\frac{a}{r_0}$ becomes greater than unity.

TEST RESULTS

In order to check the validity of the results presented by this analysis, several tests were conducted in which the deformation of the surface of a shaft subjected to a shrink pressure was accurately measured. No attempt was made to measure the shaft-surface deformations under the shrink rings; only the shaft-surface deformations external but closely adjacent to the shrink rings were measured. As shown in Figs. 14 and 16, the theoretical results were closely duplicated.

For the first test, a solid steel shaft 4 in. diam and 8 in. long was obtained, and the surface accurately mapped by an electric gage[5] of the type described by Hathaway and Lee (5), and Kuehni (6). A steel ring of $^5/_8$ in. axial length and with a shrink of 9.5 mils on the diameter was then shrunk on the shaft, and, after cooling, the shaft surface was again accurately mapped. The shaft was sufficiently long that points could be obtained at a distance so remote from the shrink ring that no effects of the shrink

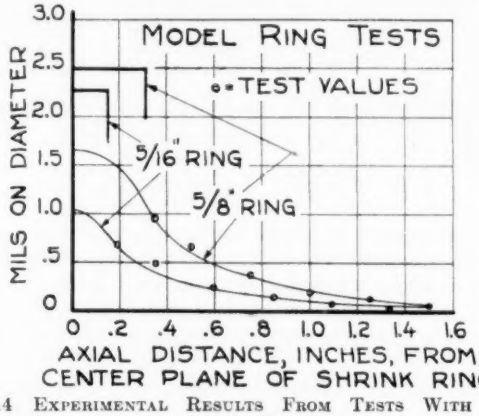

FIG. 14 EXPERIMENTAL RESULTS FROM TESTS WITH MODEL SHRINK RINGS

pressure could be observed, and these points could be used as reference levels to correlate the surface mappings with and without the shrink rings. As a consequence, the shaft-surface deformation due to the shrink ring could be obtained very accurately.

The test results obtained with the $^5/_8$-in. shrink ring are shown in Fig. 14; also shown in this figure are the test results obtained when a ring of $^5/_{16}$ in. axial length was substituted for the $^5/_8$-in. ring. The shrink on the $^5/_{16}$-in. ring was only 8.6 mils in place of the 9.5 mils of the $^5/_8$-in. ring. The two lower curves in Fig. 14

[5] The elements of this electric gage were developed by the company by whom the writer is employed and are used in the well-known precision Electrolimit gages of the Pratt and Whitney Division of the Niles-Bement-Pond Company.

were plotted from the analysis presented in this paper, and the correlation between the test and calculated results is surprisingly good. The two rectangular curves, shown in the upper half of Fig. 14, are the shaft-surface deformations calculated by the two-dimensional theory usually employed which ignores the effect of the shaft external to the axial length of the ring. It should be noted that the subject analysis and the test results indicate that the tangential stress in the $^5/_{16}$ in. ring is 20 per cent greater than the usual two-dimensional analysis would show; for the $^5/_8$ in. ring, the tangential stress is 13 per cent greater than the two-dimensional analysis would show. These are average values and do not consider the stress concentrations at the inner edges of the rings.

Fig. 15 is the testing equipment used for the foregoing tests, showing the shaft with the $^5/_{16}$-in. ring in place and resting on a

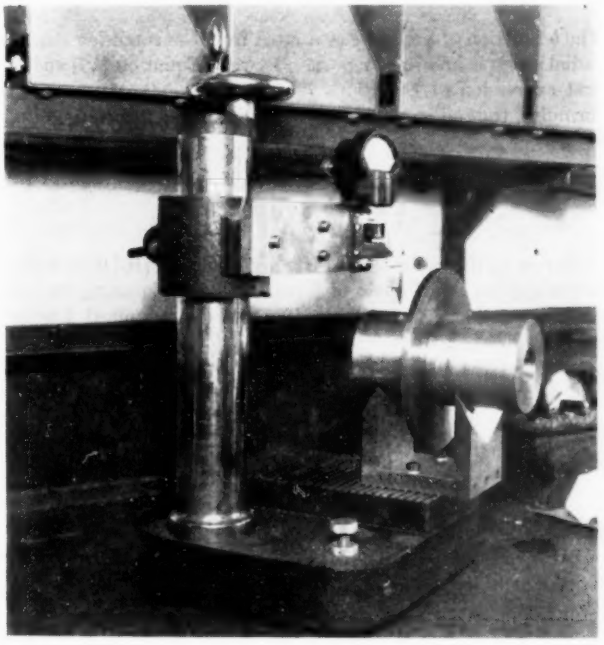

FIG. 15 ELECTRIC GAGE STAND FOR MEASURING SHAFT-SURFACE DEFORMATIONS; MODEL SHAFT WITH $^5/_{16}$-IN. SHRINK RING IN PLACE

Vee-block anvil used as a base. The measuring head of the gage can be seen above the far portion of the shaft, and the indicating meter which gives the surface deformation in tenths of a mil can be seen directly above the measuring head. The major portion of the credit for the gratifying results obtained in the tests must be given to the electric gage. It showed no tendency to drift or exhibit hysteresis and consistently duplicated its readings in a most satisfactory manner.

The results of a third test are shown in Fig. 16. In this test, a turbine shaft of 21 in. diam was used, and a small portion of the shaft between the turbine wheels and an impeller sleeve was closely measured before and after shrinking on the wheels and the sleeve. In Fig. 16, negative values of inches to the left of the zero give distances measured under the turbine wheels; the edge of the impeller sleeve is shown about 4.5 in. to the right of the edge of the last wheel. The dashed horizontal line at 8.2 mils gives the calculated surface deformation under the turbine wheels at a considerable distance to the left of the zero line; the full curve shown is a plot of the surface deformation as calculated by the methods suggested in this paper. The stiffness of the turbine wheels was calculated by the methods shown by S. H. Weaver (7). The test values as obtained are indicated by the small circles, and these values with a 5-F temperature correction are shown by the small crosses. It was necessary to include the latter correction as the shaft felt slightly warm, and factory production schedules prohibited holding the shaft until room temperature had been obtained. Considering that the data shown in Fig. 16 were obtained from factory measurements with a micrometer, and are probably correct only to $^1/_2$ mil, the correspondence between the test values and the calculated curve is satisfying.

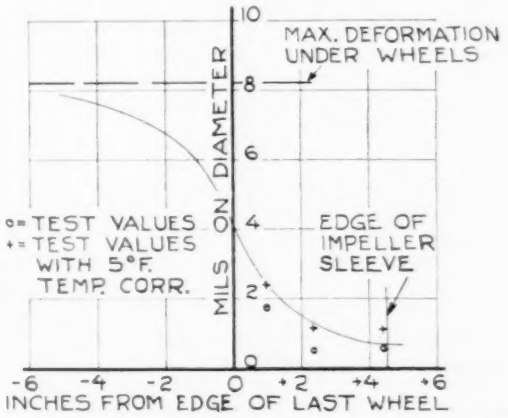

FIG. 16 EXPERIMENTAL RESULTS ON 21-IN-DIAM TURBINE SHAFT

Appendix

STRESS DISTRIBUTION ANALYSIS

It is the purpose of the following analysis to calculate the stress distribution throughout a solid circular cylinder of infinite length due to the action of a radial stress of p units magnitude applied to the surface over a single circumferential band of finite length; the application of this radial stress is shown in Fig. 1.

In order to calculate the stress within the cylinder, it will be necessary to express the applied radial stress p as a Fourier integral; one method of doing this is outlined in reference (8). Applying this method gives the following expression for the applied radial stress of Fig. 1

$$\sigma_r = \frac{2p}{\pi}\int_0^\infty \frac{\sin \lambda a}{\lambda} \cos \lambda z d\lambda \quad \ldots\ldots\ldots [8a]$$

That Equation [8a] actually represents the applied-stress distribution of Fig. 1 may be proved by means of the following definite integral[6]

$$\left.\begin{aligned} \int_0^\infty \frac{\sin mx}{x} dx &= +\frac{\pi}{2} \text{ for } m > 0 \\ &= 0 \text{ for } m = 0 \\ &= -\frac{\pi}{2} \text{ for } m < 0 \end{aligned}\right\} \quad \ldots\ldots\ldots [8b]$$

Rewriting Equation [8a] as the sum of two integrals, there results

$$\sigma_r = \frac{p}{\pi}\int_0^\infty \frac{\sin \lambda (a+z)}{\lambda} d\lambda + \frac{p}{\pi}\int_0^\infty \frac{\sin \lambda (a-z)}{\lambda} d\lambda \quad [8c]$$

Now if $z < a$, m is positive for both integrals of Equation [8c], and the latter reduces to p; if $z = a$, m is positive for the first integral of Equation [8c] and zero for the second, and Equation [8c] reduces to $^1/_2 p$; if $z > a$, m is positive for one integral of

[6] Reference (9), Equation 858.5.

Equation [8c] and negative for the second, and the algebraic sum reduces to zero as needed.

With the applied radial stress given mathematically by Equation [8a], it is now necessary to obtain a solution of the equations of elasticity such that the radial stress reduces to Equation [8a] on the surface. It has been shown[7] that for axially symmetrical stress distribution in a solid of revolution, the equations of equilibrium and the equations of compatibility are all satisfied by a stress function ϕ given by

$$\nabla^4\phi = \nabla^2\nabla^2\phi = 0 \quad [9a]$$

if the stresses are taken as

$$\left.\begin{aligned} \sigma_r &= \frac{\partial}{\partial z}\left(\nu\nabla^2\phi - \frac{\partial^2\phi}{\partial r^2}\right) \\ \sigma_z &= \frac{\partial}{\partial z}\left[(2-\nu)\nabla^2\phi - \frac{\partial^2\phi}{\partial z^2}\right] \\ \sigma_\theta &= \frac{\partial}{\partial z}\left(\nu\nabla^2\phi - \frac{1}{r}\cdot\frac{\partial\phi}{\partial r}\right) \\ \tau_{rz} &= \frac{\partial}{\partial r}\left[(1-\nu)\nabla^2\phi - \frac{\partial^2\phi}{\partial z^2}\right] \end{aligned}\right\} \quad [9b]$$

with

$$\nabla^2 = \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2} \quad [9c]$$

Assume a solution in the form

$$\phi = \int_0^\infty Rb \sin \lambda z d\lambda \quad [10]$$

in which R is a function of r alone, and b is a function of λ alone. Note that λ is merely a new variable which is used only in the integral, Equation [10], and which disappears when the integration is performed; λ has, in itself, no direct physical significance.

Substituting Equation [10] into Equation [9a], the equation for R is obtained as

$$\left(\frac{d^2}{dr^2} + \frac{1}{r}\cdot\frac{d}{dr} - \lambda^2\right)\left(\frac{d^2}{dr^2} + \frac{1}{r}\cdot\frac{d}{dr} - \lambda^2\right)R = 0 \quad [11]$$

The solution of Equation [11] is

$$R = a_0 J_0(i\lambda r) + a_1 i\lambda r\, J_1(i\lambda r) \quad [12]$$

in which J_0 and J_1 are Bessel functions of the zero and first orders, respectively, as defined in reference (9).[8] The symbol i in Equation [12] is $\sqrt{-1}$. It should be noted that the complete solution of Equation [11] contains two Bessel functions of the second kind (K_0 and K_1, as defined in reference (9),[9] as well as the two Bessels of the first kind as given by Equation [12], thereby resulting in the necessary four undetermined constants. The two Bessels of the second kind approach infinity as r approaches zero, however, and since the present problem treats only a solid cylinder with no internal bore hole, it is necessary that the coefficients of the Bessels of the second kind be zero. Equation [12], therefore, is the complete solution of R needed for the present problem.

Defining ρ as the ratio of a_0 to a_1, and removing the $\sqrt{-1}$ from Equation [12] by substituting the modified Bessels defined in the nomenclature, ϕ may be written as

$$\phi = \int_0^\infty [\rho I_0(\lambda r) - \lambda r I_1(\lambda r)]a_1 b \sin \lambda z d\lambda \quad [13]$$

[7] Reference (1), Chapt. 11.
[8] Reference (9), Equations 807.1 and 807.2.
[9] Ibid., Equations 815.1 and 815.2.

Note that a_1 is now grouped with the b function of λ, and the two will be evaluated simultaneously; ρ may be evaluated easily from the condition that there is no shear on the surface $r = r_0$.

Between Equation [13] and the last of Equations [9b], the following expression may be obtained for the shear stress

$$\tau_{rz} = \int_0^\infty \left[\begin{array}{l} \rho\lambda I'_0(\lambda r) - \lambda^2 r I_1'(\lambda r) - \\ \lambda I_1(\lambda r) - 2\lambda(1-\nu)I'_0(\lambda r) \end{array}\right] \lambda^2 a_1 b \sin \lambda z d\lambda \quad [14]$$

in which the prime values indicate differentiation with respect to λr. At $r = r_0$, there is to be no shear; this condition can be satisfied by equating the bracketed term to zero for $r = r_0$. Then, using the Bessel recurrence formulas, given by reference (9), the following expression may be obtained for ρ

$$\rho = 2(1-\nu) + \lambda r_0 \frac{I_0(\lambda r_0)}{I_1(\lambda r_0)} \quad [15]$$

The b function of λ may be evaluated from the condition that the radial stress is known at $r = r_0$. Between Equation [13] and the first expression of Equations [9b], and using Bessel recurrence formulas, the radial stress may be expressed as follows

$$\sigma_r = \int_0^\infty \left[\begin{array}{l} (1-2\nu-\rho)I_0(\lambda r) + \\ \left(\lambda r + \dfrac{\rho}{\lambda r}\right) I_1(\lambda r) \end{array}\right] \lambda^3 a_1 b \cos \lambda z d\lambda \quad [16]$$

At $r = r_0$, the radial stress given by Equation [16] must reduce to the applied radial stress of Equation [8a]. Equating [8a] and [16], the following is obtained for the undetermined function $a_1 b$

$$a_1 b = \frac{\dfrac{2p}{\pi\lambda^4}\sin \lambda a}{\left[\begin{array}{l} (1-2\nu-\rho)\, I_0(\lambda r_0) + \\ \left(\lambda r_0 + \dfrac{\rho}{\lambda r_0}\right) I_1(\lambda r_0) \end{array}\right]} \quad [17]$$

Between Equations [9], [13], [15], and [17], the stresses may be written as follows

$$\sigma_r = \int_0^\infty \frac{\left[\begin{array}{l} (1-2\nu-\rho)I_0(\lambda r) + \\ \left(\lambda r + \dfrac{\rho}{\lambda r}\right) I_1(\lambda r) \end{array}\right]}{\gamma'_{1\cdot 0}} \cdot \frac{2p}{\pi} \cdot \frac{\sin \lambda a \cos \lambda z d\lambda}{\lambda} \quad [18a]$$

$$\sigma_\theta = \int_0^\infty \frac{\left[\begin{array}{l} (1-2\nu)I_0(\lambda r) - \\ \dfrac{\rho}{\lambda r} I_1(\lambda r) \end{array}\right]}{\gamma'_{1\cdot 0}} \cdot \frac{2p}{\pi} \cdot \frac{\sin \lambda a \cos \lambda z d\lambda}{\lambda} \quad [18b]$$

$$\sigma_z = \int_0^\infty \frac{\left[\begin{array}{l} (\rho + 2\nu - 4)I_0(\lambda r) \\ - \lambda r I_1(\lambda r) \end{array}\right]}{\gamma'_{1\cdot 0}} \cdot \frac{2p}{\pi} \cdot \frac{\sin \lambda a \cos \lambda z d\lambda}{\lambda} \quad [18c]$$

$$\tau_{rz} = \int_0^\infty \frac{\left[\begin{array}{l} (\rho + 2\nu - 2)I_1(\lambda r) \\ - \lambda r I_0(\lambda r) \end{array}\right]}{\gamma'_{1\cdot 0}} \cdot \frac{2p}{\pi} \cdot \frac{\sin \lambda a \sin \lambda z d\lambda}{\lambda} \quad [18d]$$

Since the foregoing expressions cannot be integrated, it is necessary to resort to numerical integration, and for this method it is more convenient to rewrite them as follows:

Let the Bessel functions be replaced by the following asymptotic expressions[10]

$$I_0(\lambda r) = \frac{e^{\lambda r}}{\sqrt{2\pi\lambda r}} i_0(\lambda r) \qquad I_1(\lambda r) = \frac{e^{\lambda r}}{\sqrt{2\pi\lambda r}} i_1(\lambda r) \quad . . [19]$$

with

$$i_0(\lambda r) = 1 + \frac{0.12500}{(\lambda r)} + \frac{0.07031}{(\lambda r)^2} + \frac{0.07324}{(\lambda r)^3} + \frac{0.11215}{(\lambda r)^4} + \longrightarrow \ldots\ldots [20a]$$

$$i_1(\lambda r) = 1 - \frac{0.37500}{(\lambda r)} - \frac{0.11719}{(\lambda r)^2} - \frac{0.10254}{(\lambda r)^3} - \frac{0.14420}{(\lambda r)^4} - \longrightarrow \ldots\ldots [20b]$$

σ_r as given by Equation [18a] may now be written as follows

$$\sigma_r = \frac{p}{\pi} \int_0^\infty \frac{\left[(1 - 2\nu - \rho) i_0 \left(\lambda r_0 \frac{r}{r_0} \right) + \left(\lambda r_0 \frac{r}{r_0} + \frac{\rho}{\lambda r_0 \frac{r}{r_0}} \right) i_1 \left(\lambda r_0 \frac{r}{r_0} \right) \right]}{\sqrt{\frac{r}{r_0}} \gamma_{1.0}\, e^{\lambda r_0 \left(1 - \frac{r}{r_0}\right)}} \times \frac{\left[\sin \lambda r_0 \frac{a+z}{r_0} + \sin \lambda r_0 \frac{a-z}{r_0} \right]}{\lambda r_0} d(\lambda r_0) \ldots\ldots [21]$$

Let the stress component $\bar{\sigma}_r$ be defined as follows

$$\bar{\sigma}_r = \frac{p}{\pi} \int_0^\infty \frac{\left[(1 - 2\nu - \rho) i_0 \left(\lambda r_0 \frac{r}{r_0} \right) + \left(\lambda r_0 \frac{r}{r_0} + \frac{\rho}{\lambda r_0 \frac{r}{r_0}} \right) i_1 \left(\lambda r_0 \frac{r}{r_0} \right) \right]}{\sqrt{\frac{r}{r_0}} \gamma_{1.0}\, e^{\lambda r_0 \left(1 - \frac{r}{r_0}\right)}} \times \frac{\sin m\lambda r_0}{\lambda r_0} d(\lambda r_0) \ldots\ldots [22]$$

[10] The values of λr for which these asymptotic expressions yield slow convergence are also sufficiently small so that the limiting values of the integrals may be used directly.

From the two expressions, Equations [21] and [22], σ_r may be evaluated for any point by taking the sum of the two values of $\bar{\sigma}_r$ determined for the two values of m

$$m_1 = \frac{a+z}{r_0} \qquad m_2 = \frac{a-z}{r_0} \ldots\ldots [23]$$

By applying the same reasoning to σ_θ, σ_z, and τ_{rz}, the stress-component relations given by Equation [2] may be derived. Figs. 10 to 13, inclusive, give curves of the stress components versus m, and the actual stresses are obtained from these curves as shown by the numerical examples in the section headed "Stress and Strain Curves, and Discussion." As a matter of note, these curves were obtained by numerical integration using the Si (x) and Ci (x) functions of reference (4).

Acknowledgment

The author expresses his appreciation to the following members of the General Electric Company, Schenectady, New York: to H. D. Taylor of the Turbine Generator Engineering Division for suggesting this problem and for indicating the practical importance of the solution, and for his many valued suggestions; to H. P. Kuehni and A. R. Hand of the General Engineering Laboratory for their assistance and instruction in the use of the electric gage; to R. Patterson of the Turbine Generator Engineering Division for his discussions of the mathematical work and his assistance with the experimental measurements; and to M. A. Savage of the Turbine Generator Engineering Division for suggesting the publication of these results.

Measurement of the Damping of Engineering Materials During Flexural Vibration at Elevated Temperatures

By CARL SCHABTACH[1] and R. O. FEHR,[2] SCHENECTADY, N. Y.

The method and equipment developed and used by the authors for measuring the damping of materials are described. A tuning-fork specimen is set into vibration by jerking a spreader from the gap between the ends of the tines. The damping is expressed in terms of the logarithmic decrement of the decaying vibration, which is measured and recorded by means of a magnetic oscillograph, amplifiers, and a resistance-type electric strain gage cemented to the specimen. The results include (1) the damping of a number of materials during flexural vibration at approximately 1000 cycles per sec, at maximum bending stresses up to 40,000 psi, and at temperatures up to 1400 F; (2) the variation in modulus of elasticity with temperature, as determined from the specimen vibration frequencies.

Introduction

THE damping of a material is a measure of its ability to dissipate energy when subjected to fluctuating stresses. (The terms "internal friction," "mechanical hysteresis," "damping capacity," and "specific damping capacity" are used also to describe this property.) Fluctuating stresses in machine or structural elements may reach destructive size under resonance conditions, i.e., when the frequency of force pulsations applied to a system coincides with the natural frequency of the system. Under such conditions, these fluctuating stresses are limited only by damping.

In many structures, high damping is assured, regardless of the properties of the materials, by friction in mechanical connections, fluid friction, mechanical impacts, or component damping devices such as dashpots. Where these are effective in only minor degree, we must look to damping in the materials themselves for protection against excessive vibratory stresses at resonance. To this end, we must know the damping, along with other properties of materials, under conditions as nearly as possible the same as those to which they will be subjected in service.

While the results of many investigations of the damping of engineering materials have been reported,[3] the data so accumulated are meager, and our understanding of the phenomenon is, insufficient to permit application of available data to conditions materially different from those under which they were obtained.

It is the purpose of this paper to describe equipment suitable for measuring the damping of materials at temperatures up to 1400 F, over a wide range of stresses caused by bending at frequencies from 100 to 3000 cycles per sec. These cover the range of conditions under which the buckets and wheels of some steam and gas turbines operate, and for which data are needed concerning the materials used in their construction. Representative results are included, but more comprehensive data will be published later.

General Description of Equipment

There are, broadly, two ways to determine damping; one involves measuring the power required to sustain a specimen in vibration, the other measuring the rate at which a free vibration decays. The free-vibration-decay method, using a tuning-fork specimen, was adopted.

A tuning fork, Fig. 1, having a frequency of about 1000 cycles

These contain an exhaustive summary of damping data, and part 5 contains an extensive Bibliography on damping.

Presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

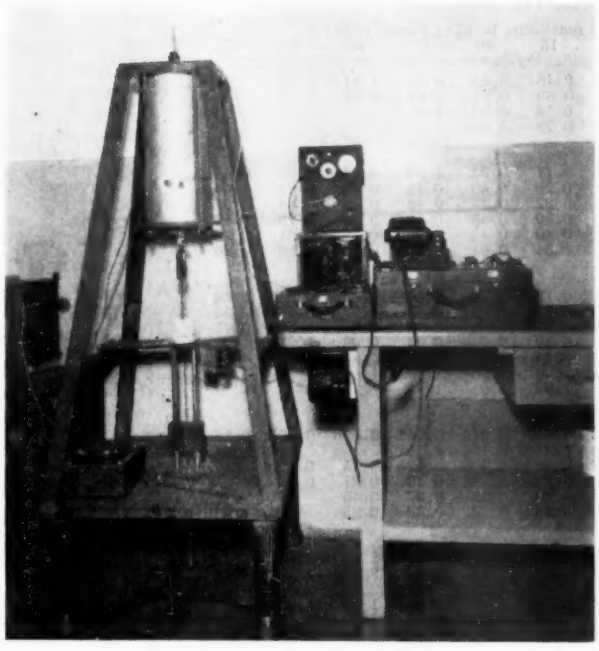

FIG. 3 VIEW OF TEST EQUIPMENT

per sec, is set into vibration by jerking a spreader from the gap between the feet on the ends of the tines. The subsequent vibration is measured with a resistance-type electric strain gage attached to the fork and is recorded on photographic film by means of a magnetic oscillograph.

Fig. 2 shows the details of the potentiometer circuit and a connection diagram for the amplifiers used in conjunction with the strain gage and oscillograph.

The equipment used for supporting and heating the specimen, and setting it into vibration is shown in Fig. 3, together with the amplifiers and oscillograph.

Details of the test equipment and the method of conducting tests are explained and discussed fully in Appendix 1.

Fig. 4 illustrates a specimen suitable for use in determining the influence of vibration frequency on damping. By cutting off the tines successively at each of the projections, the frequency is increased progressively from about 150 to 3000 cycles per sec. All of the results reported in this paper were obtained with specimens of the proportions shown in Fig. 1.

DISCUSSION OF TEST CONDITIONS AND METHOD OF COMPUTING RESULTS

At the instant the vibration starts, it comprises all modes in the same degree and phase relation that they were represented in the static deflection caused by the spreader. The vibration amplitude in the fundamental mode is by far the largest. In the second mode, whose frequency is about 6.3 times the fundamental, and which has a node about 17 per cent of the length from the free end of the tine, the amplitude is only 2 or 3 per cent of the fundamental.

Only the fundamental component of the vibration is recorded by the oscillograph, if the specimen frequency exceeds about 500 cycles per sec. The characteristics of the measuring equipment are such that the small-amplitude higher-frequency components are practically eliminated. If the frequency is below 500 cycles per sec, the second-mode vibration is recorded, but can readily be separated from the record of the fundamental.

The damping is expressed in terms of the logarithmic decrement of the fundamental mode. It is assumed that the vibration in each mode dies out independently of the others. This seems justified by the poor coupling between the different modes of vibration of the tines and by the smallness of the higher mode components. It was checked experimentally by using a fork having the feet located some distance back from the free ends of the tines, so that the static-deflection shape approximated the vibration shape more nearly and the second-mode component was much reduced. The decrement of the fundamental mode did not differ appreciably from that obtained from the same fork when the feet were located at the ends of the tines.

The rates of energy dissipation and vibration-amplitude decay are simply related to the logarithmic decrement. Provided the latter is small (less than 10 per cent), then with very little error, the percentage reduction in amplitude per cycle is equal to the percentage logarithmic decrement; the percentage loss of energy per amplitude cycle, called "specific damping capacity," is equal to twice the percentage logarithmic decrement.

The initial-vibration amplitude in the fundamental mode is determined by and from the static deflection before release. It is assumed that components of the vibration in modes higher than the second are negligible. The amplitudes of the fundamental and second mode are determined to satisfy the initial static deflection at the free ends and at the middle of the tines of the tuning fork. This fixes the fundamental amplitude of the end of the tine at 97.4 per cent of the static deflection, and of the second mode 2.6 per cent (see Appendix 2).

The bending moment at the fixed end of each tine is the sum of the inertia moments of the tine and foot due to vibration in the fundamental mode. It is assumed that the tine is fixed at a section through the bottom of the slot between tines.

All stresses are expressed in terms of the nominal maximum bending stress, obtained by dividing the bending moment at the fixed ends of the tines, as determined previously, by the section modulus of the tine. If the proportions of the specimen are reasonably close to those specified in Fig. 1, the nominal maximum bending stress at the instant the vibration starts

$$S = 0.192 \frac{f_1^2 \gamma l^2}{h} Y,$$

in terms of the nomenclature given in Appendix 2. As the vibration decays, the stress decreases in proportion to the recorded amplitude.

It should be noted that the nominal maximum bending stress neglects the effect of the fillet at the fixed ends of the tines. This is in accordance with common engineering practice, wherein the

effect of fillets at changes of section is included in a stress-concentration factor applied to the nominal stress.

It should be noted also that the nominal-maximum-stress calculation assumes that the surface stresses are below the elastic limit of the material. For surface stresses above the elastic limit, the bending moment must be divided by something greater than the section modulus of the tine, using one of the approximate methods of analysis which are available for determining the actual stress distribution. Determination of the bending moment is the same in either case, however, since the moment of the inertia forces is not greatly affected by local yielding near the fixed ends of the tines. Moreover, since the strain gage is located where the stress is considerably lower than the maximum, the recorded amplitudes will continue to be proportional to the vibration amplitudes when the nominal maximum bending stress is considerably in excess of the elastic limit.

The variation in the elastic modulus of materials with temperature is a useful by-product of the damping measurements. The square root of the ratio of the frequencies of a tuning-fork specimen at any two temperatures is equal to the ratio of the moduli of elasticity at those temperatures. The frequencies are measured at small vibration amplitudes, with nominal maximum bending stresses of the order of 5000 to 10,000 psi. The frequencies themselves have not been reported, since the proportions of many of the specimens tested so far differ slightly, and the frequencies are of no value without proper correction.

With regard to accuracy, it is estimated that damping values can be determined within 2 or 3 per cent if extreme care is used in measuring the record obtained. With ordinary care, the error is probably twice as large, and it is estimated that the results given here may be in error by as much as 5 per cent, particularly at the higher stresses. Greater refinement is not considered worth while. The stress values should be correct within 2 or 3 per cent, and the modulus ratios within 1 per cent.

Errors in the measured values of damping caused by energy losses outside the specimen, were investigated in detail and found to be negligible (see Appendix 1).

Results

Table 1 contains the damping in per cent logarithmic decrement, measured on a number of materials as a function of temperature and nominal maximum bending stress, using the specimen shown in Fig. 1. It includes also the ratios of the moduli of elasticity at elevated temperatures to the moduli at room temperature, in the column headed "Relative Modulus."

Table 2 contains the physical properties, and Table 3, the chemical composition and heat-treatment of the materials included in Table 1.

Conclusion

The materials tested differ widely in damping and in their variation in damping with temperature. Explanation of these differences, or correlation of them with other of the material properties, is beyond the purpose of this paper and probably beyond the potentialities of the data as well.

Comparison of the results with damping values measured under different types of stress and at different frequencies should recognize the effect of these factors. In a torsion-test specimen, the entire surface of the specimen is subjected to the maximum stress, whereas the maximum stress in a tuning-fork specimen is highly localized. Since damping usually increases with stress, it follows that the damping measured in torsion will be higher than that in bending, if the maximum significant stress is the same in both cases. Just what this significant stress is, i.e., whether the resultant tension or shear stress, or some more complex function of the stresses, we do not know. We do know, however, that the logarithmic decrement of a vibrating cantilever at a given maximum bending stress will differ from, and probably will be less than, that of a vibrating torsional pendulum under an equal maximum shear stress. It is generally recognized, too, that damping depends upon the frequency of stress fluctuation, although the effect of frequency is usually considered to be smaller than that of stress or temperature.

For these reasons, damping data should be obtained under conditions closely similar to those for which they are to be used. Data obtained from tuning-fork specimens are directly applicable to parts subjected to vibratory bending, whereas those obtained from the commonly used low-frequency torsional machine are particularly applicable to parts such as shafting which may vibrate in torsion. Either test, perhaps, is suitable for classifying materials as to damping under any condition of stress, but this has still to be established by carefully conducted comparative tests.

Appendix 1

Details of Test Equipment and Procedure

Mechanical Equipment

The solid portion of the fork is screwed to the lower end of a 3/8-in-diam stainless-steel rod, whose upper end is gripped in a collet fastened to a rigid framework. The spreader is screwed to the upper end of a trip rod which is positioned by guide bushings in two horizontal plates of the framework so that its axis coincides with the axis of the rod supporting the fork. The trip rod passes through a hole in the center of a 5-lb weight, which is guided parallel with the trip rod. By striking a shoulder on the bottom of the trip rod, the weight jerks the spreader from between the tines of the fork, and the specimen vibrates with an amplitude which is equal approximately to the deflection caused by the spreader.

The weight is held at the upper limit of its travel by a solenoid-operated latch connected electrically, through an adjustable time-delay relay, in parallel with the film-driving motor on the oscillograph. The fork vibration may thus be started automatically so that it is recorded at the beginning of the film.

The fork and its supporting rod are enclosed by a furnace 3 in. diam × 16 in. long inside, with a removable cover at the bottom. The spreader and trip rod are inserted through a small hole in the cover. Fig. 3 shows the cover removed and the fork lowered outside the furnace. During test, the bottom of the fork is opposite a sight hole in the side of the furnace, so that insertion of the spreader between the tines of the specimen, employing an offset spreading tool, can be viewed.

The furnace is heated electrically with alternating current through a nichrome winding around the quartz tube forming the inner wall. The temperature variation in the section occupied by the test specimen does not exceed 2 per cent of the test temperature, in degrees F, and most of this occurs in the section near the free ends of the tines which contributes very little to the damping.

The temperature is measured with a chromel-alumel thermocouple inserted in a 1/16-in-diam hole in the specimen, Fig. 1. Leads are brought out through the top of the furnace.

Since the furnace winding is inductive, and the damping capacity of magnetic materials is influenced by magnetic fields, the current must be shut off and the specimen demagnetized before taking the vibration decrement. This is accomplished by reducing slowly the current through the furnace winding to zero, using a potentiometer arrangement of resistance boxes.

Lead wires to the strain gage are connected to the 0.010-in-diam nickel leads on the fork at a terminal block clamped to the support rod just above the fork. Simple pressure-contact con-

nections are satisfactory, but the screw threads must be lubricated with a high-temperature bolting compound. One of the terminals is grounded, the other is carried by an asbestos insulating strip.

Specimen and Strain Gage

The gap between the little feet on the free ends of the tines of the tuning-fork specimen, Fig. 1, is made only large enough so that it will not close when the fork is vibrating. This is important for, with a large gap, slight misalignment of the spreader as it is jerked out will cause it to break contact with one tine before the other, with the result that some of the energy stored in the fork is imparted to the spreader and trip rod, and the two tines tend to begin vibrating with unequal amplitudes. It is important, too, that the corners on the edges of the feet and the spreader be square and sharp, so that they "break clean" and the initial vibration amplitude equals the static deflection. A slight taper on these surfaces is particularly to be avoided, since the tines will follow the contour as the spreader is withdrawn; they will not, however, follow the contour of a very small chamfer because of the high velocity at which the spreader moves (about 100 ips), compared to the transverse velocity at which the tines approach it.

The $^1/_2$-in-diam hole in the solid portion of the fork accommodates a nut on the end of the support rod and can be omitted if the material is such as to permit threading the $^1/_4$-in-diam hole at right angles to it.

No extraordinary precautions need be taken to make the frequencies of the two tines the same. Slight differences between the tines seem to have no appreciable effect on the damping, although it seems likely that if they are badly unbalanced, the energy dissipation to the support rod will be increased.

The resistance-type electric strain gage operates on the change in resistance of a wire with strain. The authors have developed a technique of using such gages suitable for measuring dynamic strains at high temperatures.[4] They consist of 0.0015-in-diam nichrome gage wire cemented to the specimen with Sauereisen No. 31 cement[5] and are built up on the specimen as follows:

The surface of the metal is roughened by cutting many shallow nicks with a sharp cold chisel. Grease and dirt are removed by washing with alcohol, and a thin coat of cement is applied. On this, the gage wire is arranged in a "W" and held in place with three loops of hair stuck to the fork. One end of the gage wire is grounded to the fork by folding a small piece of nickel ribbon around it and spot-welding. To the other end is welded a second piece of nickel ribbon $^1/_2$ in. long, insulated from the fork by cement. The ground connection, and one-half the nickel-ribbon strip are covered with a second coat of cement, which is allowed to dry and then baked at 500 F. Finally, 0.010-in-diam nickel wires are welded to the strip and fork, respectively.

Location of the gage on the fork, as shown in Fig. 1, is suitable for damping measurements; if it is moved toward the free ends of the tines, the energy absorbed by the gage increases; if it is moved in the opposite direction its sensitivity is reduced.

Such gages stand up satisfactorily at 1100 F. They usually last for 1 to 2 hr at 1300 F and sometimes long enough for a damping test at 1400 F.

[4] Gages suitable for use at temperatures up to 500 F are sold by the Baldwin Southwark Division of the Baldwin Locomotive Works under the name of SR-4 bonded resistance-wire strain gages. These are applied to the specimen by polymerization of a cementing medium in place in the presence of heat and pressure. Patent licenses for developments using wire gages of the bonded type are available from the Baldwin Locomotive Works.

[5] Obtained from Sauereisen Cements Company, Pittsburgh, Pa.

Measuring Circuit

The fluctuating resistance of the gage wire, accompanying vibration of the specimen, is converted to an alternating voltage at the output of the potentiometer circuit. The essential elements of the latter are shown in full lines in Fig. 2. The dashed lines define an auxiliary circuit used for adjusting the resistance R to equal the gage resistance and checking the battery voltage.

The output of the potentiometer circuit is supplied through two amplifiers to the oscillograph. These are standard equipment and are shown at the right in Fig. 3. One of the two oscillograph galvanometers is used for a 60-cycle timing wave. Records are made on Kodak No. 120 verichrome film, using a standard continuous-drive film holder.

Characteristics of Measuring Circuit

Gages constructed and located as described have about 50 ohms resistance and a nominal sensitivity factor of about 0.6, that is, the fractional change in resistance is about 0.6 of the strain which would be produced by a uniform stress equal to the nominal maximum bending stress. Hence a nominal maximum bending stress of 30,000 psi, in a specimen of material having a 30,000,000-psi modulus of elasticity, produces a change in resistance of $0.6 \times 0.0001 \times 50$ or 0.003 ohm in the gage wire.

At 1000 cycles per sec frequency, the corresponding alternating voltage across the output resistor of the potentiometer circuit is about 2 mv (rms). This is amplified to produce full-scale deflection (50 mm) of the oscillograph galvanometer, whose sensitivity is 1.6 mv (rms) per mm and whose resistance is 0.9 ohm.

The transient response of the measuring circuit to the impulse occurring when the vibration starts is such that an approximately true record is obtained after about 1/1000 sec or 1 cycle, from the start of the vibration. The impulse results from the abrupt change in the average gage resistance at the instant of release. The first $^1/_2$ cycle recorded is about 25 per cent too high, but this is not objectionable unless the damping is extremely high, i.e., 5 per cent logarithmic decrement or above.

Accuracy of Results

The equipment was investigated in detail for sources of error in the measured values of damping. Errors may arise from energy losses outside the specimen, nonlinearity between the actual specimen vibration amplitude and the recorded vibration amplitude, and inaccuracy in calculating the logarithmic decrement from the vibration record. The latter constitutes the only appreciable source of error, in so far as could be determined.

Energy losses outside the specimen may occur in the support rod and frame, in the strain gage, or from fluid friction in the air. A specimen of very low damping material (vitallium) suspended from a loop of fine cotton thread showed the same damping as it did when screwed to the support rod. While this does not eliminate all question of losses to the support, it seems to indicate that they are extremely small. The damping of the specimen in this case was of the order of 0.02 to 0.04 per cent logarithmic decrement, and a difference of 5 per cent of this between the decrements obtained with the two methods of support would have been discernible.

The same specimen was used to check possible energy loss in the gage by the simple expedient of testing first with two gages (one on each tine) then with one. No difference in the results could be seen.

A rough computation indicates that fluid-friction losses to the air can hardly account for more than 0.002 per cent logarithmic decrement.

Linearity between actual vibration amplitude and the recorded amplitude depends upon the characteristics of the strain gage and measuring circuit. The latter was checked electrically by observing that the oscillograph deflection was proportional to a 1000-cycle voltage applied across the gage. The gage characteristics were investigated by using a special fork, similar to the test specimen but having tines 12 in. long. The change in resistance of the gage was measured as a function of the deflection at the free ends of the tines. The relation was found to be linear at any temperature up to 1200 F, for deflections corresponding to bending stresses at the fixed ends of the tines up to 35,000 psi. It is believed the linearity will hold at higher temperatures and stresses under elastic conditions at the gage.

It has been found that log decrements calculated from the same vibration record by different persons using average care may differ by 6 or 8 per cent; with extreme care agreement within 2 or 3 per cent can be obtained.

Test Procedure

While the manner of conducting a test will be fairly apparent from the description of the test equipment, certain details of the actual procedure require further comment.

Before testing, the width of each specimen is measured at the free ends of the tines with a micrometer, and the width of the gap between the feet is measured with a taper gage.

From the properties of the material, the maximum stress at which measurements are to be made is chosen. Two spreaders are selected, one large enough to produce this maximum stress, the other to produce a stress about 40 per cent as great. The deflection produced by each is checked by inserting it in the gap and measuring the width of the fork at the ends of the tines.

The fork is connected for test and tripped 2 or 3 times until the amplifiers are adjusted for full-scale deflection on the oscillograph, and a rough estimate of the damping is made so that the film-travel speed can be chosen to obtain a decrement curve suitable for analysis.

Oscillograms are taken using first the larger, then the smaller, of the two spreaders at each test temperature, starting at room temperature and increasing. After testing at each temperature, the gap is checked with the taper gage. If yielding has occurred, the test may be stopped, or continued at lower stresses. After the test is completed and the fork has cooled, the width is checked again to determine any final permanent set, and to check the taper-gage readings taken while the fork was hot.

The specimen is held at each test temperature for about 10 min before testing. Since the bottom of the furnace is removed momentarily while the spreader is inserted, the temperature of the specimen drops slightly before the vibration is started. To compensate for this, the spreader is inserted when the specimen is a few degrees above the test temperature.

With very low-damping materials, the film-travel speed must be so low that individual cycles cannot be discerned in the record. In such cases, an additional record for frequency measurement is taken at selected temperatures, using a higher film-travel speed.

The vibration-decay records taken with the two spreaders of different size afford several useful checks on the results. Since, in general, the recorded amplitudes at the start of the vibration are proportional to the initial static deflections produced by the respective spreaders, the amplitude linearity of the vibration-measuring system is substantiated. Moreover, if it is found in certain cases that this proportionality is imperfect, those cases can be examined for the cause. Finally, the two records provide a check on the calculation of the log decrement in the medium-stress range which is usually covered by both.

Appendix 2

Mathematical Analysis and Calculations

Nomenclature

The following nomenclature is used in Appendix 2:

α = constant
b = width of tine, in.
c = distance from neutral axis to extreme fiber in bending, in.
δ = log decrement of vibration
E = modulus of elasticity, psi
f_1, f_2, f_i = vibration frequency in fundamental, second and ith modes, respectively, cycles per sec
g = acceleration of gravity, ipsps
h = thickness of tine, in.
γ = density of material, pci
I = moment of inertia of cross section of tine about neutral axis in bending, in.[4]
l = length of tine from bottom of slot, in.
$M = M_T + M_F$
M_T, M_F = bending moment at fixed ends of tine due to inertia forces of tine and foot, respectively, lb-in.
$m_1, m_2, m_i = \left(\frac{\gamma f^2 bh}{gEI}\right)^{1/4}$ for $f = f_1, f_2, f_i$, respectively
N = number of vibration cycles, measured from start of vibration
S = nominal maximum bending stress at fixed ends of tines, psi
t = time from start of vibration, sec
V = volume of foot on end of tine, in.
x = distance along tine from bottom of slot, in.
x_F = distance from bottom of slot to center of gravity of foot, in.
Y = vibration amplitude of end of tine at time t, in.
Y_1, Y_2, Y_i = initial vibration amplitude of end of tine in fundamental, second and ith modes, respectively, in.
Y_s = static deflection of end of tine due to spreader, in.
y_1, y_2, y_i = initial vibration amplitude at any point on tine in fundamental, second and ith modes, respectively, in.
y_s = initial static deflection at any point on tine due to spreader, in.
y_F = initial vibration amplitude in fundamental mode, of center of gravity of foot, in.

Initial Vibration Amplitude

Before release, with the spreader between the feet, the deflection of the tines corresponds to that of a fixed-free beam with a terminal load, and at any point[6]

$$y_s = Y_s\left[\frac{3}{2}\left(\frac{x}{l}\right)^2 - \frac{1}{2}\left(\frac{x}{l}\right)^3\right] \quad \text{[1]}$$

At the instant following release, assuming the amplitudes of modes of vibration higher than the second are negligible, the amplitudes of the fundamental- and second-mode components of the vibration must satisfy the relation

$$y_s = y_1 + y_2 \text{ at } \frac{x}{l} = 1, 0.5 \quad \text{[2]}$$

The deflection at any point of a fixed-free beam vibrating at its natural frequency in the ith mode[7]

[6] This is given in most strength-of-materials textbooks.

[7] See "Applied Elasticity," by J. Prescott, Longmans, Green & Company, New York, N. Y., 1924, for derivation of Equations [3], [4], and [5].

$$y_i = \frac{Y_i}{k_i}\left[\frac{\cosh m_i x - \cos m_i x}{\cosh m_i l + \cos m_i l} - \frac{\sinh m_i x - \sin m_i x}{\sinh m_i l + \sin m_i l}\right] \quad [3]$$

where

$$k_i = \left[\frac{\cosh m_i l - \cos m_i l}{\cosh m_i l + \cos m_i l} - \frac{\sinh m_i l - \sin m_i l}{\sinh m_i l + \sin m_i l}\right] \quad [4]$$

For the fundamental and second modes, $i = 1$ and $i = 2$, respectively

$$\left.\begin{aligned} m_1 &= \frac{1.875}{l} \\ m_2 &= \frac{4.6944}{l} \end{aligned}\right\} \quad [5]$$

By substituting Equations [1], [3], [4], and [5] in [2]

$$Y_1 = 0.9744\ Y_s \quad [6]$$

$$Y_2 = 0.0256\ Y_s \quad [7]$$

or the amplitude in the fundamental mode is 97.44 per cent of the static deflection before release, and in the second mode 2.56 per cent.

Nominal Maximum Bending Stress

The nominal maximum bending stress at a section through the tine at the base of the slot

$$S = M\frac{c}{I} \quad [8]$$

The bending moment on this section is equal to the sum of the moments of the inertia forces of the tine and foot, due to vibration in the fundamental mode, or

$$M = M_T + M_F \quad [9]$$

Due to the tine

$$M_T = \int_0^l \frac{\gamma(2\pi f_1)^2}{g}\, y_1\, x dx \quad [10]$$

whence, using y_1 from Equations [3], [4], and [5], and performing the integration

$$M_T = 0.283\,\frac{4\pi f_1^2 \gamma b h}{g}\, Y_1\, l^2 \quad [11]$$

Due to the feet, similarly

$$M_F = \frac{4\pi^2 f_1^2 \gamma V}{g}\, y_F x_F \quad [12]$$

From the proportions of the specimen, Fig. 1

$$x_F = 0.972l \quad [13]$$

and from Equations [3], [4], [5], and [6], using $i = 1$

$$y_F = 0.961\ Y_1 = 0.936\ Y_s \quad [14]$$

The section modulus of the tuning-fork tine

$$\frac{I}{c} = \frac{bh^2}{6} \quad [15]$$

By substituting Equations [13] and [14] in [12], and the result, together with Equations [11] and [15] in [9], and [8]

$$S = 0.9744\,\frac{24\pi^2}{g}\left[0.283 + \frac{0.936V}{bhl}\right]\frac{f_1^2\gamma l^2}{h}\, Y_s \quad [16]$$

Since the second term in brackets is small, its contribution to the total will not be changed appreciably by small variations in h, l, and b. Hence it may be evaluated once and for all by using the nominal dimensions of the specimen, viz., from Fig. 1

h = 0.25 in.
b = 0.5 in.
l = 2.688 in.
V = 0.0136 cu in.
g = 386 ipsps

and Equation [16] may then be reduced to

$$S = 0.192\,\frac{f_1^2\gamma l^2}{h}\, Y_s \quad [17]$$

It will be noted that no allowance has been made for the effect of the feet on the shape of the vibration-deflection curve. The resulting error in S may be estimated by comparing the actual case with the extreme case where the mass of the tine is negligible compared to the mass of the feet. Then the deflection shape during vibration would be defined by Equation [1] instead of Equation [3], and M_T would be 3 per cent less than the value given by Equation [11]. Actually, since M_F is only about 12 per cent of M, as may be seen from Equation [16], the value of S given by Equation [17] is only about $^1/_3$ of 1 per cent too high.

Logarithmic Decrement

If a sinusoidal vibration decays at a rate proportional at any moment to its amplitude, its amplitude

$$Y = Y_1 \epsilon^{-\alpha t} \quad [18]$$

By definition, the log decrement

$$\delta = \ln \frac{Y_1}{Y_1 \epsilon^{-\alpha/f_1}} = \frac{\alpha}{f_1} \quad [19]$$

Hence, since

$$N = f_1 t \quad [20]$$

Equation [18] may be written

$$Y = Y_1 \epsilon^{-N\delta} \quad [21]$$

and by differentiation

$$\frac{dY}{dN} = -\delta Y_1 \epsilon^{-N\delta} = -\delta Y$$

whence

$$\delta = -\frac{1}{Y}\cdot\frac{dY}{dN} \quad [22]$$

By employing Equation [22], δ may readily be evaluated by drawing tangents to a curve of Y versus N.

Nozzles for Supersonic Flow Without Shock Fronts

By ASCHER H. SHAPIRO,[1] CAMBRIDGE, MASS.

Flow patterns for compressible fluids at supersonic velocities are discussed, and it is shown that shock fronts form when neighboring Mach lines (envelopes of wave fronts originating from point disturbances) intersect. A criterion for divergence of Mach lines is developed for cases in which the passage is symmetrical in two or three dimensions and has a straight axis. This criterion is used as the basis for designing supersonic nozzles and diffusers. The analysis indicates that only a nozzle of infinite length can discharge a parallel stream into a tube of constant cross section without the formation of shock fronts. Methods are presented for designing nozzles of finite length, with the intensity of shock fronts reduced to as small a value as possible, and it is shown that nozzles of reasonable length may be designed so that shock fronts are insignificant. Experimental observations indicate that the proposed method of nozzle design is a practical one. With regard to supersonic diffusers having a straight axis, it is shown that shock fronts cannot be avoided, even though the diffuser is of infinite length. However, the methods of this paper may be used as an aid in determining the best diffuser design.

Nomenclature

The following nomenclature is used in the paper:

A = cross-sectional area of passage
A_t = value of A at section where stream velocity equals local sound velocity (throat area)
k = ratio of specific heat at constant pressure to specific heat at constant volume
M = Mach number (ratio of local stream velocity to local velocity of sound)
S = projection on a line perpendicular to axis of passage, of distance required for neighboring Mach lines to intersect, Fig. 4
x = distance along nozzle axis
y = distance of wall from nozzle axis
y_t = value of y at section where stream velocify equals local sound velocity
α = Mach angle = arc sin $1/M$
β = angle of passage wall with respect to axis of passage
μ = $d(dy/dx)/d\alpha$. Defined by Equation [2]
$d\phi$ = angle between Mach lines which originate at two points on the wall an infinitesimal distance apart

Subscripts

t = throat of nozzle
1 = beginning of curved contour of nozzle
2 = end of nozzle

Introduction

Nature of Problem. A characteristic which distinguishes compressible flow at supersonic velocities from flow at subsonic velocities is the possibility that discontinuities in the supersonic flow pattern may occur, accompanied by abrupt rises in pressure along a "shock front." Since the discontinuities are irreversible in the thermodynamic sense, they reduce the efficiency of any flow passage in which they occur. Furthermore, separation of the stream from the walls may take place in consequence of the large negative pressure gradients in the boundary layer at the point where the shock occurs. It is therefore important to design ducts so that shock waves are avoided, or reduced to small proportions.

Object. It is the purpose of this paper to present a method for the design of supersonic passageways which are symmetrical in two or three dimensions and which have a straight axis. Practical applications include the design of nozzles for wind tunnels and for steam and gas turbines, and the design of supersonic diffusers.

Previous Work. Meyer (1)[2] analyzed the two-dimensional parallel flow of a gas at supersonic velocities when the stream turns a sharp bend so that the flow is subsequently parallel but in a new direction. Accelerating flow around a bend (from a region of high pressure to one of low pressure) was analyzed on the basis of irrotational flow, with the special assumption that the region of changing pressure and velocity would be wedge-shaped, with its apex at the corner, and that all stream velocities would be constant along any radius within the wedge-shaped region. It was shown that the decelerating flow around a sharp bend is discontinuous, the rise in pressure and decrease in stream velocity occurring along an oblique shock front which is represented by a straight line originating at the sharp corner. Meyer further presented Schlieren photographs of a parallel stream issuing from a nozzle and passing into regions of high and low pressure, illustrating the wedge-shaped expansion for accelerating flow and the oblique shock front for decelerating flow.

Prandtl and Busemann (2) used Meyer's analysis of parallel flow around a sharp corner as the basis for an approximate method of designing the diverging portion of a two-dimensional nozzle to produce a parallel, supersonic stream at its exit. They proposed a step method in which small parts of the flow pattern for flow around a corner are transferred to the flow within the nozzle walls, yielding a nozzle contour which is wedge-shaped near the throat and tangent to a parallel section at the nozzle exit. This procedure involves the application of a flow pattern pertaining to a specific set of boundary conditions to a problem having a different set of boundary conditions. The method is therefore approximate and involves errors of uncertain magnitude.

Busemann (3) gave Schlieren photographs of the flow within the diverging portions of two-dimensional Laval nozzles having walls which become parallel at exit. The photographs showed

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

that the curvature of the walls was the chief factor in the formation of oblique shock fronts. Specifically, when the curvature at any point along the nozzle contour was too great, an oblique shock front was formed within the nozzle. A parallel stream without visible shock fronts was produced at the nozzle exit only when the curvature of the walls was very small.

Formation of Shock Fronts

Propagation of Disturbances. A small disturbance in a stream of fluid is propagated in all directions with respect to the fluid at the speed of sound (4). When the stream itself is moving at subsonic velocities, the disturbance can be propagated upstream; therefore, the flow pattern upstream of an obstacle is affected by the presence of the obstacle. If the stream is moving at supersonic velocity, a small disturbance cannot be propagated upstream, since the velocity of the stream exceeds the velocity with which a disturbance can be propagated relative to the stream. Therefore, the flow pattern of a stream approaching an obstacle at supersonic velocity is altered only in a region downstream of the obstacle. For example, Fig. 1 shows a parallel stream approaching a thin sharp-pointed object. The disturbance caused by the sharp point is propagated into the stream along the wave front shown by the dotted lines, the latter being known as Mach lines. The angle α is called the Mach angle, and its magnitude is determined by the ratio of the stream velocity to the local velocity of sound in the fluid, thus (5)

$$\sin \alpha = 1/M$$

where M represents the Mach number and is defined as the ratio of the local velocity of the stream to the local velocity of sound. The disturbance caused by the point affects the stream only in the cone of angle 2α.

Accelerating Flow. At supersonic velocities, acceleration of a stream is accompanied by a divergence of the streamlines. Fig. 2 (6) shows a parallel two-dimensional flow approaching a curved foil which, for analysis, is divided into an infinite number of short chords, each infinitesimal in length. Above the foil the streamlines tend to diverge, so that the velocity of the stream increases while the pressure drops in the direction of flow. However, no

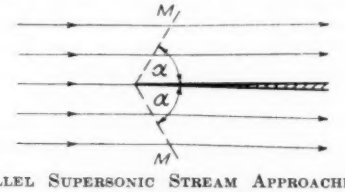

Fig. 1 Parallel Supersonic Stream Approaching a Sharp-Pointed Obstacle

The dotted line M represents the envelope of pressure waves which are propagated into the stream from the point disturbance.)

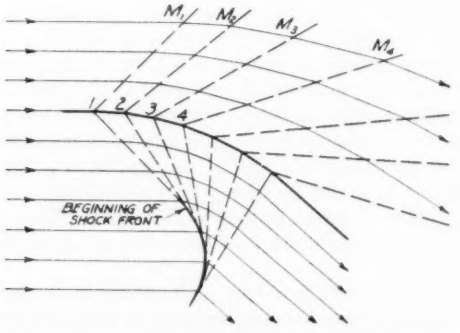

Fig. 2 Parallel Supersonic Stream Approaching a Curved Foil

(Mach lines originating on the top surface diverge. Mach lines originating on the bottom surface converge and form a shock front.)

change occurs until the stream reaches the Mach line M_1, at which point the stream bends downward in response to the disturbance caused by the corner 1. The influence of the corner 2 is not felt until the stream approaches the Mach line M_2, which is propagated into the fluid at a Mach angle corresponding to the local stream velocity and the local velocity of sound. If the flow takes place without friction and without heat transfer (that is, isentropically), an increase in velocity will result in a decrease in temperature and a consequent decrease in the local sound velocity. It follows that along the upper side of the foil, the Mach number increases and the Mach angle decreases. Neighboring Mach lines must therefore diverge, both from the standpoint of the change in stream direction and from the standpoint of the change in Mach angle.

Decelerating Flow. The flow under the foil of Fig. 2 is accompanied by a rise in pressure and a decrease in velocity, since the streamlines are caused to converge by the presence of the foil. The changes in pressure and in velocity are propagated along Mach lines which originate at each corner and which cross the streamlines at the local Mach angle. Since a decrease in velocity causes a rise in temperature and, in turn, an increase in the local velocity of sound, the local Mach angle increases in the direction of flow. This, together with the change in direction of the stream, causes neighboring Mach lines to converge. The chords into which the foil is divided are infinitesimal in length, and each makes an infinitesimal angle with its neighbor. Therefore, the change in pressure and change in velocity across each Mach line are infinitesimal, and, were it not for the convergence of Mach lines, the pressure and velocity fields would be everywhere continuous. However, along the envelope of converging Mach lines, shown by the heavy line in Fig. 2, the infinitesimal changes in pressure and velocity of many Mach lines accumulate, so that this line becomes a discontinuous shock front across which both pressure and velocity change by a finite amount in an infinitesimal distance, corresponding to infinite pressure gradients and accelerations. In the illustration shown, the shock front is detached from the body. When the body itself has sharp bends in it (or the limiting case of a smooth bend with zero radius of curvature), as in Fig. 3, the shock front starts at the sharp bend.

As further instances of shock fronts caused by convergence of neighboring Mach lines, Fig. 3 shows two examples. In Fig. 3(*a*) a parallel stream at supersonic velocity enters a conical diffuser which is joined to the straight passage by a sharp angle. An oblique shock front starts at the corner. In Fig. 3(*b*), a stream leaving the conical section of a converging-diverging nozzle enters a straight passage of constant cross section, with a finite angle at the joint. Although there is no change in cross-sectional area across the joint, a shock front is formed because the change in the direction of the stream results in a convergence of the Mach lines immediately before and after the sharp corner.

Criterion for Avoidance of Shock Fronts. It may be concluded from the foregoing discussion that, if shock fronts are to be absent, the boundaries of a stream must be curved in such a manner that neighboring Mach lines do not intersect. In the following analysis this criterion is given mathematical form for the case of flow within a passageway having a straight axis, and it is

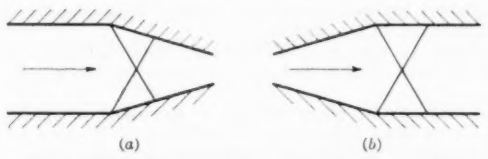

Fig. 3 Shock Fronts Caused by Convergence of Neighboring Mach Lines

(*a*, Parallel supersonic stream entering a diffuser. *b*, Stream leaving the conical portion of a supersonic nozzle and passing into a straight tube.)

shown how this mathematical statement may be used as a basis of nozzle design.

The Design of Shockless Passages

Assumptions. The following assumptions are made:

1 The axis of the passage is a straight line.

2 The passage may be two-dimensional, with a rectangular cross section; or three-dimensional, with a circular cross section.

3 The angle between the passage wall and the axis is small enough so that the tangent of the angle may be taken equal to the angle itself.

4 The velocity of the stream is uniform over any cross section perpendicular to the axis of the passage. This will be satisfied when the angle between the passage walls is small and when frictional effects are absent.

5 The direction of the stream at the solid boundary is identical with the tangent to the solid boundary.

6 Velocities are supersonic.

Criterion for Shockless Flow. Consider a short section of passage of length dx, as shown in Fig. 4. The distance y represents

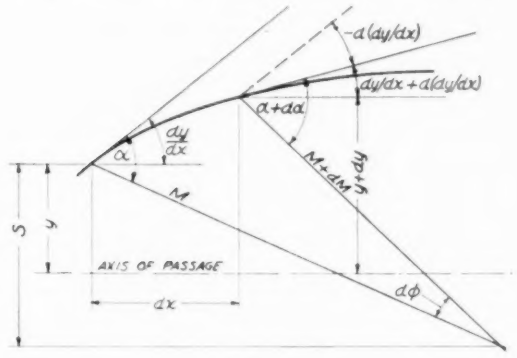

Fig. 4

one half the width of a rectangular passage for two-dimensional flow, and the radius of a circular passage for three-dimensional flow. A geometric analysis shows that the angle between two neighboring Mach lines, originating at points on the boundary an infinitesimal distance apart, is given by[3]

$$d\phi = d\alpha - d(dy/dx) \quad [1]$$

If μ is defined arbitrarily by the relation

$$d(dy/dx) = \mu d\alpha \quad [2]$$

it follows from Equation [1] that

$$d\phi = (1 - \mu)\, d\alpha \quad [3]$$

In a symmetrical passage, the slope of the streamlines and the rate of change of slope with respect to distance along the axis will increase as the distance from the passage axis increases. On the other hand, the Mach angle α is uniform over a cross section perpendicular to the axis. It follows that the angle between neighboring Mach lines is greatest at the wall, so that the criterion for the generation of shock fronts may, for the simple case of flow within a symmetrical passage having a straight axis, be expressed in terms of conditions at the wall.

Shock fronts will be absent when the angle $d\phi$ is negative (or in the limit, zero) at all points along the passage, since positive values of $d\phi$ correspond to convergence of neighboring Mach lines. Therefore, the criterion for the absence of shock fronts is

$$(1 - \mu)\, d\alpha \leq 0 \quad [4]$$

When the stream accelerates in the direction of flow, the Mach number increases and the Mach angle decreases; it follows from Equation [4] that for shockless flow in a diverging passage

$$\mu \leq 1 \quad [5a]$$

In similar fashion it may be shown that for shockless flow in a converging passage

$$\mu \geq 1 \quad [5b]$$

Likewise, shock fronts will occur in a diverging passage when $\mu > 1$; and in a converging passage when $\mu < 1$.

Since the value of μ is arbitrary, it may be constant over the length of the passage, or it may be an arbitrary function of α.

Application to Design of Nozzles. The foregoing criteria will be applied to the design of a nozzle passage of the type shown in Fig. 5. The contour t–1 is wedge-shaped or cone-shaped, with walls at an angle β_1 to the axis of the nozzle. The contour 1–2 is tangent to the contour t–1 at section 1 and to a passage of constant cross section at section 2 and is curved to avoid shock fronts.

Equation [2] shows that the value of μ is zero for the contour t–1, so that shock fronts cannot form in this section of the nozzle.

The contour between sections 1 and 2 will be based upon the criterion for shockless flow, employing a constant value of μ. Equation [2] may be integrated, thus

$$d(dy/dx) = \mu d\alpha \quad [2]$$

$$dy/dx = \mu\alpha + c_1 \quad [6]$$

where the constant of integration c_1 is evaluated with the aid of either of the following boundary conditions

when $dy/dx = 0$, then $\alpha = \alpha_2$ [7a]

when $dy/dx = \tan \beta_1$, then $\alpha = \alpha_1$ [7b]

Combination of Equations [7a] and [7b] yields an important relation between the boundary variables, as follows

$$c_1 = -\mu\alpha_2 = \tan \beta_1 - \mu\alpha_1$$

or

$$\tan \beta_1 = \mu(\alpha_1 - \alpha_2) \quad [7c]$$

Substitution of Equation [7a] into Equation [6] yields the equation

$$dy/dx = \mu\,(\alpha - \alpha_2) \quad [8]$$

After rearrangement and integration, Equation [8] becomes

$$\frac{x - x_1}{y_t} = \frac{1}{\mu} \int_{(y/y_t)1}^{(y/y_t)} \frac{d\,(y/y_t)}{\alpha - \alpha_2} \quad [9]$$

The value of y/y_t is related to the area ratio A/A_t, which in turn is related to the Mach angle α. Integration of Equation [9] yields the curved contour between sections 1 and 2 of Fig. 5.

For a two-dimensional nozzle

$$y/y_t = A/A_t \quad [10a]$$

and for a three-dimensional nozzle

$$y/y_t = \sqrt{A/A_t} \quad [10b]$$

The relation between the area ratio A/A_t and the Mach angle α depends upon the properties of the gas and on the wall friction at the solid boundaries. For frictionless adiabatic flow of a perfect gas, this algebraic relationship is given by

[3] This equation gives the angle between neighboring Mach lines at the wall; the angle between the same pair of Mach lines may be different in the core of the stream.

$$\frac{A}{A_t} = \frac{\sqrt{\left(\frac{k-1}{k+1}\right)\left(\frac{2}{k+1}\right)^{\frac{2}{k-1}}}}{\sqrt{\frac{Z-1}{Z^{(k+1)/(k-1)}}}}$$

where

$$Z = 1 + \left(\frac{k-1}{2}\right)\left(\frac{1}{\sin \alpha}\right)^2$$

This expression is sufficiently complex so that the right-hand side of Equation [9] does not appear to be algebraically integrable by ordinary methods. The integration may be carried out either graphically or numerically. For the latter purpose, a table relating $\sqrt{A/A_t}$ and α, and having equal intervals in $\sqrt{A/A_t}$, permits the numerical integration to be carried out simply and rapidly with the aid of the trapezoidal rule or Simpson's rule. Table 1 gives this relationship for the isentropic flow of a perfect

gas with $k = 1.40$. This table may be used directly for three-dimensional nozzles and may be employed as well for two-dimensional nozzles with the aid of the auxiliary relationship

$$d(A/A_t) = 2\sqrt{A/A_t} \times d\sqrt{A/A_t}$$

Friction between the stream and the nozzle walls may be taken account of either by using a coefficient of friction between the stream and the walls, or by assuming some relationship between a nozzle velocity coefficient and the area ratio A/A_t. In either case, a table relating A/A_t and α could be constructed. The effect of friction is to increase the tendency toward formation of shock fronts, since at any section friction acts to increase the Mach angle by reducing the velocity of the stream and by increasing the velocity of sound. It is suggested that friction be allowed for by designing on the basis of frictionless flow, but with a conservative value of μ to insure that appreciable shock fronts are not formed.

Nozzles of Finite Length. The integrand of Equation [9] becomes infinite when $\alpha = \alpha_2$. Further study indicates that the integral itself is infinite if carried to the upper limit; thus the nozzle must be infinite in length if it is to be tangent to a tube with straight walls. One method of altering the design to obtain a nozzle of finite length is illustrated in Fig. 5(*b*). The calculations are carried out as though the nozzle were to be infinite in length. At some finite length, corresponding to section 3, the curved contour is connected to the straight tube with the wedge-shaped or cone-shaped length 3–2, the latter being tangent to the curved contour at section 3, and making the angle β_3 (or β_2) with the straight tube at section 2. According to Equation [2], μ is infinite at the sharp corner of section 2, so that a shock front will originate at the corner.

The sharp angle β_2 becomes progressively smaller as the length of curved section 1–3 increases. Meyer (1) shows for two-dimensional parallel flow that the ratio of the pressure rise across the shock front to the pressure before the shock is approximately directly proportional to the Mach number and to the angular change in direction of the stream, provided that the change in direction is small. As an example showing orders of magnitude, when $k = 1.4$, with an initial Mach number of 2, and a change in direction of 3 deg, the rise in pressure across the shock is 19 per cent of the pressure before the shock.

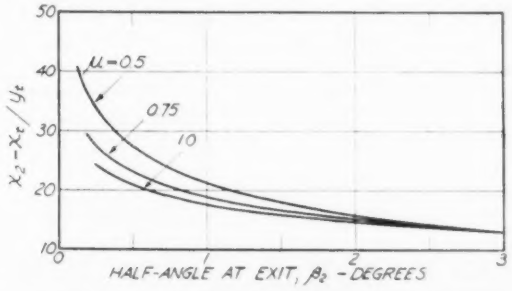

FIG. 6 EFFECT OF μ AND EXIT HALF-ANGLE β_2 ON LENGTH OF A THREE-DIMENSIONAL NOZZLE SIMILAR TO FIG. 5(*b*)
(Exit area ratio $A_2/A_t = 2.82$, and entrance half-angle $\beta_1 = 3$ deg; designed for isentropic flow.)

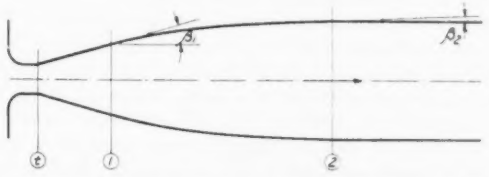

FIG. 7 NOZZLE DESIGN IN WHICH A CURVED CONTOUR IS TANGENT ON ONE END TO A WEDGE-SHAPED OR CONE-SHAPED SECTION, AND IS JOINED AT THE OTHER END TO A STRAIGHT TUBE, WITH A SMALL FINITE ANGLE β_2 AT THE JOINT BETWEEN CURVED CONTOUR AND TUBE

In a practical design, one would compromise between the reduction of β_2, so that shock fronts originating at the corner are very small, and the reduction of the nozzle length so as to avoid excessive losses on account of wall friction.

As an example of how nozzle length depends upon the half-angle at exit and upon the value of μ, Fig. 6 shows the total length of nozzle between throat and exit, expressed in terms of the radius at the throat, as a function of the half-angle at exit, for a three-dimensional isentropic nozzle. It appears that the exit half-angle can be made so small that the pressure rise across the shock front may be ignored, without at the same time requiring excessive nozzle lengths.

Alternate Design of Nozzle of Finite Length. An alternate type of nozzle of finite length is shown in Fig. 7. The length t–1 is wedge-shaped or cone-shaped, with a half-angle β_1, and is joined to a straight tube by the curved contour 1–2, which is tangent to the wedge or cone at section 1 and makes the sharp angle β_2 with the walls of the straight tube at section 2.

Equation [2] may be integrated, thus

$$d\,(dy/dx) = \mu\, d\alpha \quad \ldots\ldots [2]$$

$$dy/dx = \mu\alpha + c_2 \quad \ldots\ldots [11]$$

The constant of integration c_2 is evaluated with the aid of either one of the following boundary conditions:

when $dy/dx = \tan \beta_2$, then $\alpha = \alpha_2$ $\ldots\ldots [12a]$

when $dy/dx = \tan \beta_1$, then $\alpha = \alpha_1$ $\ldots\ldots [12b]$

Combination of Equations [12*a*] and [12*b*] yields an important relation between the boundary variables, as follows:

$$c_2 = \tan \beta_2 - \mu\alpha_2 = \tan \beta_1 - \mu\alpha_1$$

so that

$$\tan \beta_1 - \tan \beta_2 = \mu\,(\alpha_1 - \alpha_2) \quad \ldots\ldots [12c]$$

Equation [11] now becomes

$$dy/dx = \mu\,(\alpha - \alpha_2) + \tan \beta_2 \quad \ldots\ldots [13]$$

After rearrangement and integration, Equation [13] takes the form

$$\frac{x - x_1}{y_t} = \int_{(y/y_t)_1}^{(y/y_t)} \frac{d\,(y/y_t)}{\mu\,(\alpha - \alpha_2) + \tan \beta_2} \quad \ldots\ldots [14]$$

Numerical integration of Equation [14] yields the curved contour between sections 1 and 2.

A comparison of the design equations leads to the conclusion that, for fixed values of μ, β_1, and β_2, the nozzle of Fig. 7 is shorter than the nozzle of Fig. 5(*b*) and is to be preferred from the standpoint of avoiding wall friction.

Following is a suggested computation procedure for the design of the nozzle of Fig. 7. The area ratio, value of μ, and the values of β_1 and β_2 are selected beforehand. From Equation [12*c*], the value of α_1 may be calculated, which enables y_1/y_t to be found. By trigonometry, the length $(x_1 - x_t)/y_t$ may be computed. Then, by numerical integration of Equation [14], the value of $(x - x_1)/y_t$ is calculated for each corresponding value of y/y_t.

The Choice of μ. In a nozzle of given area ratio A_2/A_t and entrance half-angle β_1, good design requires:

1 A value of μ which is less than unity, to avoid shock fronts within the nozzle.

2 A small exit half-angle β_2, so that changes in pressure across the shock front at the nozzle exit are very small.

3 A short nozzle, to avoid the reduction in nozzle efficiency which attends large wall areas on which frictional shear stresses act.

These requirements are not mutually compatible, since small values of μ and small values of β_2 both tend to increase the nozzle length.

It is conceivable that, having restricted the nozzle length to a certain value, the smoothest flow pattern will exist in the stream leaving the nozzle when the exit half-angle β_2 is reduced at the expense of increasing the value of μ over unity, thus tending to the formation of shock fronts because of excessive wall curvature. Stated differently, it may be better to have weak shock fronts due to wall curvature together with a weak shock front due to a sharp angle at exit, rather than have no shock fronts due to wall curvature, and a relatively intense shock front at exit. In this connection, the point of intersection of neighboring Mach lines for a value of μ greater than unity is of interest and importance.

With reference to Figs. 4 and 7, trigonometric analysis shows that the ratio of the projected length perpendicular to the nozzle axis of a Mach line before it intersects a neighboring Mach line originating an infinitesimal distance downstream, to the half-width of a rectangular passage (or the radius of a circular passage) is given approximately by the relation[4]

$$\frac{S}{y} = -\frac{\dfrac{1}{y/y_t}\dfrac{d(y/y_t)}{d\alpha}}{(\mu - 1)\,[\mu(\alpha - \alpha_2) + \tan\beta_2]} \quad \ldots\ldots [15]$$

It is seen that when μ is infinite, S/y is zero, so that, at a sharp corner, the shock front will itself start from the corner. When μ is unity, S/y is infinite, indicating no intersection of Mach lines. When μ is less than 1, S/y is negative, indicating a divergence of Mach lines. For values of μ only slightly greater than unity S/y is very large, so that neighboring Mach lines will not intersect until several reflections at the nozzle walls have occurred. It is reasonable to expect that disturbances propagated along Mach lines will be weakened during each reflection because of the damping action of the viscous boundary layer. Thus if the value of μ requires many reflections to take place before intersecting Mach lines form a shock front, the intensity of the latter may be reduced to insignificant proportions.

Equation [15] allows a rough estimate to be made of the number of reflections necessary for neighboring Mach lines to intersect. The numerator of this expression increases with y/y_t while the denominator decreases with an increase in y/y_t. Therefore, when μ is constant throughout the curved section of nozzle, shock fronts are most likely to be formed due to the intersection of Mach lines originating at the beginning of the curved section, rather than at the end of the curved section.

Example of Nozzle Design. Fig. 8 illustrates the design of a three-dimensional nozzle for isentropic flow. Figs. 8(*a*) and 8(*b*) are scale drawings for values of μ of 2 and 5, respectively. Fig. 8(*c*) shows how the total nozzle length and the length of curved contour depend upon μ; for convenience, the abscissa is plotted as the reciprocal of μ. Fig. 8(*d*) shows the effect of μ on the distance required for the intersection of neighboring Mach lines which originate near the beginning of the curved contour.

It may be concluded from Fig. 8(*c*) that, in this instance, values of μ greater than 10 yield little advantage as to nozzle length, but materially heighten the probability of formation of shock fronts of appreciable intensity. Furthermore, it appears from Fig. 8(*d*) that shock fronts will not form without reflections, unless μ exceeds a value of approximately 50.

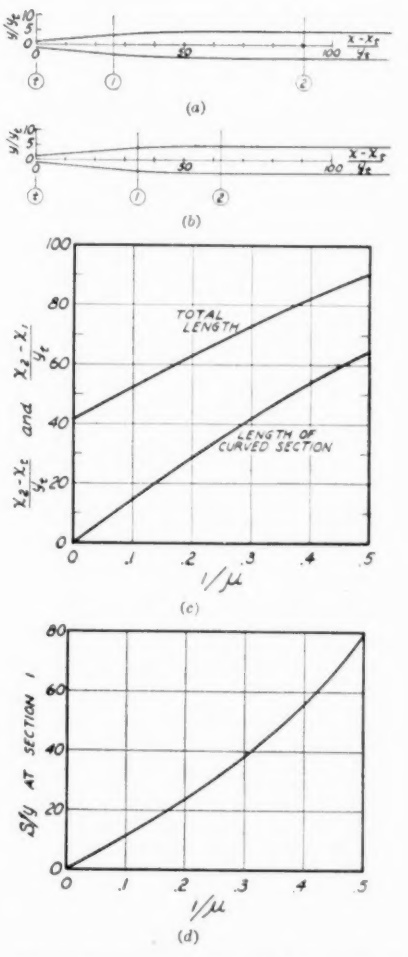

FIG. 8 THREE-DIMENSIONAL NOZZLE SIMILAR TO FIG. 6
(Nozzle designed for isentropic flow with exit area ratio $A_2/A_t = 21.52$, entrance half-angle $\beta_1 = 5$ deg, and exit half-angle $\beta_2 = 0.15$ deg. *a* Scale drawing for $\mu = 2$; *b* scale drawing for $\mu = 5$; *c* effect of μ on nozzle length; *d* effect of μ on S/y.)

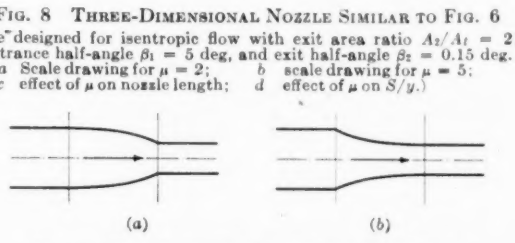

FIG. 9 TWO FORMS OF SUPERSONIC DIFFUSERS

The Supersonic Diffuser. Shock fronts will form in the supersonic diffuser of Fig. 9(*a*), since neighboring Mach lines tend to intersect both because of the change in Mach angle and because of the change in the slope of the streamlines at the wall. The same conclusion may be reached by noting from Equation [2] that μ can have only negative values for this type of contour, and that the criterion for shockless flow, Equation [5*b*], requires values of μ greater than unity if shock fronts are to be absent.

An alternate form of diffuser, Fig. 9(*b*), has a finite angle at the joint between the straight tube and the converging passage, and a curved contour which is convex inward. Such a contour can be designed to avoid shock fronts, in accordance with Equations [2] and [5*b*]. However, there will exist a relatively intense shock front at the sharp corner.

It appears that no diffuser having a straight axis, not even one

[4] This expression is based on the assumptions that Mach lines are straight and that the angle between neighboring Mach lines is constant, neither of which is exact. The relation should therefore be taken as a rough but convenient measure of the distance required for intersection.

of infinite length, can receive a parallel stream and increase the pressure of the stream isentropically and without shock fronts.

The methods of this paper may be of aid in determining, for a diffuser of finite length, the best design from the standpoint of diffuser length, intensity of shock fronts, and distribution of shock fronts.

Comparison With Experiment

There are in the technical literature (1) many Schlieren photographs showing the oblique shock fronts which originate at the wall when a stream leaves a nozzle and discharges into a region where the pressure is higher than at the nozzle exit. The sharp change in direction of the stream at the nozzle exit corresponds to an infinite value of μ, so that a shock front originates at the bend.

Busemann (3) shows in a qualitative way, with the aid of Schlieren photographs, that when the diverging walls of a nozzle are curved very gradually so as to become parallel to each other, shock fronts are not formed. On the other hand, large wall curvatures lead to the formation of a shock front which is detached from the nozzle walls.[5] These two cases correspond to small and large values of μ, respectively, and confirm in a qualitative sense the criteria proposed in the present paper.

More recently, DeFrate (7), presented Schlieren photographs of two-dimensional nozzles discharging into a tube of rectangular cross section. Each of three nozzles had a total included angle of 6 deg between the walls for some distance following the throat, and each nozzle had the same ratio of exit to throat area. One of the nozzles was wedge-shaped to the exit, with a sharp angle of 3 deg between nozzle exit and tube, corresponding to a value of μ of infinity at this point. The photographs for this nozzle exhibit intense shock fronts originating at the corners, confirming the work of other experimenters. A second nozzle had curved walls designed with μ equal to 0.75, and an exit half-angle of 0.18 deg. No shock fronts were visible within the nozzle, and the shock front due to the sharp bend at exit was so slight that it could not be seen with the Schlieren apparatus. The third nozzle also had curved walls, with a value of μ of 2.27, and an exit half-angle of 0.18 deg. The results were the same as those for the second nozzle, i.e., no visible shock fronts either within the nozzle or in the straight tube to which the nozzle was joined. It is not surprising that appreciable shock fronts were not formed with this nozzle, even with μ equal to 2.27, since Equation [15] indicates that in this instance approximately twelve reflections of neighboring Mach lines would have to occur before they could converge.

In a project carried out in the mechanical engineering department of the Massachusetts Institute of Technology, under the direction of Prof. J. H. Keenan, pressure measurements were made at various points along the length of a smooth tube with circular cross section. When the supersonic stream entered the tube from a converging-diverging nozzle having a conical divergent section, the pressure measurements exhibited a scattering which could be accounted for only by oblique shock fronts, and which extended some 30 diam downstream. The effect of the shock fronts on the measured pressures was so great that both negative and positive pressure gradients appeared to exist in the tube. Two different three-dimensional nozzles with curved contours were constructed according to the following schedule:

A_2/A_t	μ	β_1 deg	β_2 deg	$(S/y)_1$
2.82	0.75	3	0.18	Negative
21.52	5.0	5	0.15	23

[5] Fig. 5 of Busemann's paper (3) shows very clearly how individual Mach lines originating at the wall converge to form a shock front, and is in excellent agreement with Fig. 2 of this paper.

The area ratios (A_2/A_t) for these two nozzles were the same as for conical nozzles which had been used previously. Pressure measurements made in the tube following the "shockless" nozzles showed that the pressure fluctuations due to shock fronts had been eliminated, at least within the experimental error of the observations. This is of particular interest with regard to the nozzle having $\mu = 5$ and $(S/y)_1 = 23$, since it shows that the shock front may be negligible when a large number of reflections are required before neighboring Mach lines converge.

It is hoped that further experimental work will show how large a value μ may attain before appreciable shock fronts are formed.

Conclusions

Shock fronts in supersonic flow are formed when neighboring Mach lines converge. This is most likely to occur during the deceleration of a stream, but may occur as well for an accelerating stream due to rapid changes in curvature of the passage walls.

The criterion for divergence of neighboring Mach lines can be set forth in mathematical form, for the case of flow in symmetrical passages having a straight axis, in terms of a parameter, μ, which is the ratio of the change in slope of the wall of the passage for a short increment in distance along the axis to the corresponding change in the Mach angle. Shock fronts cannot form when μ is less than unity for an accelerating flow, or when μ is greater than unity for a decelerating flow. The criterion for shockless flow may be used as the basis of designing wall contours for both two-dimensional and three-dimensional passageways. It appears that shocks can be avoided entirely only with nozzles of infinite length, if the nozzle discharges into a tube of constant cross section. A practical nozzle of finite length requires a small finite angle between nozzle exit and tube entrance. The shock front associated with the sharp bend in wall contour can be made very small by reducing the angle of the bend. Excessive nozzle lengths can be avoided by employing values of μ greater than unity; the shock fronts formed as a consequence may be negligible, provided that many reflections take place before neighboring Mach lines intersect. An equation is given to permit an estimate of the number of reflections which occur before neighboring Mach lines intersect, and it is found that μ may reach values of the order of 50 before shock fronts will be formed in the nozzle without reflection of Mach lines.

It appears impossible to design shockless supersonic diffusers having a straight axis, even if the length of diffuser is infinite.

Experimental data on two-dimensional and three-dimensional nozzles are in agreement with the concepts set forth in this paper, and indicate that the shock fronts for nozzles of reasonable length may be made so small that the pressure rise across the shock front is a small fraction of 1 per cent of the pressure before the shock.

Acknowledgment

Mr. E. P. Neumann was principally responsible for the experimental work carried out at M.I.T. with two-dimensional and three-dimensional nozzles. The careful nature of this work made the results of great value in testing the validity of the proposed method of nozzle design.

Forced and Free Motion of a Mass on an Air Spring

By B. SUSSHOLZ,[1] WASHINGTON, D. C.

Results are given of a theoretical investigation of the transient response of a simple nonlinear mechanical system to various types of applied forces. A cylindrical tube closed at one end, with a light piston inserted in the other, was used experimentally, the nonlinear elasticity of the confined column of air governing the motion of the piston. Such systems have been used in ballistic studies to measure transient pressures, as well as for the measurement of pressures caused by other types of explosions in air.

Nomenclature

The following nomenclature is used in the paper:

- m = mass of piston
- X = displacement of piston from position where internal pressure is equal to atmospheric pressure
- A = constant cross-sectional area of air column
- L = length of air column when internal pressure is equal to atmospheric pressure
- P_0 = atmospheric pressure
- P_e = applied external pressures in excess of atmospheric pressure
- $E(X)$ = elastic spring force
- P_i = internal pressure corresponding to any displacement X
- V_0 = original volume of air column ($V_0 = AL$)
- V = volume of air column corresponding to any displacement X
- K = stiffness of air column for small displacements about position X
- T_0 = natural period of oscillation for small displacements of piston about $X = 0$
- X_m, X_n = maximum positive and negative displacement of piston during a cycle
- τ = duration of positive pressure in excess of atmospheric pressure
- E_0 = energy contained in system at the time $t = 0$
- v_0 = velocity of piston at the time $t = 0$
- P_G = internal pressure above atmospheric corresponding to X_m
- n = overshoot factor
- P_m = maximum excess pressure in blast wave
- γ = ratio of specific heats
- t = time
- v = velocity of piston

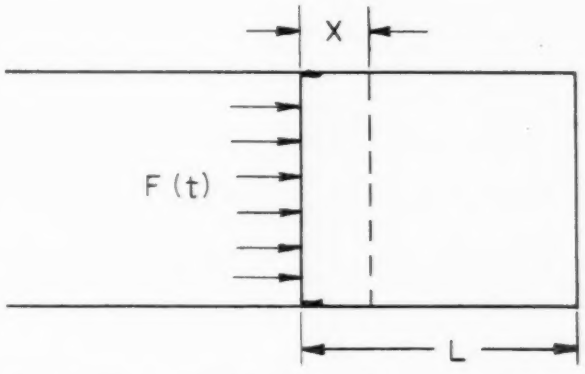

Fig. 1 Schematic Diagram of Nonlinear Mechanical System

General Considerations of Study

The purpose of this paper is to present the results of a theoretical investigation of the transient response of a simple nonlinear mechanical system to various types of applied forces. The system consists essentially of a cylindrical tube closed at one end, with a light piston inserted in the other end. The nonlinear elasticity of the confined column of air governs the motion of the piston. Systems of this type have been used to measure transient pressures caused by explosions in air. A schematic diagram of the system is shown in Fig. 1.

The considerations of this paper are based upon four assumptions, as follows:

1 The pressure within the air column follows the law of adiabatic compression, $P_i V^\gamma$ = constant, for the entire scope of the analysis.

2 The system is conservative with regard to dissipative forces such as heat loss, friction, and leakage.

3 No diffraction effects are introduced by the mouth of the tube.

4 The internal pressure is uniform throughout the air column at any instant.

The equation of motion of the system in response to a general force $F(t)$ is

$$m\ddot{X} + E(X) = F(t) \quad \ldots\ldots [1]$$

where m = mass of the piston, X = displacement of piston, $E(X)$ = restoring force. The elastic restoring force $E(X)$, corresponding to any given displacement, is determined by the unbalance existing between the absolute internal pressure and the static atmospheric pressure. The restoring force will always be directed toward the position of static equilibrium under no external load, $F(t) = 0$.

Without an external load the system is at equilibrium when $X = 0$, $v = 0$, and the internal and external pressures are equal to atmospheric pressure P_0. Under these conditions the length of the air column will be denoted by L. The cylinder is assumed to be long enough to allow for the negative positions of the piston. The uniform cross-sectional area of the column is A. By as-

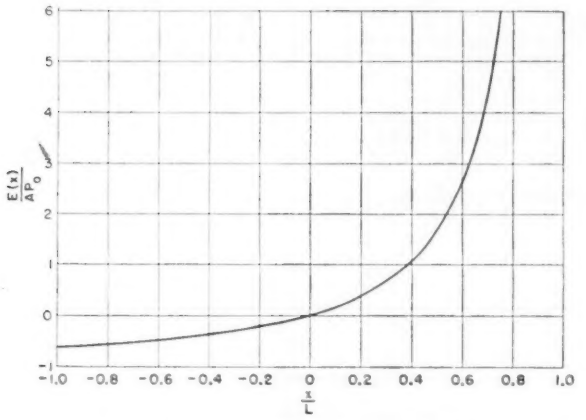

FIG. 2 ELASTIC AIR-SPRING FORCE CORRESPONDING TO GIVEN DISPLACEMENTS

sumption a positive displacement will correspond to an increase in internal pressure.

At any position X the unbalanced internal pressure is $P_i - P_0$ where

$$P_i = P_0 \frac{1}{\left(1 - \frac{X}{L}\right)^{\gamma}}$$

By applying the adiabatic law $P_i V^{\gamma} = P_0 V_0^{\gamma}$ the spring force $E(X)$ is determined as

$$E(X) = AP_0 \left[\frac{1}{\left(1 - \frac{X}{L}\right)^{\gamma}} - 1 \right] \quad \ldots\ldots\ldots\ldots [2]$$

Fig. 2 is a plot of Equation [2] with $\gamma = 1.4$.

The stiffness of the system K is not uniform but varies with X.

By definition $K = \frac{d}{dX} E(X)$, therefore

$$K = \frac{\gamma AP_0}{L} \cdot \frac{1}{\left(1 - \frac{X}{L}\right)^{\gamma + 1}} \quad \ldots\ldots\ldots\ldots [3]$$

The natural period of the system for small displacements about the equilibrium position $X = 0$ is given by

$$T_0 = 2\pi \sqrt{\frac{m}{K}} = \frac{2\pi}{\sqrt{\gamma}} \sqrt{\frac{mL}{AP_0}} \quad \ldots\ldots\ldots\ldots [4]$$

The corresponding natural frequency f_0 is equal to $\frac{1}{T_0}$.

CASE 1 $F(t) = 0$

The differential equation of motion is

$$m\ddot{X} + E(X) = 0$$

Standard methods of integration (numerical integration, Rauscher's graphical method,[2] Meissner's method[3]) yield the free-vibration curves shown in Fig. 3(*a*), for the cases where $\frac{X_m}{L} = +0.1$, 0.3, 0.5, and 0.7. A series of phase space diagrams is shown in Fig. 3(*b*). These contours indicate the relation between the relative velocity $v/\bar{v}$ and displacement X/L of the piston for free vibratory motion. The factor $\bar{v}$ is used to denote $\sqrt{\frac{AP_0L}{m}}$ or in another form $\frac{2\pi}{\sqrt{\gamma}} \cdot \frac{L}{T_0}$.

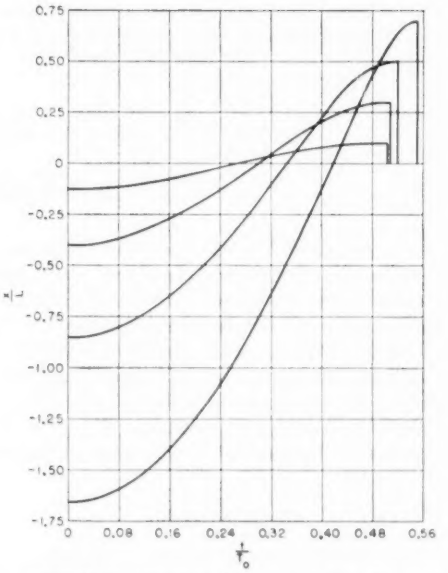

FIG. 3 (*a*) TIME-DISPLACEMENT RELATIONS FOR FREE VIBRATORY MOTION OF SYSTEM

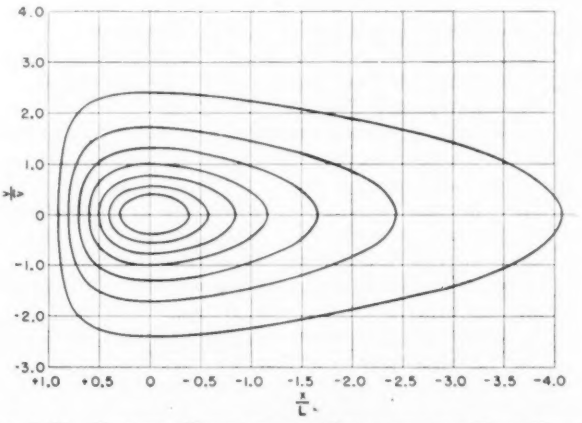

FIG. 3 (*b*) VELOCITY-DISPLACEMENT RELATIONS FOR FREE VIBRATORY MOTION OF SYSTEM

In the case of nonlinear systems the free oscillations are generally not symmetrical about the neutral position either in form or amplitude. For a conservative system the relation between maximum positive and negative amplitudes is governed by the condition that the potential energies be equal at the two extremities of a stroke. The relation is determined from

$$\int_0^{X_m} E(X)dX = \int_0^{X_n} E(X)dX$$

to be

$$\frac{1}{(\gamma - 1)\left(1 - \frac{X_m}{L}\right)^{\gamma - 1}} - \frac{X_m}{L} = \frac{1}{(\gamma - 1)\left(1 - \frac{X_n}{L}\right)^{\gamma - 1}} - \frac{X_n}{L} \quad \ldots\ldots [5]$$

[2] "Steady Oscillations of Systems With Nonlinear and Unsymmetrical Elasticity," by Manfred Rauscher, Trans. A.S.M.E., vol. 60, 1938, pp. A-169 to A-177.

[3] "Graphische Analysis vermittelst des Linien bildes einen Funktion," by E. Meissner, *Schweizerische Bauzeitung*, vol. 104, 1934, p. 35.

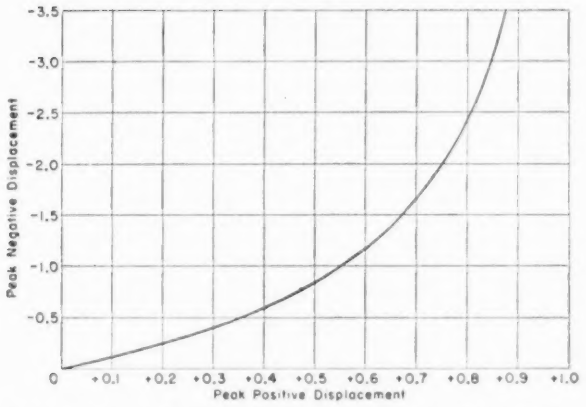

FIG. 4 RELATION BETWEEN PEAK NEGATIVE AND PEAK POSITIVE DISPLACEMENTS IN FREE VIBRATION

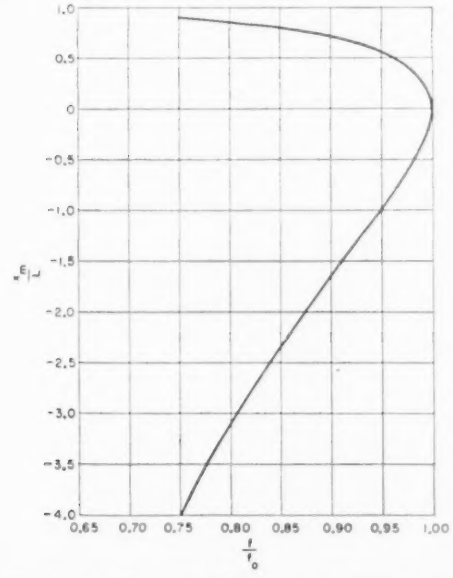

FIG. 5 EFFECTIVE NATURAL FREQUENCIES CORRESPONDING TO VARIOUS MAXIMUM NEGATIVE AND POSITIVE AMPLITUDES FOR FREE VIBRATORY MOTION

where X_m is the peak positive displacement and X_n is the peak negative displacement, i.e., $X_m > 0$ and $X_n < 0$. This relation is plotted in Fig. 4.

For free oscillations of large amplitude, the effective natural frequency depends upon the maximum amplitude, as is characteristic of nonlinear systems in general. Suppose the piston is displaced to a position X and suddenly released. The number of free oscillations per second the system will then execute is plotted in Fig. 5, as a function of the maximum displacement.

CASE 2 BALLISTIC IMPULSE

Consider the response of the system to a pure ballistic impulse of magnitude $P_e\tau$, where P_e is a constant pressure above atmospheric applied for a time τ. The value of τ is considered to be small as compared to T_0. Since $mv_0 = AP_e\tau$, the energy imparted to the system is given by

$$E_0 = \frac{1}{2} mv_0^2 = \frac{(AP_e\tau)^2}{2m} \quad \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

The piston comes to rest at a position, X_m, where the potential

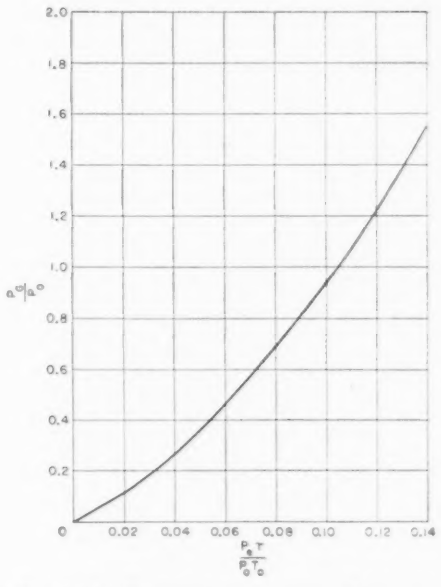

FIG. 6 (*a*) RESPONSE TO BALLISTIC IMPULSE

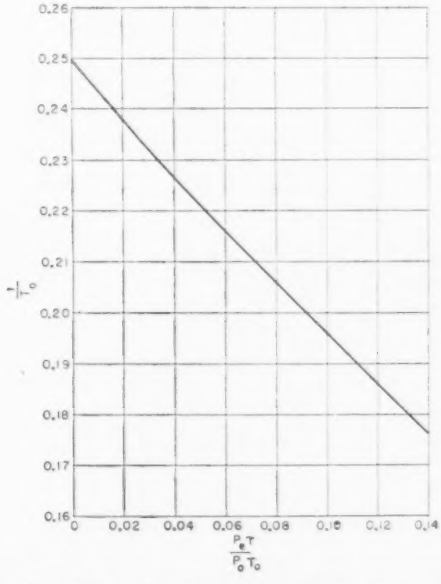

FIG. 6 (*b*) TIME TAKEN TO REACH FIRST PEAK DISPLACEMENT IN RESPONSE TO BALLISTIC IMPULSE

energy, $\int_0^{Xm} E(X)dX$, is equal to E_0. Substituting for E_0 in Equation [6], the ballistic response can be reduced to the form

$$\left(\frac{P_e\tau}{P_0T_0}\right)^2 = \frac{1}{2\pi^2} \cdot \frac{\gamma}{\gamma - 1} \left[\frac{\gamma + \frac{P_G}{P_0}}{\left(1 + \frac{P_G}{P_0}\right)^{1/\gamma}} - \gamma \right] \quad \ldots\ldots [7]$$

where

$$\frac{P_G}{P_0} = \frac{1}{\left(1 - \frac{X_m}{L}\right)^{\gamma}} - 1$$

which is the excess internal pressure corresponding to the displacement X_m. The relation shown in Equation [7] is plotted in

Fig. 6(*a*). A plot of the time taken by the piston to reach the peak displacement X_m in response to a ballistic impulse is shown in Fig. 6(*b*).

CASE 3 $F(t) = AP_e$

Consider a pressure wave of constant amplitude and long duration, Fig. 7, suddenly applied to the system, with P_e as the pressure above atmospheric. Equation [1] becomes

$$m\ddot{X} + E(X) = AP_e$$

Substituting for $E(X)$ from Equation [2] and integrating, yields the energy equation

$$\frac{1}{2}mv^2 = \frac{AP_0L}{\gamma - 1}\left[(\gamma - 1)\left(1 + \frac{P_e}{P_0}\right)\frac{X}{L} - \frac{1}{\left(1 - \frac{X}{L}\right)^{\gamma - 1}}\right] + C \quad \ldots\ldots [8]$$

where C is a constant of integration. When the initial conditions are $X = 0$, $v = 0$, and $P_i = P_0$, C becomes $\dfrac{AP_0L}{\gamma - 1}$.

At the maximum displacement, X_m, the total work done by the applied force is stored as potential energy, namely, $AP_eX_m = (\text{P.E.})_{X_m}$. The fractional "overshoot," n, is given by P_G/P_e. Determination of the "overshoot," n, by the preceding energy considerations yields the following two relations

$$\frac{P_e}{P_0} = \frac{1}{(\gamma - 1)a}\left[\frac{1}{(1 - a)^{\gamma - 1}} - (\gamma - 1)a - 1\right] \quad \ldots [9a]$$

$$n = \frac{(\gamma - 1)a \quad [1 - (1 - a)^{\gamma}]}{(1 - a) \quad [1 - (1 - a)^{\gamma} - \gamma a\,(1 - a)^{\gamma - 1}]} \quad \ldots [9b]$$

where $a = \dfrac{X_m}{L}$. A plot is shown in Fig. 8 of n as a function of P_e/P_0.

The time-displacement motion of the piston is determined by substituting for v in the relation

$$t = \int \frac{1}{v}dX$$

and integrating. Since the integrand becomes infinite when $v = 0$, namely, at the extreme positions during a cycle, the integration methods used should avoid this mathematical discontinuity or allow as close an approach to such limiting positions as may be desired.

Fig. 9 is a plot of the time taken by the piston to reach its first maximum displacement under given applied pressures P_e.

Now consider the case where the pressure is terminated at a time τ, Fig. 10. As the value of τ is varied from 0 to t', where t' is given in Fig. 9 as a function of the pressure P_e, the peak response of the system will vary correspondingly from zero to $P_G = nP_e$, where the values of n are shown in Fig. 8. The variation of

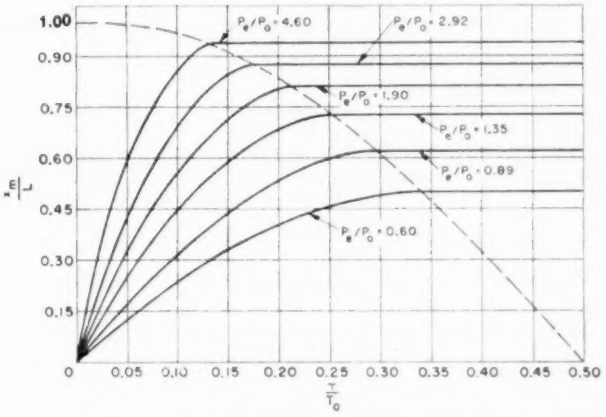

FIG. 11 RESPONSE TO RECTANGULAR PRESSURE PULSES OF CONSTANT AMPLITUDE AND VARYING DURATION

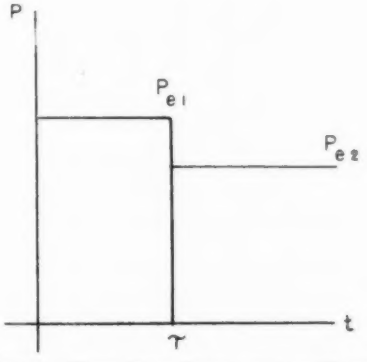

FIG. 12 SYSTEM WITH TWO RECTANGULAR WAVES IMPOSED

$\frac{X_m}{L}$ with τ for several values of P_e is shown in Fig. 11. The limiting broken curve in Fig. 11 is the same as the plot in Fig. 9.

An interesting point might here be mentioned. The results of the foregoing analysis with regard to rectangular pressure waves can be determined by different but parallel considerations. At $t = 0$, when the pressure P_e is suddenly applied the initial conditions were $X = 0, v = 0$ and $P_i = P_0$. The forced motion of the piston has been examined. Now consider a second system where the internal and external pressure is $P_e + P_0$ for $t \leq 0$. The position of the piston is at X_e relative to the first system. At $t = 0$, the piston is displaced to $X = 0$ where $P_i = P_0$ and is suddenly released. The physical conditions for both systems are identical, and therefore the free vibrations of system 2 and forced vibrations of system 1 will be the same with regard to the position and velocity of the piston at any time t.

Consider now the forced response of the original system to two rectangular waves as shown in Fig. 12. Suppose initially the displacement of the piston is zero, velocity zero, and internal pressure atmospheric. The response from $t = 0$ to $t = \tau$ has already been discussed in detail. At $t = \tau$, the system has a displacement X_1 and velocity v_1. The differential equation of motion under the second rectangular wave is

$$m\ddot{X} + E(X) = AP_{e2}$$

Integrating and introducing the initial conditions the energy equation becomes

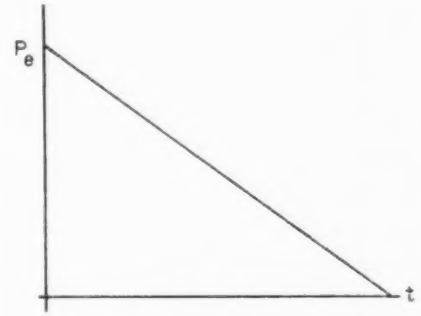

FIG. 13 (*a*) TRIANGULAR PRESSURE WAVE

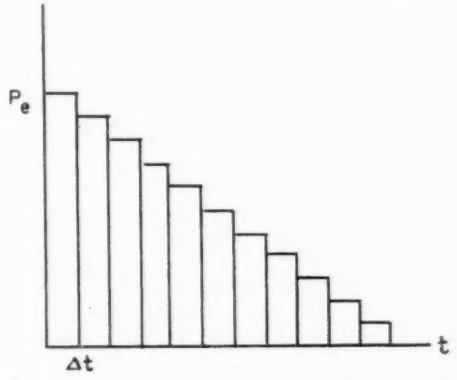

FIG. 13 (*b*) TRIANGULAR PRESSURE WAVE OF FIG. 13 (*a*) RESOLVED INTO RECTANGULAR WAVES

$$\frac{1}{2}mv^2 = \frac{AP_0L}{\gamma - 1}\left[(\gamma - 1)\left(1 + \frac{P_{e2}}{P_0}\right)\frac{X}{L} - \frac{1}{\left(1 - \frac{X}{L}\right)^{\gamma - 1}}\right] + \frac{AP_0L}{\gamma - 1}\left[1 + (\gamma - 1)\left(\frac{P_{e1}}{P_0} - \frac{P_{e2}}{P_0}\right)\frac{X_1}{L}\right] \quad \ldots\ldots [10]$$

Substituting for v in $\int \frac{1}{v}\,dX$, the integration of Equation [10] is to begin with $X = X_1$ and continue from there on. Two separate sections of the time-displacement response curve of the piston will thus be determined, namely, for $0 \leq t \leq \tau$ and $t \geq \tau$. At $t = \tau$ both sections will have the same ordinate X_1 and also the same slope v_1. Therefore, the two sections may be joined to give a continuous curve with the displacement X always referred to the original equilibrium position of the system. A numerical example is presented in the Appendix to indicate the application of the foregoing method.

It is evident that the preceding process can be extended to any number of rectangular step pulses. Therefore the response to a general pressure wave may be determined by simply considering the wave as composed of a series of rectangular step pulses. For example, the triangular pressure wave of Fig. 13(*a*) may be resolved into rectangular waves as shown in Fig. 13(*b*). The system is therefore considered as subjected to a series of rectangular waves of different amplitudes but equal duration Δt. The value of Δt depends upon the degree of accuracy desired.

This step-pulse approximation method can be applied to any undamped nonlinear system whose elastic restoring force is a continuous function of displacement. The system must necessarily be stable.

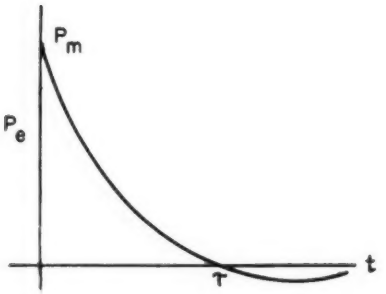

FIG. 14 APPLICATION OF STEP-PULSE METHOD

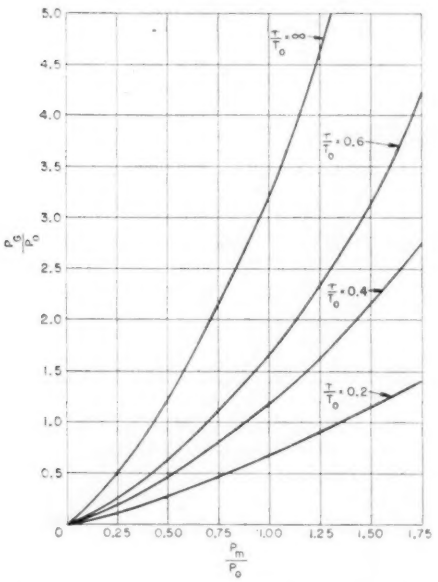

FIG. 15 RESPONSE TO BLAST PRESSURE WAVES OF VARIOUS PEAK AMPLITUDES AND DURATIONS AS GIVEN BY

$$\frac{P_e}{P_0} = \frac{P_m}{P_0}\, e^{-t/\tau}\left(1 - \frac{t}{\tau}\right)$$

$$\text{CASE 4} \quad F(t) = AP_m\, e^{-\frac{t}{\tau}}\left(1 - \frac{t}{\tau}\right)$$

As a special case the step-pulse method was applied to a pressure wave of the type shown in Fig. 14. Such pressure waves originate in gun blasts and bomb explosions in air. They are closely approximated analytically by the expression

$$P_e = P_m\, e^{-\frac{t}{\tau}}\left(1 - \frac{t}{\tau}\right)$$

where P_m is the maximum blast pressure and τ is the duration of the positive phase of the wave. An investigation was made of the maximum displacement of the piston in response to waves of this type for various values of P_m and τ. Fig. 15 is a plot in nondimensional form for the cases where $\frac{\tau}{T_0} = 0.2, 0.4,$ and 0.6 with P_G being the maximum internal pressure above atmospheric. The case of the rectangular wave, $\frac{\tau}{T_0} = \infty$, is included for purposes of comparison.

Fig. 16 shows a plot of the same relations indicated in Fig. 15, but with P_G constant along the contours. It is evident that when two of the factors, P_m, P_G, and τ are given, the third is uniquely determined. A series of time-displacement curves are shown in Fig. 17 for the cases where $\frac{\tau}{T_0} = 0.6$ and $P_m = 0.67$, 1.00, 1.33, 1.67, and 2.00 atm.

CONCLUSION

In conclusion, the effect of modifications in the construction of the system should be considered. The components of the system, namely, m, L, and A, appear throughout the analyses in two basic forms, X/L and $\frac{mL}{A}$. The first combination is nondimensional and, therefore, independent of the absolute value of L. The second combination is found only in the factor T_0 which is defined by Equation [4]. However, the absolute value of T_0 was eliminated from the development of the response curves by the use of nondimensional time co-ordinates. Therefore the curves presented in this paper can be applied directly to any specific system of the type considered.

ACKNOWLEDGMENT

The writer wishes to express his appreciation for the encouragement and helpful criticism offered by Commander J. Ormondroyd, U.S.N.R.

Appendix

As a numerical example of the step-pulse method, consider a system of the type shown in Fig. 1, where the weight of the piston is 6 g, and for the air column $A = 0.786$ sq in., $L = 7.5$ in., $\gamma = 1.4$, and $P_0 = 14.7$ psi. Suppose a rectangular pressure wave with $P_s = 25$ psi, and $\tau = 0.003$ sec were applied to this system. As a general case, let the piston be displaced initially 1 in. in the positive direction and have an initial positive velocity of 100 ips.

By introducing the initial conditions in Equation [8] the constant of integration C is found to be $0.916 \frac{AP_0L}{\gamma - 1}$ and by substituting the numerical values given, Equation [8] becomes

$$v = 3560 \sqrt{0.916 + 0.144\,X - \frac{1}{(1 - 0.133\,X)^{0.4}}} \quad [11]$$

The relation $t = \int \frac{1}{v}\,dX$ then becomes

$$t = 0.000281 \int \frac{1}{f(X)}\,dX \quad [12]$$

where $f(X)$ is defined in Equation [11]. A plot of the integrand against X is shown in Fig. 18. The area under the curve has been divided into nine arbitrary sections to be integrated with a planimeter. The development of the analysis is shown in Table 1.

TABLE 1 DEVELOPMENT OF ANALYSIS

Section	Area	Total area, A	Total time, 0.000281A, in sec	Displacement x, in.

Fig. 19 shows a plot of the last two columns of Table 1 which give motion of the piston from $t = 0$ to $t = 4.25$ millisec, if the pressure wave were acting on the system for that length of time. However, since the duration of the wave was assumed to be 3 millisec, the curve in Fig. 19 does not hold true after that time. At $t = 3$ millisec, the displacement is 3.45 in. From Equation [11], the velocity at this time is determined to be 1310 ips.

Now if another pressure wave is assumed to act on the system at $t = 3$ millisec, then the initial conditions are $x = 3.45$ in., and $v = 1310$ ips, and the entire foregoing process is repeated.

When the piston comes to a stop at an extreme position, the integrand of Equation [12] becomes infinite. However, the value of the maximum displacement X_m can be determined to the desired degree of accuracy by continuing the process for $X < X_m$ until the increase in area becomes negligible. To continue the analysis after $X = X_m$, the process begins over again. However, now the initial velocity is zero. In this case, the simple transformation $Z = X_m \sin \theta$, as suggested by Rauscher,[2] can be used to avoid the discontinuity.

Second Law of Thermodynamics for Changes of State and Quantity of Working Substance With Particular Reference to Steam Engines[1]

By G. ZERKOWITZ, HAIFA, PALESTINE

For many years the author had devoted increased attention and study to the problems of the change of state and quantity of thermal working substances.[2] These thermal processes particularly occur in piston engines, e.g., in steam engines during admission and release, in internal-combustion engines in the exhaust, and in compressors during the inlet to and the outlet from the cylinder. In turboengines they also can play a part, e.g., in gas turbines with explosion chambers, such as the Holtzwarth turbine. In the author's former essay numerous instances based on the first law of thermodynamics have been dealt with whereas, in this paper, first some other applications of the first law of thermodynamics and then the formulation of the second law of thermodynamics for changes of state and quantity will be presented. Particular attention will be devoted to the thermodynamic aspect of the entropy diagrams dealing with variable quantities, and the sources of errors which may occur when using such diagrams.

The First Law of Thermodynamics

According to the first law of thermodynamics for changes of state and quantity

$$dQ + h_x dG = dU + pdV \quad [1]$$

or

$$dQ + h_x dG = d(Gu) + pd(Gv) \quad [1a]$$

where

Q = quantity of heat received from outside source
G = alterable weight of working substance
u = internal energy of 1 lb of working substance
U = internal energy for G lb of working substance
p = pressure of working substance
v = specific volume of working substance
V = volume of G lb of working substance
h_x = enthalpy of 1 lb of substance entering or leaving
dG = element of weight of working substance

For the sake of uniformity and simplicity, the mechanical equivalent of heat has been omitted, and it is proposed that all quantities be specified in British thermal units. Again, dW where W denotes external work produced can in many cases be substituted for pdV.

Let us now state the first law of thermodynamics regarding the changes of state and quantity of the working substance in a modified form. Writing $H = U + pV$, where $H = Gh$, we have

$$dQ + h_x dG = dH - Vdp \quad [2]$$

or

$$dQ + h_x dG = d(Gh) - (Gv)dp \quad [2a]$$

where

h = enthalpy of 1 lb of substance
H = enthalpy of G lb of substance

If the substance is homogeneous, then $h_x = h$, since the element dG in the outlet is in the same state as when inside the chamber. On the other hand, for the admission process, h_x is generally unequal to h. In a steam engine, for example, where h_k is the enthalpy inside the boiler,

$$h_x = h_k = \text{const} \quad [3]$$

Though admission processes are generally irreversible, and therefore accompanied by an increase of entropy, it is possible to calculate the external work W for processes in piston engines from the expression

$$dW = pdV = pd(Gv) \quad [4]$$

and

$$-VdP = -(Gv)dp \quad [5]$$

also

$$W_t = \int_{p_2}^{p_1} Vdp$$

where W_t is the so-called "work of a cycle."

Formulation of Second Law of Thermodynamics for Changes of State and Quantity

Let T be the absolute temperature and s the entropy for 1 lb of the working substance, then the form adopted for the second law of thermodynamics for reversible changes of state, not involving changes of quantity, will be

$$dq = Tds \quad [6]$$

In order that the latter expression should also involve changes of quantity we must introduce in Equations [1] and [2], the following equations applying to 1 lb of the working substance:

---

[1] The present paper is the last written by Dr. Ing. G. Zerkowitz, an excellent mechanical engineer who left Germany when Hitler had come to power. He died in 1942, as Professor of Thermodynamics of the Hebrew Technical College (Institute of Technology) in Haifa, Palestine. The writer of this footnote has changed the symbols according to the American standards, corrected some minor errors and added an explanatory footnote. The original manuscript included two more parts, one dealing with Boulvin's method of replacing the varying quantity by a fictitious constant quantity, the other one dealing with internal-combustion engines. These parts had to be omitted because of space limitations. (*Signed*) Max Jakob, research professor of mechanical engineering, Illinois Institute of Technology, Chicago, Ill. Mem. A.S.M.E.

Presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

$$Tds = du + pdv \quad [7]$$

or

$$Tds = dh - vdp \quad [7a]$$

These equations apply to both reversible and nonreversible processes when no chemical changes of the substance occur. When the real process is nonreversible, it can be replaced by a reversible one, performed between the same initial and final states, as established by M. Planck in his treatise on thermodynamics.

Substitute $U = Gu$ and $V = Gv$ in Equation [1]; then

$$dQ + h_x dG = udG + Gdu + Gpdv + pvdG$$

The first and fourth terms on the right-hand side of this expression combine to hdG, while the second and third terms, from Equation [7], become equal to $GTds$; hence

$$dQ + h_x dG = hdG + GTds \quad [8]$$

or

$$dQ + (h_x - h)dG = GTds \quad [8a]$$

which is a suitable form of the second law of thermodynamics for changes of state and quantity. As to the outflow of a homogeneous working substance, $h_x = h$, and consequently

$$dQ = GTds \quad [9]$$

in analogy to Equation [6].

The right-hand side of Equation [9] can be integrated only if G is known or can be deduced. If $dQ = 0$, i.e., no heat is absorbed from environment or from walls, $\int GTds = 0$ which, for example, occurs in emptying a receptacle of constant volume. In the admission process h_x may be equal to h, but mostly $h_x \gtrless h$.

Adiabatic Emptying and Filling of a Receptacle

First, let $h_x = h$; hence, from Equation [1]

$$hdG = d(Gu) = udG + Gdu$$

or

$$(h - u)dG = Gdu$$

But

$$h - u = pv$$

so that

$$pvdG = Gdu$$

or, as

$$vdG = d(Gv) - Gdv$$

and V_0 = constant volume of receptacle

$$d(Gv) = dV_0 = 0$$

Hence[3]

$$du + pdv = 0 \quad [10]$$

which is the equation for the adiabatic change of state.

Similarly, since it has been assumed that $dQ = 0$

$$ds = 0 \quad [10a]$$

viz., the entropy is constant.

The foregoing consideration has established the relation for the emptying of a receptacle; for the filling, however, we have to distinguish between several different cases.

Filling a Receptacle by Means of a Compressor Without Any Cooling. In the following, it is assumed that the state of the gas drawn in by the compressor is identical with that initially within the receptacle. Also, that the pressure prevailing in the pressure-side piping of the compressor is permanently held equal to that inside the receptacle, which means that no valve is provided between the pressure-side piping and the receptacle, the compression taking place adiabatically with no losses.

Let the initial pressure be p_1, e.g., 1 atm; the final pressure p_2; the initial weight of the gas in the receptacle $G_1 = V_0/v_1$, where v_1 = initial specific volume; and the final weight of the gas therein G_2, where $V_0 = G_2 v_2$, and v_2 = specific volume.

The difference, $G_2 - G_1 = \Delta G$, therefore, is the weight of gas forced into the receptacle by the compressor, and the work expended on the compressor is

$$W_c = \int (h - h_1)dG \quad [11]$$

where h is the variable enthalpy of 1 lb of gas at the exit of the compressor and inside the receptacle.

$$W_c = \int hdG - h_1(G_2 - G_1)$$

By a partial integration of the first expression

$$\int_1^2 hdG = (G_2 h_2 - G_1 h_1) - \int_1^2 Gdh$$

Since the process is adiabatic, $dh = vdp$

$$\int_1^2 Gdh = \int_1^2 Gvdp = V_0 (p_2 - p_1)$$

hence

$$\int_1^2 hdG = (G_2 h_2 - G_1 h_1) - V_0(p_2 - p_1)$$

and

$$W_c = G_2(h_2 - h_1) - V_0(p_2 - p_1) \quad [12]$$

This work is represented by the area 3-2-1-3 in the p, v diagram shown in Fig. 1. In the h, s diagram (Fig. 2), however, it cannot be represented.

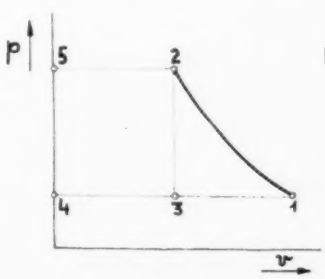

Fig. 1

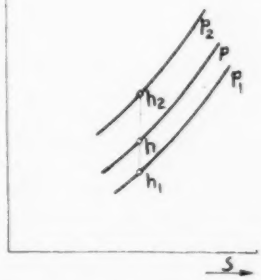

Fig. 2

Complete Cooling of Compressor and Receptacle. It will be supposed that both the compressor and receptacle are cooled by means of an infinite quantity of cold water, so that all processes are isothermal at the constant temperature T_k. Here, under ideal gas conditions, $h_x = h_k$ = const, and $u = u_k$ = const. From Equation [1]

$$dQ + h_k dG = d(Gu)$$

$$dQ + h_k dG = d(Gu_k)$$

and because

$$h_k - u_k = p_k v_k$$

$$dQ + p_k v_k dG = 0 \quad [13]$$

[3] Namely, from: $d(Gv) = Gdv + vdG = 0$; and $pvdG = Gdv$. (Added by M. Jakob.)

dQ is negative because heat is permanently extracted.

The weight of the gas inside the receptacle at any instant is

$$G = \frac{V_0 p}{RT_k} \text{ or } dG = \left(\frac{V_0}{RT_k}\right) dp \quad \ldots\ldots [13a]$$

The work expended on the compressor, assumed to be without any losses, is

$$dW_c = \left(RT_k \ln \frac{p}{p_1}\right) dG$$

or, from Equation [13a]

$$dW_c = V_0 \left(\ln \frac{p}{p_1}\right) dp$$

By integration

$$W_c = V_0 \left[p_2 \ln \left(\frac{p_2}{p_1}\right) - (p_2 - p_1)\right] \quad \ldots\ldots [14]$$

This work is represented by the area 1-2-3-1 in Fig. 3.

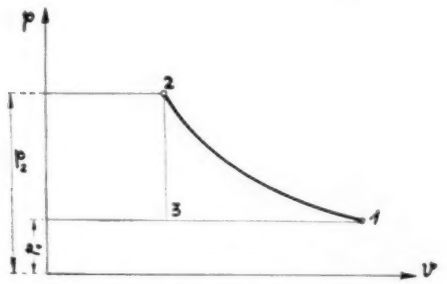

FIG. 3

Filling by Means of a Completely Cooled Compressor Without Cooling of Receptacle. Equation [1a] for the process in the receptacle takes the following form

$$h_k dG = d(Gu)$$

Here the state of the gas supplied by the compressor differs from that inside the receptacle during the filling, even though the two were identical at the beginning of the filling. For the state of the gas inside the pressure-side piping

$$h_k = c_p T_k + C$$

$$u_k = c_v T_k + C$$

whereas for the energy of the gas inside the receptacle

$$u = c_v T + C$$

where c_p, c_v are the specific heats of 1 lb at constant pressure and at constant volume, respectively; hence

$$c_p T_k dG = c_v d(GT) \quad \ldots\ldots [15]$$

Now

$$pV_0 = GRT$$

hence

$$d(GT) = \frac{V_0}{R} dp \quad \text{and} \quad dG = \frac{V_0}{R} \cdot d\left(\frac{p}{T}\right)$$

From Equation [15]

$$c_p T_k \cdot d\left(\frac{p}{T}\right) = c_v dp$$

Substituting $\kappa = c_p/c_v$

$$\kappa T_k d\left(\frac{p}{T}\right) = dp \quad \ldots\ldots [16]$$

and by integration

$$\kappa T_k \left(\frac{P_2}{T_2} - \frac{P_1}{T_1}\right) = p_2 - p_1 \quad \ldots\ldots [17]$$

The weight of the gas admitted into the receptacle is

$$G_f = G_2 - G_1 = \frac{V_0}{R}\left(\frac{p_2}{T_2} - \frac{p_1}{T_1}\right)$$

or, from Equation [17]

$$G_f = \frac{V_0}{R}\left(\frac{p_2 - p_1}{\kappa T_k}\right) \quad \ldots\ldots [18]$$

Since the compression is isothermal the work input may be obtained from

$$dW_c = RT_k \ln \left(\frac{p}{p_1}\right) dG$$

But from Equation [18]

$$dG = \frac{V_0}{\kappa RT_k} dp$$

hence

$$dW_c = \frac{V_0}{\kappa} \ln \left(\frac{p}{p_1}\right) dp$$

$$W_c = \frac{V_0}{\kappa}\left[p_2 \ln \left(\frac{p_2}{p_1}\right) - (p_2 - p_1)\right] \quad \ldots\ldots [19]$$

which is $1/\kappa$ that of the preceding case.

Filling With Compressor of Constant Maximum Pressure p_2. Finally, it will be assumed that compression takes place continuously up to the maximum pressure p_2, which is maintained constant by the insertion of a reducing valve between the piping and receptacle. Temperature T_2 is in this case derived from Equation [17]. T_k is the temperature before and after the reducing valve. The "filling effect" is greatest when initially the vacuum in the receptacle is perfect, i.e., $p_1 = 0$. In this case

$$\kappa T_k = T_2 \quad \ldots\ldots [17a]$$

If, for example, $T_k = 300$ deg K, then

$$T_2 = 1.4 \times 300 = 420 \text{ deg K}$$

The foregoing relation holds for ideal gases only; the fundamental equations, however, apply equally to all working substances.

APPLICATION TO STEAM-PISTON ENGINES

It is clear that both expansion and compression, each referring to 1 lb of steam, or to some other constant weight, can be represented in the T, s diagram. It should be further noted here that modern experimental investigations show the working substance within the cylinder to be nonhomogeneous. Due to heat transfer from the steam to the walls, it is possible that the steam is superheated inside the cylinder, whereas a liquid film is formed on the surface of the walls. The thickness of this film increases if the steam is condensing, while a decrease indicates that the liquid is evaporating. Thus the working substance can exist in both the liquid and gaseous phases. This fact, however, will not

be taken into account. Hence, the expansion and compression will be regarded as simple changes of state, whereas the admission and outflow are changes of state and quantity.

Let G_f, G_r be the weights of steam admitted and remaining in the clearance space, respectively, then the weight of steam involved in the expansion is

$$G_1 = G_f + G_r$$

The theoretical p, v diagram of a steam engine is shown in Fig. 4, the p, v diagram, corresponding to Fig. 4, is shown in Fig. 5, and the h, s diagram of the same engine is shown in Fig. 6. If h_k is the enthalpy of incoming steam then h_1 is the enthalpy of the steam inside the cylinder at the end of the filling, and the difference $h_1 - h_k$ represents the filling effect. The point a in Fig.

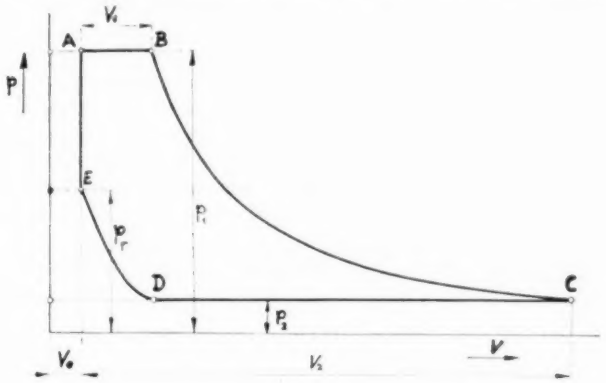

Fig. 4

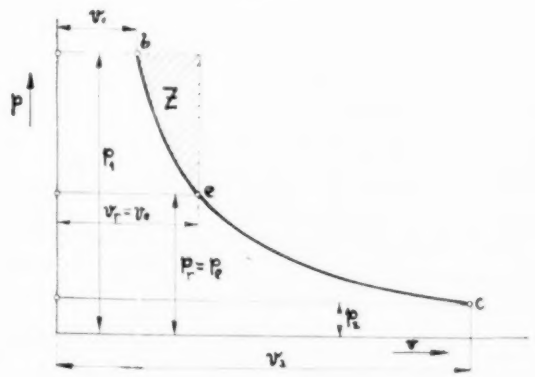

Fig. 5

6, corresponds to A in Fig. 4, and represents the end of the partial filling at constant volume. The enthalpy at this point is still higher than h_1. Calculating the work of the whole cycle from Fig. 4, we have

$$W = (G_f + G_r)\ \Delta h - G_r \Delta h_r - (p_1 - p_r)V_0$$

where $V = G_r v_r$, and Δh_0, Δh, and Δh_r are the adiabatic enthalpy drops, corresponding to the initial state in the boiler, the state inside the cylinder at the end of the admission, and the compression, respectively.

Writing $G_r = \rho G_f$ and after some mathematical derivations, we obtain

$$h_1 - h_k = \rho z \ldots\ldots\ldots\ldots\ldots\ldots [20]$$

where z equals the cross-hatched area in Fig. 5.

For an engine with no clearance, the work is

$$W_0 = G_f \Delta h_0$$

The loss of work caused by the clearance is $W_0 - W_1$, or for 1 lb

$$\frac{W_0 - W_1}{G_f} = \Delta h_0 - (\Delta h - \rho z)$$

In the h, s diagram of Fig. 6, Δh_0 is represented by the line

$$b_0 c_0 = h_k - h_2'$$

while

$$\Delta h' = h_1 - h_2$$

The loss due to the filling of the clearance is

$$\Delta h_1 = h_2 - h_2' \ldots\ldots\ldots\ldots\ldots\ldots [21]$$

or, expressed in terms of temperature and entropy in the case when the steam at the end of the expansion is wet

$$\Delta h_1 = T_2 \Delta s \ldots\ldots\ldots\ldots\ldots\ldots [21a]$$

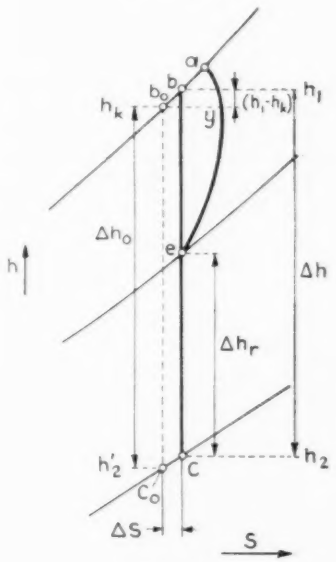

Fig. 6

Now the behavior of the entropy during the filling will be examined. In the ideal case, the filling consists of two stages, i.e., a quantity isometric EA and a quantity isobaric AB (Fig. 4). The quantity isometric behaves very similarly to that of the filling of a receptacle in accordance with the case "Filling with Compressor of Constant Maximum Pressure, p_2," previously discussed. It is a nonreversible process and the entropy does not remain constant but describes the curve e-y-a in Fig. 6. The adiabatic branch b-e is valid only for the expansion, while, for the return stroke of the piston, the adiabatic is valid only for the compression stage c-e.

According to curve e-y-a, the entropy attains its maximum value at a point y, where $h = h_k$. The shape of this actual curve can be obtained point by point by using the following two equations

$$h_k \cdot \Delta G = h_k(G - G_e) = Gu - G_e u_e \ldots\ldots\ldots [22]$$

where G_e and u_e refer to the beginning of the compression at the point E. $G_e = G_r$ = quantity of steam remaining in the clearance and

$$\Delta G = G - G_e = V_0 \left(\frac{1}{v} - \frac{1}{v_e}\right) \ldots\ldots\ldots [22a]$$

Preliminary values of temperature T are chosen for any pressure between p_a and p_1, and u and v are then calculated. The preliminary temperature is deemed correct when the same value of ΔG is obtained from both Equations [22] and [22a]. In similar manner also the final point a, corresponding with the pressure p_1 is determined. For the second stage of the filling process AB carried out at constant pressure, the following equations apply

$$h_k(G - G_r) = Gh - G_a h_a$$

$$\frac{V_0}{V_0 + V_1} = \frac{G_a v_a}{Gv}$$

For the final point B we have

$$\left.\begin{aligned} h_k(G_1 - G_a) &= G_1 h_1 - G_a h_a \\ \frac{V_0}{V_0 + V_1} &= \frac{G_a v_1}{G_1 v_1} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [23]$$

In this manner the form of the change of state is obtained also in the T, s and h, s diagrams. In comparing such a diagram with that drawn from readings taken experimentally, differences in areas are observed; these differences are due to heat transfer with the walls. In both cases $\int TGds$ has to be formed.

From the experiments of Ulsamer[4] it is evident that also in the case of slight superheating of the live steam during the filling, expansion, and compression, a core of superheated steam fills up the inside of the cylinder. It is therefore clear that the working substance in the true processes in the actual engine is not homogeneous. If this phenomenon is disregarded, we arrive at the filling effect in accordance with Equations [20] to [23] as for example: $p_1 = 10$ atm; temperature of incoming steam $t_0 = 300$ C; $p_2 = 0.1$ atm; $\rho = 0.1$; hence

$$h_1 - h_k = 11 \text{ kcal/kg and } t_1 - t_k = 22 \text{ deg C (filling effect)}$$

Conclusions

In the present paper, the fundamental principles regarding the changes of state and quantity of a working substance are presented, beginning with the more usual cases, such as the filling of a receptacle. On the basis of the general formulation of the second law of thermodynamics for changes of state and quantity the important case of the steam engine has been dealt with.

It is shown that only for pure changes of state, i.e., changes of state with constant quantity of the working substance, the entropy diagram can be unrestrictedly used, whereas in change of state and quantity it is necessary to examine in each case if and in what manner the entropy diagram may be applied.

An Investigation of the Cross-Spring Pivot

By W. E. YOUNG,[1] EAST PITTSBURGH, PA.

It is the purpose of this paper to describe the characteristics of the cross-spring pivot, or elastic hinge, for large deflection angles. Design formulas are established for certain standard forms of the two-spring pivot on the basis of experimental results. Formulas are developed for the spring constant, bending stress, and motion of the pivot point; their application is illustrated by an example. A comparison of the various pivots, when used in lever systems, is made, and suggestions for the design of two-spring pivots are included.

1 Introduction

THE cross-spring pivot, or elastic hinge, consists of a system of flat springs intersecting as in the letter X. The ends of the springs are fastened to the two members which it is desired to connect. This system has the characteristic of rotating approximately about the intersection of the springs and in many applications it can advantageously replace the knife-edge.

The cross-spring pivot appears to have several qualities which often make it superior to either knife-edges or pin connections in controlling an oscillating motion. It is perfectly elastic since there are no moving parts in contact to produce friction; also its construction enables it to withstand a sudden reversal of load which might unseat a knife-edge. Its chief advantage over a pin connection lies in the fact that with no moving parts in contact, no lubrication is necessary and no wear takes place.

This type of pivot has been used for small angular deflections in a number of cases (1)[2] but little has been known regarding its applicability to large angles of deflection. A mathematical approach was made to the problem and equations were derived, connecting the interreacting forces and moments in the linkage. The system was found to be statically indeterminate, and these equations become extremely complex. Due to the difficulties of solution, it seemed wiser to attempt an experimental analysis. Accordingly, a series of tests has been made for the purpose of analyzing the motion of the mechanism, particularly for deflection angles up to 45 deg.

2 Test Apparatus

A sketch of the principal parts of the test apparatus is shown in Fig. 1. Four flat springs *a* may be seen, forming two separate pivots. The ends of each spring are held in spring blocks *b* which in turn are fastened to end plates *c* and *d*. End plate *c* is attached to a bedplate through the support *e* while end plate *d* is constrained to a rotation approximately about the axis *o* through the initial intersections of the springs. To end plate *d* is bolted a pointer *f* by which the angle of deflection may be measured (see Fig. 2). A stylus *g* at the front end of the pointer plots its path on the drawing board *h* as the springs deflect. At the same time, stylus *i*, attached to the rear of the pointer and set initially on the axis *o*, plots the motion of this axis. Slots *j* cut in each end plate allow an adjustment of the initial spring intersection angle (see Fig. 2), while the spring blocks permit any length, width, and thickness of flat spring to be used.

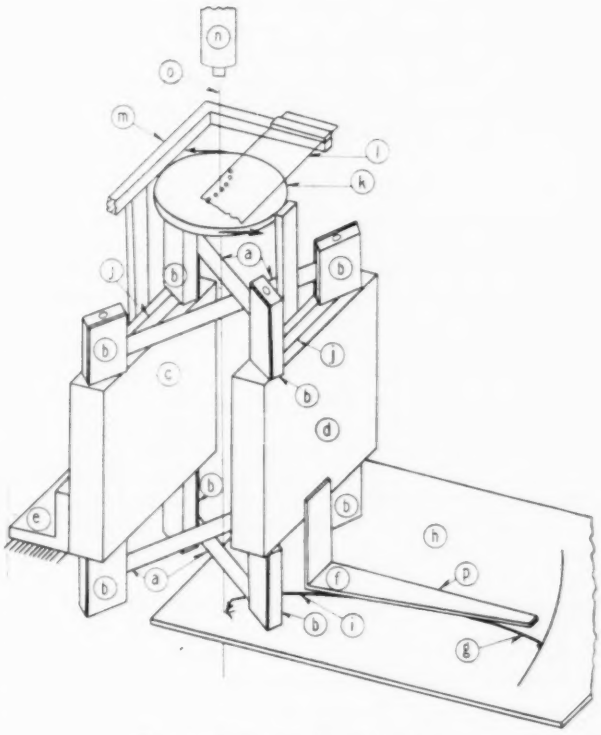

Fig. 1 Sketch of Test Apparatus

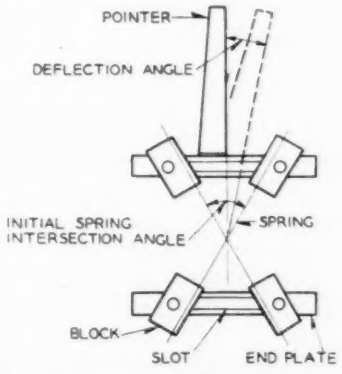

Fig. 2 Sketch of Experimental Setup

Loading is accomplished by means of disk *k* which is rigidly fastened to end plate *d* and set with its center on the axis *o* of initial spring intersection. In order that a pure moment be supplied to the springs, equal forces are applied at the extremities of a diameter of the disk in the form of a couple.

In locating instantaneous centers of rotation, use is made of a piece of transparent film *l* held in frame *m* which in turn is rigidly attached to the stationary end plate *c*. For each angular position of the pointer, a point may be located on the disk which

Presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th St., New York, N. Y., and will be accepted until July 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of authors and not of the Society.

rotates without translating for small angular oscillations of the pointer about this position. Microscope n was used to locate these centers of rotation through the transparent film on the disk. Once located, the centers could be recorded on the film by means of a microscope diamond point objective.

The apparatus as just presented appears extremely complicated since it was designed to accommodate and test many different sizes of springs with various intersection angles. It should be understood, however, that the cross-spring pivot as generally used is a very simple construction since it is not necessary to provide for changing such variables as spring length and intersection angle.

3 General Test Procedure

For each test, the flat springs were first attached to their respective blocks and set at the required length. The blocks were then bolted to the end plates with such spacing in the slots that the springs intersected at their mid-points. The correct angle of intersection was then obtained with a protractor. Next, the pointer was adjusted so that its reference edge p cut the axis of initial spring intersection as shown in Fig. 1; the loading disk also was set with its center on this axis. Loads were applied to the disk circumference by coil springs, the corresponding lengths of which were obtained from a coil spring calibration curve. The two styli traced the paths of the initial spring intersection point and the front end of the pointer, respectively, as shown in Fig. 3, and for each recorded loading the position of the pointer was plotted on the drawing board by a line drawn along its reference edge.

At the same time the microscope was manipulated to locate the center of rotation for each pointer position, and this center was marked on the transparent film with the microscope diamond point objective. These instantaneous centers for the various

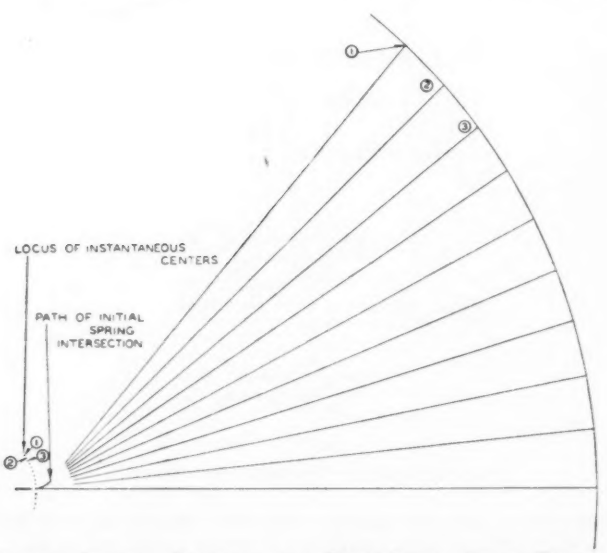

Fig. 3 Pointer Positions for Cross-Spring Pivot Tester (0.012 in. spring thickness; 3 in. spring length; 90 deg spring angle.)

pointer positions may be seen in Fig. 3. Center No. 1 corresponds to pointer position No. 1, Center No. 2 to pointer position No. 2, and so on.

4 Specific Tests

Five separate tests were made for certain standard spring angles, lengths, and thicknesses, with the springs initially intersecting at their mid-points; 0.012 × 3/8 in. and 0.0085 × 0.470 in. springs were used. For the 0.012-in. spring, a length of 3 in. was tested at 30, 60, and 90 deg initial spring intersection angles with the purpose of finding the effect of this angle.

In order to find the effect of spring length and also spring thickness, tests were made on 3 and 1 1/2-in. lengths of the 0.0085-in. springs. For comparison, a 60-deg intersection angle was used with both the 3 and 1 1/2-in. lengths.

For each of the foregoing five tests, data similar to Fig. 3 were obtained, and from these data, the curves in Fig. 4 were plotted.

5 Derivation of the Spring Constant for Small Angles

Let K_1 = spring constant for one spring
M_1 = total moment on one spring
θ = angle of pointer deflection
l, E, and I = characteristics of the spring
n = number of springs
K = total spring constant

By means of the first area moment proposition, it may easily be shown that for small angles,

$$\theta = \frac{M_1 l}{EI}$$

also

$$K_1 = \frac{M_1}{\theta}$$

and combining

$$K_1 = \frac{M_1}{M_1 l/EI}$$

for one spring

$$K = n\,\frac{EI}{l}$$

for n springs

This derivation assumes only a moment on the springs and no reaction forces, which is not the case except at zero degrees deflection. A calculation of each setup using this formula should give values approximating zero deflection on the curve. This was found to be true as shown in Table 1.

TABLE 1 COMPARISON OF THE CALCULATED CONSTANT FOR SMALL ANGLES TO THE MEASURED CONSTANT AT 0 DEFLECTION FOR EACH TEST

	Spring designation	Calculated constant	Measured constant
1	3 × 0.012 × 3/8 in.	2.16 lb-in. per radian	2 lb-in. per radian (Average value from three tests)
2	3 × 0.0085 × 0.470 in.	0.96 lb-in. per radian	0.9 lb-in. per radian
3	1 1/2 × 0.0085 × 0.470 in.	1.93 lb-in. per radian	1.95 lb-in. per radian

The spring angle has no effect on the derived constant for small angles.

These results all check within 7 1/2 per cent which is within the combined liable error for the test measurements, calculation, and curve scatter.

6 Design of the Cross Spring Pivot

1 *Dimensions of the Springs Used (for Required Spring Constant)*

A torque problem may be stated in one of two ways. First, assuming that a cross-spring pivot is to be used, it may be desired to obtain a certain instantaneous spring constant at a given deflection; or, second, a definite amount of torque may be available and a maximum total deflection may be permitted for this torque because of strength limitations.

From the curves in Fig. 4 it was found possible to determine the effect of the various spring dimensions and angles on the spring constant for steel springs. These observations are shown in the following tabulation:

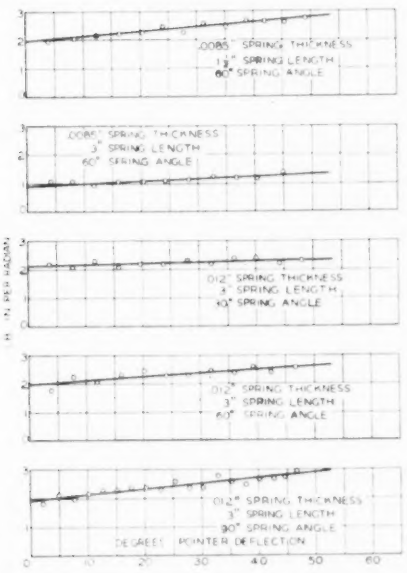

FIG. 4 SPRING CONSTANT CURVES FOR THE CROSS-SPRING PIVOT

1 From the curves for the $1^1/_2 \times 0.0085$ in. and the 3×0.0085-in. springs, the increase in constant for a given deflection is seen to vary inversely as the length of spring used.

2 Since the curves in each case approximate straight lines, the increase is directly proportional to the displacement angle.

3 It was found from the tests on the 0.012×3-in. springs that the increase in constant varies approximately as the 1.4 power of the spring intersection angle. This exponent was arrived at by trial.

4 Although no tests were made to determine the effect of spring width, it seems logical to assume that the increase in constant varies directly with the width of spring used.

5 If the foregoing assumption is allowed, an examination of the 0.0085×3-in. and 0.012×3-in. springs (both with a 60-deg intersection angle) indicates that the increase in constant varies with the square of the spring thickness.

Finally we obtain the relation

$$K_i = C\left(\frac{bd^2\theta\phi^{1.4}}{l}\right)$$

where K_i is the increase in spring constant over the value for small angles nEI/l, as derived. The unit for K_i will be lb-in. per radian. Other terms are:

C = arbitrary constant
b = spring width, in. (sum of all springs)
d = spring thickness, in.
l = spring length, in.
θ = deflection angle in radians
ϕ = intersection angle in deg

From the various tests, an average value of C may be obtained. For the 0.012×3-in. spring with a 30-deg intersection angle, the solution becomes

$$C = \frac{K_i l}{bd^2\theta\phi^{1.4}}$$

Substituting test values in this equation

$$C = \frac{0.20 \times 3 \times 57.3}{4 \times 0.375 \times 0.012^2 \times 45 \times 30^{1.4}}$$

$$= 30.5$$

The average value of C for all tests is about 31 with values ranging from 29.5 to 32.7. The final formula is approximately

$$K_i = 31\left(\frac{bd^2\theta\phi^{1.4}}{l}\right)$$

The formula is, of course, entirely empirical, and a greater number of tests would doubtless result in a more accurate value for the arbitrary constant as well as for the exponent of the spring intersection angle.

Now, if a certain spring constant is desired at a given deflection, its value may be substituted in the relation

$$K = n\frac{EI}{l} + K_i$$

(K = total constant)

where I is the moment of inertia of one spring and n is the number of springs to be used. This may be rewritten

$$l = \left(\frac{E}{K}\right)\left(\frac{bd^3}{12}\right) + \left(\frac{31}{K}\right)(bd^2\theta\phi^{1.4})$$

Next, a standard-dimension spring may be chosen, and the b and d values substituted in this formula for l. The intersection angle, ϕ, would generally be 90 deg, but this will be considered later. Since only steel springs were tested, the modulus does not appear in the increase of constant. However, it is quite possible that this increase would be proportional to the spring stiffness and hence to the modulus of elasticity of the material.

If the resulting value of the length is unduly short or long, spring stock with a different thickness or width dimension must be chosen.

As a second case, suppose that a definite torque is required for a given deflection. Since the spring constants considered have been instantaneous values, an average increase over the range of deflection in question must be determined for use in the basic relation, $M = K\theta$. This means that the total average constant would be

$$K = n\frac{EI}{l} + \frac{1}{2}K_i$$

where $n\dfrac{EI}{l}$ is the constant for small angles (either average or instantaneous). Since the instantaneous spring constant increases linearly from 0 deg deflection to its value, K_i, at the given deflection, the average increase for that range is $^1/_2$ the instantaneous value, K_i, occurring at the given deflection.

The total torque developed at the given deflection becomes

$$M = \left(n\frac{EI}{l} + \frac{K_i}{2}\right)\theta$$

which may be rewritten

$$l = \frac{\theta}{M}\left(\frac{bd^3E}{12} + 15.5\ bd^2\theta\phi^{1.4}\right)$$

where M is the total torque and the number of springs n has been included in the quantity b. From this relation l may be solved as before.

To use the formulas developed above, it becomes necessary to raise the value of the spring intersection angle ϕ to the 1.4 power. In order to eliminate such a calculation, curves have been drawn of increases in spring constant for various $\dfrac{bd^2\theta}{l}$ ratios. The curves in Fig. 5 have been plotted for the standard intersection

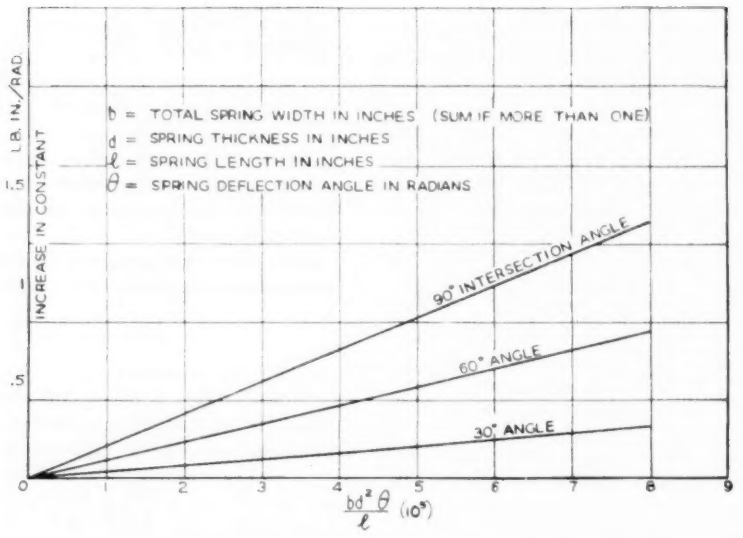

FIG. 5 INCREASE IN SPRING CONSTANT OVER VALUE FOR SMALL ANGLES $\left(K = \frac{EI}{l}\right)$

angles, 30, 60, and 90 deg. These values may be used in place of K_i in these formulas.

Since both the curves and the formulas have been built up from various test data, which were intended to lie in a range frequently used, they may not be applicable for values which differ greatly from these test data.

For this reason, calculations for springs over 3 in. long and greater than 0.012 in. in thickness should be used with discretion, particularly if the deflection angle is greater than 45 deg. The same applies to the very low ranges where small variations due to clamping and eccentricities may greatly affect the spring constants of short and thin springs at small angular deflections. Values have not been checked for thickness below 0.008 in., lengths of 1 in. or less, and angular deflections of less than 5 deg.

2 *Stress in the Springs at Maximum Deflection*

Stress for small deflection angles of cross springs is usually determined on the basis of a constant moment throughout the length of the spring. This assumes that the springs are bent in circular arcs of equal radii, which does not seem to be exactly the case for large deflection angles. Apparently, auxiliary forces and moments are introduced at the ends of the springs by the larger deflection angles. These end reactions are probably responsible for the increase of constant over that value for small angles. At the same time the bending stress increases.

Since the exact nature of the end reactions is not known, it has been assumed that the increase in bending stress will be proportional to the increase in spring constant over the value for small angles, or the stress due to bending will be proportional to the bending moment as derived. If this approximation is allowed, we obtain the relation

$$\frac{\sigma_a}{\sigma_i} = \frac{M_a}{M_i}$$

where σ_a = the bending stress to be determined
σ_i = the bending stress as determined on the basis of the spring constant for small angles
M_a = the bending moment as calculated from the foregoing formulas
M_i = the bending moment as calculated on the basis of the spring constant for small angles

but

$$\sigma_i = \frac{M_i C}{I}$$

where $C = {}^1/_2$ spring thickness

$$M_i = \left(\frac{EI}{l}\right)\theta$$

$$M_a = \left(\frac{EI}{l} + \frac{K_i}{2}\right)\theta$$

from the foregoing.

Assume

I = total moment of inertia of the springs

then

$$\sigma_i = \frac{C\theta}{I}\left(\frac{EI}{l} + \frac{K_i}{2}\right)$$

This result appears reasonable since even at large angles of deflection the springs appear to be bent in circular arcs. For an approximate calculation then, the bending moment will be assumed to be constant throughout the length of the spring and the stress will be assumed to be the same in both springs.

This stress may be rewritten

$$\sigma_a = \frac{C\theta E}{l} + \frac{K_i C\theta}{2I}$$

but

$$K_i = 31\left[\frac{b(4C^3\theta\phi^{1.4})}{l}\right]$$

(since $d = 2C$)

$$\sigma_a = \frac{C\theta E}{l} + 62\left[\left(\frac{2C^3\theta\phi^{1.4}b}{l}\right)\left(\frac{C\theta}{2I}\right)\right]$$

$$= \frac{C\theta}{l}\left[\mathrm{E} + 62\left(\frac{bC^2\theta\phi^{1.4}}{I}\right)\right]$$

If

$$I = \frac{bd^3}{12}, \qquad d = 2C$$

$$I = \frac{2bC^3}{3}$$

and substituting in the foregoing

$$\sigma_a = \frac{C\theta}{l}\left[E + 93\left(\frac{\theta\phi^{1.4}}{C}\right)\right]$$

This formula may be used only for steel springs.

If the stress as calculated by the foregoing formula appears excessive, the design on a torque basis must be repeated and either the length of the springs increased or the thickness decreased.

3 *Amount of Travel of Initial Pivot Point*

In some instances, it may become necessary to limit the travel of the initial pivot point. For example, if a cross-spring mechanism were being used to center a coil in an air gap, any undue shift of the pivot point might lessen or actually close the air gap. From the tests it appears that this shift is proportional to the spring length. Consequently curves have been drawn for springs one inch long using the results of the foregoing tests (see Fig. 6). The curve ordinate must be multiplied by the spring length in order to get the actual displacement in hundredths of an inch. This displacement is best defined by the accompanying sketch Fig. 7.

As the springs deflect to the positions shown by the dash lines, the initial pivot point travels along the arc F and the displacement as read from the curve sheet is the radial or chord distance E, assuming that the springs are one inch in length.

If we consider the curves to have equations of the approximate form

$$y = AX + BX^2 + CX^3 + DX^4$$

where y is the amount of travel in 0.01 in. per in. spring length and X is the angular deflection of the pointer and springs in degrees, the constants, A, B, C, and D may be solved by substituting points on the curve and the equations become

$y = 0.04133X - 0.001225X^2 + 0.0001267X^3 - 0.00000075X^4$ (for a 90-deg intersection angle)

$y = -0.02865X + 0.006115X^2 - 0.0001333X^3 + 0.000001833X^4$ (for a 60-deg intersection angle)

$y = 0.03924X - 0.004595X^2 + 0.0002675X^3 - 0.00000304X^4$ (for a 30 deg intersection angle)

The value of y may then be multiplied by the actual spring length to obtain the total displacement at that deflection angle. From the curves of Fig. 6 it may be seen that the pivot point travels less for a smaller intersection angle, but from the tests it was found that the apparatus was likely to be less rigid.

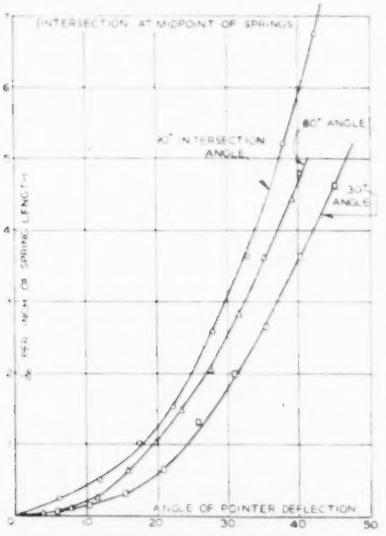

FIG. 6 DISPLACEMENT OF THE INITIAL PIVOT POINT FROM ITS ORIGINAL POSITION FOR VARIOUS DEFLECTION ANGLES AND SPRING INTERSECTION ANGLES

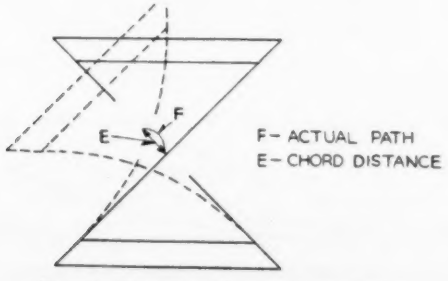

FIG. 7 TRAVEL OF INITIAL PIVOT POINT

4 *Change in Magnification Ratio for Given Deflections*

One general use of this pivot is as a fulcrum for a simple lever. In this case, a force is applied at a single point and for small angles the torque is equal to this force multiplied by the distance from this point to the initial spring intersection. As the deflection angle increases, however, the pivot will shift and the moment arm may change. If it was originally quite short, the effect of this change in moment arm becomes very noticeable. By trial it is actually possible to cancel the effect of the increasing spring constant with an increasing moment arm and obtain a flat spring constant curve over part of the deflection range. The torque formula developed applies only where the moment arm change is compensated or where the arm is so long in respect to the change that the effect is negligible.

Two lever systems are shown in Figs. 8 (*a*) and (*b*). Both the long arm, L_2, and short arm, L_1, tend to change length as the springs deflect, but in Fig. 8 (*b*) due to the geometry of the system, the long arm changes more than the short, and both arms change length in the same direction. Consequently the ratio of long to short arm may remain nearly constant over a wide range of deflection. Finally the transmitted motions may remain in the same ratio as the springs deflect although the resulting moments would not be the same as for a knife-edge type fulcrum.

The sketch, Fig. 9, was copied from Fig. 3 and a lever system of the type Fig. 8(*b*) was assumed. Only two positions of the pointer and the corresponding geometry are shown, but Table 2 gives the arm lengths and ratios for all the pointer positions shown in that figure. A 5 to 1 ratio was assumed at the start.

TABLE 2 MAGNIFICATION RATIO VALUES FOR FIG. 3 ON SPRING

(0.012 × 3 in. with 90-deg intersection angle; initial ratio, 5 to 1)

Position	Short arm, in.	Long arm, in.	Ratio	Per cent error to initial
1	1.84	9.37	5.09/1	+1.8
2	1.85	9.39	5.07/1	1.4
3	1.86	9.41	5.06/1	1.2
4	1.87	9.42	5.04/1	0.8
5	1.88	9.43	5.02/1	0.4
6	1.89	9.45	5/1	0
7	1.89	9.45	5/1	0
8	1.89	9.45	5/1	0
9	1.89	9.45	5/1	0
10 (Start)	1.89	9.45	5/1	0

In Table 3 are shown magnification ratios for the other four spring setups tested. The starting ratio in each case was 5 to 1

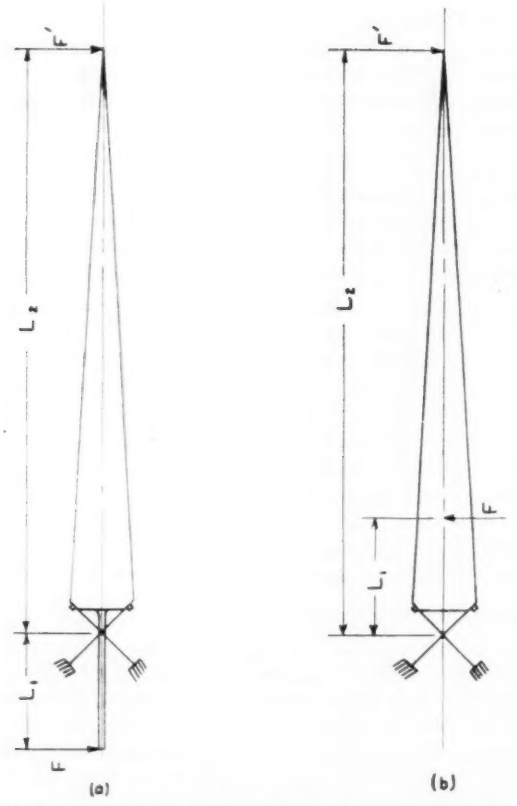

FIG. 8 SKETCHES OF PIVOTS USED IN LEVER SYSTEMS

and the length of the short arm was about two inches. (1) refers to the final pointer position as shown in Fig. 3. Only the starting and final ratios are shown. Fig. 8(*b*) lever system was assumed.

TABLE 3 INITIAL AND FINAL MAGNIFICATION RATIOS FOR FOUR OF THE STANDARD SPRING SETUPS TESTED

Spring designation	Position	Long arm, in.	Short arm, in.	Lever ratio	Per cent error (final ratio to initial)
60 deg × 3 × 0.012 in.	Start	9.87	1.97	5/1	0
	1	9.80	1.92	5. 1/1	2
30 deg × 3 × 0.012 in.	Start	10	2	5/1	0
	1	10.15	2.12	4. 8/1	—4
60 deg × 3 × 0.0085 in.	Start	10.16	2.03	5/1	0
	1	10.2	2.06	4.95/1	—1
60 deg × 1½ × 0.0085 in.	Start	9.17	1.84	5/1	0
	1	9.13	1.77	5.15/1	3

These changes appear to be less for a large intersection angle than for a small one. It also seems as if more change may be expected from short springs than from long ones. However, these changes are so small that in most cases they may be neglected. For that matter they lie within the liable error of the tests. Finally, the fact that the change is sometimes positive and sometimes negative indicates errors in test measurement rather than experimental fact.

However, if a lever system as in Fig. 8(*a*) is assumed, a very noticeable change in magnification ratio takes place as the lever is deflected. This change is due to the fact that as one arm elongates, the other becomes shorter. In the preceding case, Fig. 8(*b*), as one arm becomes longer, the other arm simultaneously elongates and the resulting change of ratio is naturally smaller. The curves in Fig. 10 show a comparison of the two lever systems for the spring data of Fig. 3. The per cent change of ratio for the system Fig. 8(*a*) is seen to be roughly twice that for the system Fig. 8(*b*). An initial ratio of 5 to 1 was assumed.

Using the same method as before, arm lengths and magnification ratios have been found for all the pointer positions included in each spring combination of lengths, thicknesses, and intersection angles tested. The type Fig. 8(*a*) lever has been assumed, and in each case the initial lever arm ratio is 10 to 1 measured at 0 deg pointer deflection angle. The results of these measurements are shown in Fig. 11 from which it is apparent that the greatest change in magnification ratio takes place for the smaller spring intersection angles. As might be expected, the change in ratio becomes much greater for deflection angles over 35 deg, and each curve rises sharply beyond this angle.

For smaller initial magnification ratios used with the same

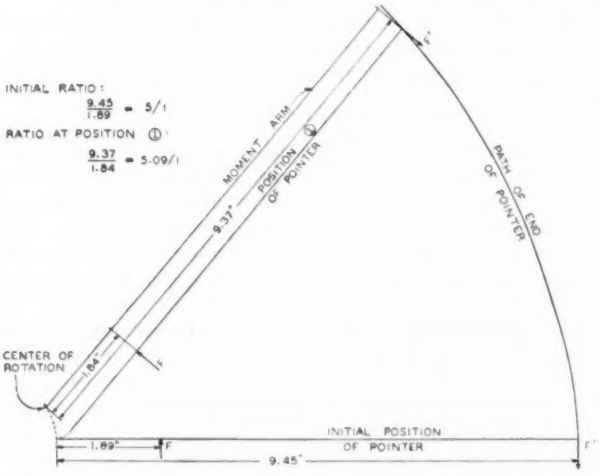

FIG. 9 A TYPE FIG. 8(*b*) LEVER SYSTEM COPIED FROM FIG. 3

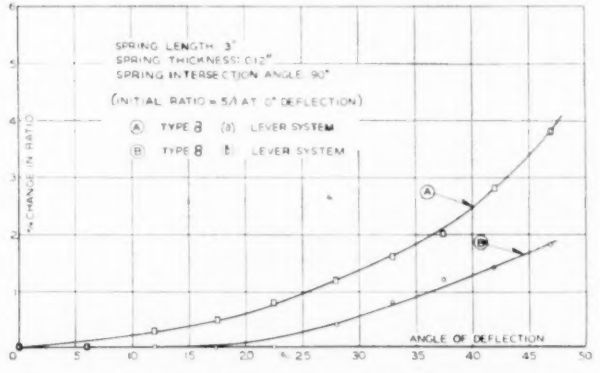

FIG. 10 CHANGE IN MAGNIFICATION FOR VARIOUS ANGULAR DEFLECTIONS

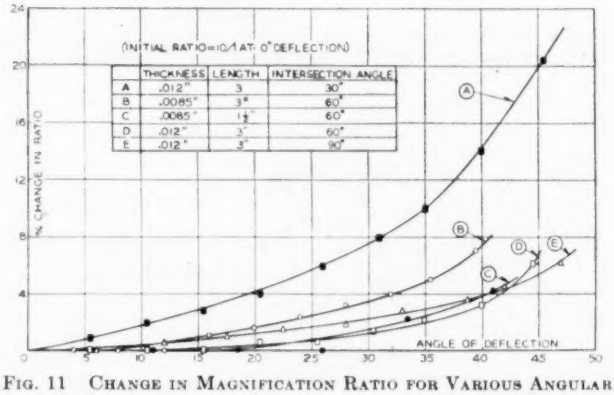

FIG. 11 CHANGE IN MAGNIFICATION RATIO FOR VARIOUS ANGULAR DEFLECTIONS

length of the longer arm, this change is less noticeable. For instance, measurements have been made on the spring system shown in Fig. 3, assuming an initial magnification ratio of 5 to 1. At an angle of 47 deg pointer deflection, this change amounts to 3.8 per cent as compared to 6.2 per cent for the same position where the initial magnification ratio was 10 to 1.

This change in magnification ratio suggests that the pivot may be dynamically unstable. That is, it may be in equilibrium at its neutral position under a system of forces, but if displaced slightly from this position, it may become unbalanced and continue to deflect until checked by some external means. This has been found to be the case where a heavy lever system is supported by extremely light springs. This characteristic is not easily corrected, and at present the only solution seems to be to use supporting springs of such a thickness that their resisting moment counteracts the unbalanced condition in the lever system and returns the lever to its neutral position.

5 *Example of the Use of the Formulas*

As an illustration of the formulas and at the same time as a check on their validity, a specific problem has been worked out. The device checked was a "spindle dynamometer." It consisted of a motor, mounted vertically with its shaft in line with two spring pivots. These pivots supported the weight of the motor and at the same time produced a resisting moment to measure the torque exerted by the motor. From the spring dimensions, the spring constant curve was drawn after which several test points were plotted which showed a surprisingly close agreement with the calculations. Measurements were made with the same disk and coil spring setup previously described and the angle was read from the dynamometer scale.

The springs, four in number, were one inch in width and slightly under 10 mils in thickness. A value of 0.00975 in. was used for calculating. The free length was $1^3/_8$ in.

From the formula

$$K_i = \frac{31(bd^2\theta\phi^{1.4})}{l}$$

Substituting spring dimensions at 20 deg angular deflection

$$K_i = \frac{(31 \times 4 \times 0.00975^2 \times 20 \times 90^{1.4})}{(1.375 \times 57.3)}$$

$$= 1.615 \text{ lb-in. per radian at 20 deg}$$

Also at 0 deg

$$K = \frac{EI}{l}$$

$$= \frac{(30{,}000{,}000 \times 4 \times 0.00975^3)}{(12 \times 1.375)}$$

$$= 6.74 \text{ lb-in. per radian}$$

Total constant

$$= 6.74 + 1.615$$

$$= 8.355 \text{ lb-in. per radian at 20 deg}$$

The test results are shown in Table 4. The torque value for 2 deg was used only to determine the constant at 6 deg. Due to a slight buckling of the springs near the initial position, this value was thought to be incorrect. Readings for such small angles are generally in error for this reason. It is practically impossible to line up the springs perfectly. Consequently there is some point of instability near the initial position and a reading near this point might indicate more or less force than would be required had there been no buckling. Since the second point was obtained from the first point, this too may be inaccurate, but the error at this angle will be very much smaller.

TABLE 4 TEST RESULTS

Angle, deg	Torque, lb-in.	Torque difference, lb.-in.	K, lb-in. per radian
2	0.306	..	..
6	0.827	0.521	7.45
10	1.35	0.523	7.50
14	1.90	0.55	7.88
18	2.46	0.56	8.02

SPRING CONSTANT CURVE FOR A SPINDLE DYNAMOMETER

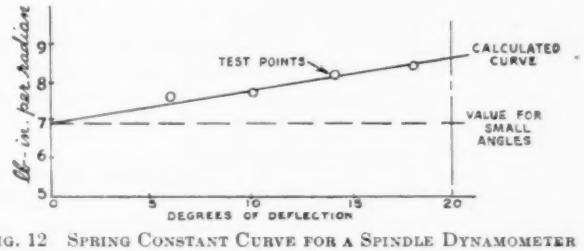

FIG. 12 SPRING CONSTANT CURVE FOR A SPINDLE DYNAMOMETER

The stress as calculated from the formula

$$\sigma = \frac{C\theta}{l}\left[E + 93\left(\frac{\theta\phi^{1.4}}{C}\right)\right]$$

$$= \frac{(0.005 \times 20)}{(57.3 \times 1.375)}\left[30{,}000{,}000 + 93\left(\frac{20}{57.3}\right)\left(\frac{90^{1.4}}{0.005}\right)\right]$$

$$= 42{,}500 \text{ psi}$$

If a concentration factor of 2 is assumed at the point of clamping, the stress becomes about 85,000 psi which may not be excessive for a good grade of spring steel.

Although the motion of the initial pivot point was not important in this case, it is interesting to consider it. Roughly, from Fig. 6 for a 90-deg pivot, the displacement for 20 deg is 1.24 for one inch of length or

$$\frac{(1.375 \times 1.24)}{100}$$

$$= 0.017 \text{ in. of travel at 20 deg}$$

From the formula

$$y = 0.04133X - 0.001225X^2 + 0.001267X^3 - 0.00000075X^4$$

$$= (0.04133 \times 20 - 0.001225 \times 400 + 0.0001267)$$

$$(8000 - 0.00000075 \times 160{,}000)$$

$$= 1.2302$$

$$\text{Displacement} = \frac{(1.375 \times 1.23)}{100}$$

$$= 0.0169 \text{ in. of travel at 20 deg}$$

6 *Notes on the Design of the Cross-Spring Pivot*

Briefly, the following points should be considered in designing two-spring pivots:

(*a*) If possible, the springs should be crossed at their midpoints[3] as this reduces the stress due to sharper bending.

(*b*) A 90-deg intersection angle should generally be used because it produces a greater rigidity of the pivot as a whole. If it is

[3] Other tests were made on springs not intersecting at their midpoints as well as springs initially curved. Pivots with more than two springs were also tested.

necessary to reduce the pivot motion, an intersection angle as low as 30 deg may be resorted to.

(*c*) As great a length of spring as is consistent with lateral stability and pivot motion should be used to lower the stress due to bending. Thin wide springs also lower the stress but are more apt to buckle.

(*d*) When used as a pivot for a heavily loaded lever system, the springs should be placed so that one of the springs is in direct tension.

(*e*) Displacement of the initial pivot, change of center of rotation, and increase in spring constant can frequently be neglected for deflection angles at high as 15 deg.

(*f*) In a lever system, the short arm should be kept at least equal to the spring length in order that its change may not be appreciable. The change in magnification ratio is less for a large spring intersection angle and is also less for a lever system where the fulcrum is at the end of the lever rather than between the loading points.

(*g*) The amount of load which may be supported in a direction perpendicular to bending is not easily determined. In his book "Theory of Elastic Stability" Timoshenko offers formulas for the calculation of critical loads in regard to lateral buckling for cantilever beams. These formulas may be used, but they are definitely on the safe side as the springs in the pivot exert restraining forces on each other which tend to prevent lateral buckling. This restraining action is increased by a large deflection angle, hence, greater stability.

Conclusion

Except in the case of very accurate instrumentation, the cross-spring pivot may sometimes be used for deflection angles as high as 45 deg. In general, the initial pivot point will be displaced only a few hundredths of an inch and the resulting change in lever arm ratio will rarely exceed 5 per cent. Bending stresses appear to be moderate and although the spring constant tends to increase quite rapidly, this tendency may usually be taken into account in design.

Discussion

A Photoelastic Study of Bolt and Nut Fastenings[1]

G. E. Campbell.[2] In this paper is shown a type of nut which gives a 30 per cent increase in strength of the fastening over the conventional nut. An increase of 30 per cent in strength of a machine part is certainly an accomplishment. The paper also outlines clearly an excellent method for analyzing other types of nuts and bolts which may be developed later, or which may have already been developed and not yet subjected to the tests outlined.

The tapered nut described, although proved stronger than the regular nut, presents machining difficulties which may be hard to control in production and which, if not controlled, may lessen its advantage.

A construction for a nut of tapered-lip design has been illustrated in a report[3] by involving the introduction of a re-entrant fillet into the working face of the nut. This construction not only provides a self-contained support for the nut but simplifies its use.

It would be interesting to learn what advantages would be derived by using a bolt and nut of differential pitch as suggested by the author. From experience with this type of nut, the writer is inclined to believe that, if the pitch of threads in the nut (measured parallel with center of the bolt) were slightly greater than the pitch of threads on the bolt, a distribution of stress would be accomplished that would be beneficial to the fastening. A special straight thread tap would be the only special equipment required, and this tap could be used with the same advantage for tapping the holes to receive studs.

Elongating the thread pitch of the nut will require a slight reduction in area of thread in the nut. The elongated pitch should be such that, when the nut is pulled up tight, there will be full contact throughout the length of thread. However, the stress in the bolt would be more nearly uniformly distributed.

An investigation of this type nut would be interesting and might disclose advantages.

Undoubtedly bolt and nut fastenings could be greatly improved. We have at present the U. S. Standard thread for bolts and nuts which perhaps is used more in this country than any other system. Under this heading we have both coarse and fine thread standards. The standards for nuts are further divided into American Standard Regular, American Standard Heavy, and American Standard Light. All of these nuts and threads are applicable to the same diameter of bolt.

It is well known that the Whitworth Standard Thread Form is stronger than the American Standard Thread Form, and in the writer's opinion we would do well to adopt it. The number of threads per inch for each bolt size should be established on a basis commensurate with the strength of the bolt and the distinction of fine or coarse thread eliminated.

It is hoped that this subject will be further studied and some standards developed which will be of great benefit to the industry.

Sabin Crocker.[4] The author's reputation as a pioneer in the application of "stress-freezing" methods to the study of three-dimensional stress-distribution problems gives assurance that his description of the technique used in this investigation is a particularly valuable contribution.

Several observations in the paper have a direct bearing on the assumptions underlying the design of bolt threads. One of these observations is: "Even if the threads of the bolt and nut match with perfect evenness in the unloaded condition, as soon as load is applied, the bolt stretches while the nut is compressed so that even contact along the threads will not be possible, and the load will be transmitted chiefly at one point of contact which will be at the seat of the nut."

Most of the demands for extreme accuracy in pitch of bolt and nut threads are based on the assumption that better distribution of load along the threads will be obtained with more perfect threads. It would be of interest to know what class of fit the author attempted to secure in the bakelite bolting assembly.

A second observation of the author's which deserves attention is: "The deformation set up in the threads prevented. . . . . in most cases the unscrewing of the nuts after test."

It is apparent from the test assembly used that the deformation mentioned must have been of a permanent character. In usual pipe-flange bolting the threads of bolt and nut also are elastically deformed by the bolt load that is being maintained so that both types of thread distortion affect the ability to unscrew a nut, at least up to the point where it is unseated. The seizure of nuts on bolts subjected to high temperature is a rather common occurrence. An American War Standard on Straight Screw Threads for High-Temperature Bolting (ASA B1.4) has just been developed which provides a neutral zone or intentional clearance between mating parts. This standard will facilitate assembly of bolts and nuts and is intended also to reduce the difficulties in disassembling bolts and nuts after high-temperature service. The writer would be interested in the author's opinion as to the effect of clearance between bolt and nut threads as a means of reducing the tendency to seizure.

Evidence of permanent distortion of threads causing difficulty in removing nuts was encountered when disassembling flanged joints in The Detroit Edison Company's experimental 1100 F superheated-steam line. In some instances, the nuts could be backed off about one turn before the threads jammed, indicating that thread distortion rather than metal seizure was the cause of trouble. This seems to corroborate the author's statement regarding thread distortion as a cause of nuts freezing to bolts.

The tapered-lip nut is an interesting development, but it would seem to be limited to rather special applications, such as turbine-casing joints, valve-bonnet joints, and heater heads where the larger bolt holes required can be provided for in the design.

J. N. Goodier.[5] This study is of the greatest interest both as an investigation of possible improvements of threaded fastenings, and as a demonstration of the powers of the freezing method to deal with three-dimensional stress problems, at least those having axial symmetry.

The device of the tapered thread, which seems to be a good one, raises the question of how the model stress will correspond to that of the real nut and bolt. The author comes to the conclusion that the taper must be altered on account of the different elasticity of the model material.

This is but one aspect of the whole question of similarity, which may be examined by means of dimensional analysis. If we consider the solution of the general problem of the behavior of the threaded fastening, whatever its geometrical form, material, and load, we should be concerned with a set of lengths a, b, c, etc., specifying the linear dimensions, and a dimensionless ratio, α, specifying the taper (or equally well a fractional pitch difference), the elastic constants E and ν (Young's modulus and Poisson's ratio), a coefficient of friction μ, and the load P. Given these, we should be able to calculate, if we had adequate analytical resources, the extent of thread in contact, the stress distribution, and any other determinate feature. Consider for instance the stress σ, of a given type, at a given point, x, y, z. There is one relation, i.e., the required formula, between the quantities

$$\sigma, a, b, c \ldots, \alpha, E, \nu, \mu, P, x, y, z$$

From the requirement that the same stress must be found no matter what system of units is used, dimensional analysis[6] shows that the relation must be one between dimensionless arguments, as in

$$\frac{\sigma}{E} = f\left(\frac{b}{a}, \frac{c}{a}, \ldots \frac{x}{a}, \frac{y}{a}, z, \alpha, \nu, \mu, \frac{P}{Ea^2}\right) \quad \ldots\ldots [1]$$

Then if each argument on the right is made the same in the model as it is in the prototype, the quantity σ/E must be the same for both. Making the length ratios b/a, c/a the same simply means geometrical similarity, but also α must be the same. The Poisson's ratio ν and the friction μ must be the same, and we must also make

$$\frac{P_m}{E_m a_m^2} = \frac{P_p}{E_p a_p^2} \quad \ldots\ldots [2]$$

where m refers to the model, p to the prototype. We shall then have

$$\frac{\sigma_m}{E_m} = \frac{\sigma_p}{E_p} \quad \ldots\ldots [3]$$

that is, the stress distribution will be the same, but stresses at corresponding points are in the ratio of the Young's moduli.

The condition, Equation [2], means that we can only have this similarity if the relation between stress and load is not linear (it would seem that it cannot be linear if there is tapering, or pitch difference, which results in more threads being in contact at higher loads), provided the model load is chosen from Equation [2], which may be interpreted as equality of average strains.

The values of average strain given in the paper are 0.00133 for steel (at 40,000 psi), and 0.0400 for the bakelite model (at 40 psi). The condition of Equation [2] was therefore not satisfied. Also of course the taper, α, was not made the same for model and prototype. If then the view as outlined of the similarity conditions is sound, the model tests cannot be interpreted as in the paper. In fact the requirement of equal strains Equation [2] would seem to offer an obstacle to the use of the freezing method with its necessarily rather large strains.

In the conventional, nontapered threads, if perfect pitch equality and perfect elasticity can be assumed, the stress must be proportional to P, and, therefore, the group P/Ea^2 in Equation [1] must appear as a factor. Then

$$\frac{\sigma a^2}{P} = \phi\left(\frac{b}{a}, \frac{c}{a} \ldots \frac{x}{a}, \frac{y}{a}, \frac{z}{a}, \nu, \mu\right)$$

and geometrical similarity, with equality of ν and μ, will be all that is necessary as similarity requirements. The stress distribution will be independent of the Young's modulus and the same at all loads.

S. Timoshenko.[7] The author must be congratulated upon a fine piece of work illustrating the application of three-dimensional photoelastic analysis to the solution of important problems on stress distribution in threaded connections. Since this work is one of the first practical applications of three-dimensional photoelasticity, it seems very desirable to have more detailed information regarding the accuracy with which stresses can be measured in such cases. It is also desirable to have some discussion of the fact that in three-dimensional problems the stress distribution depends upon the elastic constants of the material.

The photoelastic study can give us the factor of stress concentration at the bottom of the thread. How this stress concentration affects the strength of a threaded connection depends upon physical properties of the material, and a proper answer can be obtained only by running fatigue tests. Considerable work of this kind has been carried out abroad.[8] These experiments showed that the strength of a threaded connection can be considerably improved by using for the nut a material with a small modulus of elasticity. In the case of a bolt and nut of steel, having ultimate = 80,000 psi and yield point = 55,000 psi, the fatigue tests in a prestressed condition gave for the endurance limit the value 13,500 ± 9200 psi. Replacing the steel nut by a magnesium-alloy nut (magnesium alloy, electron, ultimate = 15,500 psi, yield point = 13,500 psi), with 5 times smaller modulus of elasticity, the fatigue strength of the threaded connection was raised to the limit 17,500 ± 13,500 psi. The effect of the shape of thread on fatigue strength was only of secondary importance in those experiments. It will be interesting to have the author's photoelastic work supplemented by fatigue tests.

P. R. Vogt.[9] There are two ways in which this paper can be received. One is to emphasize the uncertainty of photoelastic results, particularly in a contact problem such as this, where the relation of the loading to the modulus of elasticity of the material and the plastic deformation is of prime importance; and thus to criticize the numerical results. The other, and in the writer's opinion a much more satisfactory attitude, is to recognize the author's work as a lucid qualitative demonstration of the unnecessarily severe stress concentrations in threaded fastenings of conventional design. His numerical results should be taken merely as guidance for further testing which we all know must be done on the actual metal parts before the problem is really solved. This paper, with its graphic illustration of stress concentration and ways by which it may be reduced, should be a powerful stimulus to get this much needed testing program under way.

Of the various methods suggested for reducing stress, the simplest one from a design and mass-production standpoint would seem to be the expedient of increasing slightly the lead or pitch

[9] Project Engineer, Research, Chrysler Corporation, Detroit, Mich. Jun. A.S.M.E.

of the nut. Since this method was not very clearly explained in the paper, a few remarks on it may be in order. What is contemplated is simply to mesh, for example, a bolt having 20 threads per in. with a nut having 20 threads per 1.002 in., or conversely, a 20-thread per in. nut with a bolt having 20 threads in 0.998 in. Such components could be made by standard production methods and would, of course, screw together without any trouble over the entire length of the bolt provided a small amount of backlash were present.

The action in relieving the first threads of load is identical to the action of the tapered nut; engagement of threads progresses from the end of the bolt inward as the load is applied. This is accomplished in both cases by having the mating faces of the threads in the unloaded condition progressively further separated as one moves inward from the end of the bolt. With the tapered-nut thread, the separation after 1 in. of length is $^1/_2 \times$ diametral taper $\times \tan \alpha$ (where α = angle between the working face of the thread and a plane perpendicular to the axis of the bolt). For an American Standard thread this angle is 30 deg. Thus an equivalent action to the author's suggested taper of 0.003 in. per in. could be obtained by a pitch difference of $^1/_2 \times 0.003 \times \tan 30$ deg = 0.00087 in. (about 0.001 in. per in.).

There may be some objection to controlling the taper or pitch to such close limits. However, this work will be of greatest importance to high-stress precision fastenings, such as aircraft-engine connecting-rod bolts, the pitch of which is customarily controlled to closer than $\pm$ 0.0005 in. This also brings out the point that if pitch is not carefully controlled there may be a pitch differential in the wrong direction. Such a condition would result in a dangerous increase in stress; so that an exaggeration of nominal pitch differential, above the small values previously suggested, may be justified in order to prevent manufacturing variation from ever creating a differential in the wrong direction. Furthermore, an increased differential (or taper) will throw the load toward the outer end of the nut; and then if the bolt should fail at this outer end, there will still be inner threads (possibly one half the length of the nut) left in engagement to carry the load until a repair is made.

As clearly shown by the photoelastic studies the standard fastening concentrates the load on only a few threads, so that even a very exaggerated differential could hardly create a worse concentration. Bearing this in mind, we may suggest for practical consideration a nominal pitch differential of about twice the theoretically correct value (possibly 0.002 in. per in.).

E. F. Miller.[10] The author's investigation of bolt-fastening stresses by the three-dimensional photoelastic technique was undertaken to substantiate the validity of certain changes in practice on alloy-steel bolting for high-temperature steam-turbine joints and was expanded to evaluate the new designs by comparison with certain ideal arrangements.

The absolute values of the results may be affected somewhat by the thread shape employed since the Whitworth thread section is somewhat thinner at the root and thicker at the apex than the U. S. Standard. This would alter the relative flexibility; however, the comparative values between different arrangements may not necessarily be affected by the choice of Whitworth threads.

The correction made to compensate for the bakelite modulus of elasticity on the tapered thread allows only about 0.035 in. engagement of the bottom threads which again may affect the elastic distortion of the assembly as compared with an actual bolting member.

A properly designed tapered thread appears to offer a suitable solution to the problem of stress distribution and, from the test results, it appears that a larger taper would offer yet greater improvement for highly stressed bolts. The use of a different thread pitch for the bolt and the nut would not result in an improved structure since the radial clearance would need to be increased to permit free assembly of the varipitched parts.

The tapered lip is ideal for special applications where bolts are widely enough spaced to accomodate the larger nut diameters which are required to maintain adequate bearing area. The required increase in bolt pitch would tend to offset the advantage of the tapered lip in many pressure-joint applications.

The writer's company has found that properly proportioned nuts tend to expand in diameter due to the radial component of the thread load angle. This produces the same effect as taper threading. Tapered threads are therefore employed only on the ends of large studs which are driven into relatively massive flanges where radial deformation of the female threaded part is restricted. Spherical washers are employed under the nuts used on these tapered-end studs to assure an axial loading in order to eliminate secondary bending stresses in the threads.

Author's Closure

An increase of the pitch of the threads in the nut with respect to that in the bolt, as suggested by Mr. Campbell, is known to lead to a better distribution of stress and was perhaps the first means used in practice to improve the strength of threaded connections. As was pointed out in the paper, however, one can always find a certain tapering of the threads in the nut which is equivalent to a given differential pitch as far as stress distribution is concerned. Which one of these to choose is mainly a production problem. The proposition of Mr. Vogt to adopt a 0.002-in. per in. pitch differential appears to be a good practical solution.

Seizure of nuts on bolts due to permanent deformation of the threads, as described by Mr. Crocker, is likely to take place not because of the magnitude but of the unevenness of the deformation, the deflection of the first engaged thread being much larger than that of the rest. Thus the rational method of preventing seizure of this type would be not through the provision of an excessive clearance, but through the application of an improved nut design which, with a more even distribution of the load among the threads, would also increase the strength of the connection. With regard to Mr. Crocker's question concerning the accuracy of fit in the bakelite models, we have to point out that, though the machining error in making the models was probably of the order of 0.001 in. per in., because of the low modulus of elasticity of the material, this accuracy would be about equivalent to a practically unattainable 0.00003-in. per in. precision of fit in steel prototypes of the fastenings.

The author agrees completely with the conclusions of Professor Goodier's dimensional analysis, according to which a correct test of a nut with tapered threads would require a geometrical similarity between model and prototype and, at the same time, an equality of strains in the two cases. This second condition, however, was impossible to satisfy in the tests; it would have required the application of an average stress of only 1.33 psi in the model, and this would have produced hardly any optical effect in polarized light. This being the case, the next best thing appeared to be, as has been done in the tests reported in this paper, to have the tapers in the same ratio as that defined by the average strain values. The resulting model with an exaggerated tapering of the threads can be expected to give, of course, only an approximate solution of the original problem. The most obvious source of error due to the abandonment of geometrical similarity is probably the fact, pointed out by Mr. Miller, that due to the large tapering in the model the points of

[10] Section Engineer, Mechanical Section, Westinghouse Electric & Manufacturing Company, South Philadelphia, Pa. Mem. A.S.M.E.

engagement between threads shifted outward by almost one third of the depth of the threads. A test is conceivable in which both of Professor Goodier's conditions would be fulfilled, but in that case the minuteness of the resulting relative retardations would necessitate point to point measurements by a Babinet compensator or a similar instrument and no record of the stress distribution could be obtained by photographic means.

As has been mentioned by Professor Timoshenko, the actual increase in the strength of threaded fastenings, through the application of the improved nut designs of the paper, can be established only by tests with steel specimens. In this connection it is of interest to note that fatigue tests of nuts with tapered threads and tapered lips of about the same proportions as those in the paper were made by H. Wiegand[11] who found that the application of these two designs resulted in a 20 and 30 per cent increase of strength respectively, which figures are about the same as the photoelastic results of the paper. Wiegand has also investigated the effect of using materials of lower modulus of elasticity in the nut and, similarly to the tests quoted by Professor Timoshenko, found that the application of a cast-iron nut, for instance, increased the strength of the fastening by 40 per cent. Thus we find that the strength of the present conventional nut fastening can be increased by about 40 per cent whether it be through a change in the design of the nut or by the application of a softer material in that part of the threaded connection.

Temperature Relations in Journal-Bearing Systems[1]

G. P. SUTTON.[2] This paper is of interest, especially the fact that the time lag to reach equilibrium temperature is surprisingly long. The temperature calculated according to the authors' method is higher than the measured temperature. From the diagram, it seems that the thermocouples did not extend into the oil film directly, which may account for the difference in the measured and the calculated lubricant temperature.

How would the film temperature be affected by different surface finishes and different bearing materials? Would this temperature be affected by convection around the bearing?

L. M. TICHVINSKY.[3] Boswall (1)[4] has shown that in the calculation of bearing performance the average temperature of the oil film may be used with a fair degree of accuracy.

The lubricating-oil temperatures at the inlet and outlet of a bearing are easily measured by thermometers. The temperatures of the bearing metal in the proximity of the rubbing surfaces are also conveniently measured by means of thermocouples. During such experimentation, as many as 10 to 12 temperatures may be obtained which are used for the evaluation of the average oil-film temperature. However, it will not be at all surprising if several experimenters would arrive, on the basis of the same 10 to 12 temperatures, at different values of the average oil-film temperature. For this reason the investigation conducted by the authors is timely, because it represents an attempt to evaluate accurately the average oil-film temperature. It is hoped that the method, which consists of inferring the temperature from friction-loss measurement, can be made applicable to such loaded bearings where the Harrison formula should accurately predict the frictional behavior of a bearing.

A method (2), simpler than the one proposed by Kingsbury (3), may be mentioned here. This approximate method may be used for the evaluation of the average oil-film temperature of a loaded bearing by calculating the heat flow through the film, h, which is assumed to be of a uniform average thickness, as in a guide or high-speed bearing. The same quantity of heat Q flows from the oil film to the bearing shell and then from the latter to the ambient air by convection and radiation. The quantity of heat Q which flows from the shell can be easily calculated from the temperatures of the shell and ambient air, the dimensions of the bearings, and known heat-transfer data (4, 5). In most bearings the flow of heat through the shaft is negligible (4), and the shaft temperature is usually taken as equal to that of the oil film. For such cases, the temperature distribution through the oil-film thickness may be calculated from the known equation of the steady flow of heat through a body, such as the oil film wherein heat is being uniformly generated. This temperature distribution is parabolic, and the average value of the temperature rise, t, of the oil film above the bearing shell is

$$t = Qh/3K = 80\,Qh$$

for the majority of mineral lubricating oils [$K = 0.0042$ w per sq in. per deg C per in. (5)]. This method of calculation will still hold when heat is carried away by means of circulating oil since it applies only to the flow of heat through the bearing shell. Such a method has been successfully applied for the evaluation of the average temperature rise of the oil film above the measured temperature of a loaded bearing shell (2).

AUTHOR'S CLOSURE

Mr. Sutton's comment that the times observed by the authors to reach equilibrium temperatures were surprisingly long is probably due to the fact that in his experiments the speeds may have been much greater, thus rapidly accelerating the rate of heat generation without corresponding increases in the equilibrium temperatures. For the lower range of speeds used by the authors, the rate of heat generation is relatively low. In fact, it may be shown[5] that at least the asymptotic exponential coefficient determining the rate of approach to equilibrium, and which corresponds to the slopes of the linear segments of Figs. 6 to 9, is given by

$$\alpha = \text{const.} \left[1.35N^{0.52} + \frac{\beta N^2}{T_\infty} \right]$$

[5] cf. *Journal of Applied Physics*, vol. 14, 1943, pp. 234–244.

where β is the slope of the viscosity-temperature curve as of Fig. 2, and T_∞ is the equilibrium temperature. Thus the asymptotic rate of approach increases with the speed and may even approach a variation with the square of the journal speed, N.

It is true, as Mr. Sutton suggests, that the thermocouples were set flush with the bearing surface. This was done to avoid any disturbance in the lubricant flow or local heat generation. As to the reason for the film temperature being higher than the bearing temperature, it is believed that the surface roughness plays no significant role. The surfaces used were actually quite smooth, and the microscopic roughness was extremely small as compared to the clearance. The main reason for the observed lower bearing temperature is felt to lie in the low heat losses from the journal, as also mentioned by Mr. Tichvinsky, and as originally pointed out by Karelitz. Although no data are yet available, it is believed that the journal temperatures were even higher than the film temperature, and that a large part of the heat generated at the journal surface was taken up by the journal until equilibrium was reached. Experiments are on the way to test this point.

Mr. Tichvinsky's remarks are well taken. In fact, it was one of the main conclusions of the paper that the bearing surface temperatures may be equated to the oil-film temperature to a fair degree of approximation, unless special means are provided for controlling the bearing or journal temperatures. In order to explore the possibilities of the method the simpler case was tried first wherein the bearing was loaded lightly and the Petroff formula was used for predicting the friction behavior. We see no reason, however, why the same method could not be used in the case of loaded bearings, applying Harrison's or other equivalent formulas pertaining to nonconcentric journal bearing systems.

Photoelastic Separation of Principal Stresses by Oblique Incidence[1]

M. M. Frocht.[2] The author is to be commended on his ingenious and interesting method for determining the principal stresses from photoelastic stress patterns.

The published results have been recalculated and were found

Fig. 1 Stress Pattern of a Bakelite Ring Subjected to Concentrated Diametral Loads With Light Rays Normal to Face of Ring

(P = 54 lb, approximately; D = 1.02 in.; $2r$ = 0.51 in.; t = 0.110 in.; F = 782 psi tension or compression.)

(Photographs were taken with model in Halowax oil.)

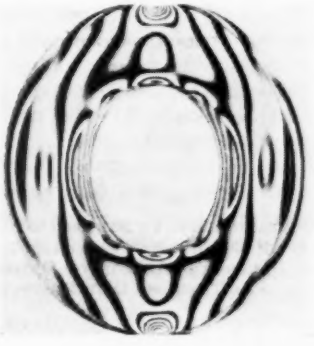

Fig. 3(*a*)

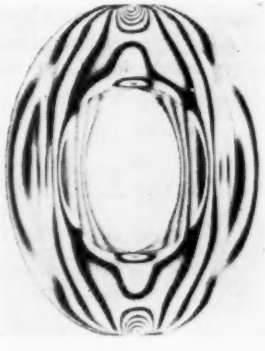

Fig. 3(*b*)

Fig. 3 Stress Patterns of the Same Bakelite Ring, Shown in Fig. 1, Except That It Has Been Rotated About Its Vertical Axis Until the Angle Between the Normal and the Light Ray Is 30 Deg for (*a*) and 45 Deg for (*b*)

to be in substantial agreement with those given by the author.

The proposed method was then applied to another problem somewhat more difficult than the simple illustration presented in the paper. For this purpose a circular ring, 1.02 in. OD, 0.51 in. ID, and 0.11 in. thickness, was subjected to concentrated diametral loads. The normal stress pattern is shown in Fig. 1 of

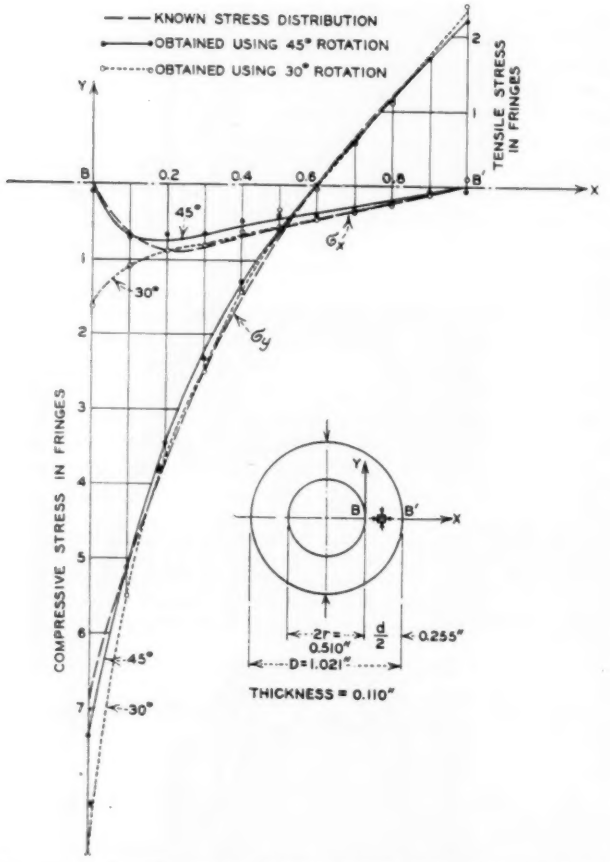

FIG. 4 CURVES COMPARING KNOWN STRESS DISTRIBUTION ALONG HORIZONTAL AXIS OF RING SHOWN IN FIGS. 1 AND 2, AND DISTRIBUTION OBTAINED BY DRUCKER'S METHOD OF OBLIQUE INCIDENCE, USING ANGLES OF 30 AND 45 DEG, RESPECTIVELY

this discussion. Fig. 2 shows the stress patterns obtained after a rotation of the model of 30 and 45 deg, respectively, about the horizontal axis, and Fig. 3 shows a similar stress pattern for a rotation about the vertical axis. The writer's calculations, based on these photographs and the equations given by the author, yielded quite satisfactory results for the horizontal section, especially for a rotation of 45 deg. The stress distribution along the horizontal axial section of the ring is shown in Fig. 4. Along the vertical section of symmetry through the points of application of the loads, however, the results differed considerably from the known stress distribution for that section.

It should be pointed out that these verifications were of a preliminary nature. The model used was rather small and also was relatively thick for its other dimensions. The curves of $(p-q)$ were taken from ordinary enlargements with no greater precautions or care than those used when other photoelastic methods are employed, rather than plotting the curves directly from the negatives using both light and dark backgrounds, as the author recommends. It became apparent after some work had been done that the values of $(p-q)$ must be known with great accuracy since the equations involve small differences in the two stress patterns.

Except for sections of symmetry, the proposed method belongs to the "point-by-point" exploration methods. In addition, the directions of p and q at each point must be known before the equations can be applied. The main merit of the proposed method lies in its ability to determine the principal stresses of an isolated point.

The proposed equations are special cases of general equations which are free from the basic objections inherent in the present procedure, i.e., the "point-by-point" character, and the necessity for knowing the directions of the principal stresses and effecting the rotation about these as axes.

Such equations have also been developed and used by the discusser for some time. Although the probable errors are very large the general equations may yield useful results.

AUTHOR'S CLOSURE

The work of Professor Frocht is, as usual, unusually good. It is extremely gratifying to see that the method of oblique incidence yields accurate results even for a very small principal stress. Inspection of Professor Frocht's Fig. 4 shows that of the 44 plotted points only two are off by appreciable amounts.

The author would like to again point out the need for estimating in advance the probable accuracy to be obtained by any experimental method. General equations mentioned by Professor Frocht were, of course, considered by the author. However, they were not presented mainly because rotation about an axis which is not a principal axis requires too close a knowledge of the principal directions.

Book Reviews

Dictionary of Science and Technology

DICTIONARY OF SCIENCE AND TECHNOLOGY in English-French-German-Spanish. By Maxim Newmark, Ph.D. Philosophical Library, Inc., New York, N. Y., 1943. Cloth, 6 × 9 in., viii and 386 pp., $6.

REVIEWED BY M. HETÉNYI[1]

THIS dictionary comprises the French, German, and Spanish equivalents of some 10,000 English terms currently used in technical literature. The corresponding words in these languages are entered first under English headings which are numbered and referred to in separate indexes of French, German, and Spanish. In this manner the system permits a two-way use of any of these languages with the English.

Since the work endeavors to deal with all technical fields and in four languages in less than 400 pages, it is naturally not as comprehensive as some of the recognized scientific dictionaries which are often limited to a specialized field. Its authoritativeness may also be questioned at places as there are words, listed as equivalents, which could not be used as such with any degree of precision.

The book has, on the other hand, some features which give an advantage above older publications of this type. Much of it deals with the newer technical fields which brought in a short time a wealth of specific terms into circulation; over ten per cent of its content is, for instance, on aeronautics and there are entries in the fields of radio, television, and technical warfare which are not likely to be found in other dictionaries. It also makes a welcome distinction between American and British usage of terms in cases where these grossly differ. Because of these features the book may be recommended for consultation to anyone engaged in reading foreign technical literature.

Experimental Electronics

EXPERIMENTAL ELECTRONICS. By Ralph H. Müller, R. L. Garman, M. E. Droz. Prentice-Hall, Inc., New York, N. Y., 1943. Cloth, 6 × 9 in., xv and 334 pp., $4.75.

REVIEWED BY J. A. HIPPLE[2]

NOT many years ago a working knowledge of vacuum-tube circuits was possessed generally only by electrical engineers and experimental physicists. However, the vast possibilities of electronic circuits in the field of measurement and control as evidenced in the literature of the last decade has made this knowledge an essential tool in the equipment of the well-trained technical man in many fields. This book, written by three chemists, is a striking illustration of this. Its purpose and scope is stated clearly in the first paragraph of the preface:

"This book has been written to supply definite practical information on the characteristics and noncommunication applications of electron tubes. It is an outgrowth of the authors' experience in courses given for several years at New York University to students and industrial and academic research workers in chemistry, biology, and engineering. In these courses, students of widely different backgrounds and interests have found competence in handling electronic circuits most stimulating and helpful, revealing to them many applications in their own fields."

The authors have done an excellent job in selecting and organizing the material presented in this book as the basis of such a course. The student gets a veritable baptism by fire; after the completion of these seventy experiments, no longer will he stand in awe of a vacuum tube. In the discussions before each experiment no attempt has been made to be profound, but they are usually quite adequate to provide the student with an intelligent approach to the experiment. In addition sufficient references for more detailed study are provided. Sometimes one feels that the discussion could be carried a bit further. For instance, since several pages are devoted to the low-grid-current electrometer tubes, it would seem desirable to describe the method of measuring this grid current.

The equipment required in each experiment is itemized. The values of the components in the circuit drawings are given in the figure captions; this is desirable in a book of this type. There is some annoying inconsistency, however, in sometimes omitting the tube type, making it necessary to refer to the list of materials required for the experiment. In one figure (Fig. 7–10) it is necessary to notice in the bill of materials that there is only one filament battery, and hence a filament that at first glance appears to be floating is actually connected to this battery.

The experiments cover a wide range. After the completion of the first half of the book, the student should be familiar with the operation of the various electronic tubes including photoelectric cells and gaseous tubes, as well as power supplies (including regulated supplies). The second half of the book can be considered an application of the principles learned previously to measurement and control circuits of interest to scientists. Indeed, the many circuits collected here will make this section a handy reference for the general scientific worker. The general subjects treated are d-c and a-c voltmeters, phototube applications, untuned amplifiers, oscillators, and the cathode-ray tube. The great number of circuits included have evidently been chosen very carefully to have the widest applicability in various technical fields.

Treatment of Experimental Data

TREATMENT OF EXPERIMENTAL DATA. By Archie G. Worthing and Joseph Geffner. John Wiley and Sons, Inc., New York, N. Y., 1943. Cloth, 6 × 9 in., ix and 342 pp., illus., tables, diagrams, $4.50.

REVIEWED BY JOSEPH KAYE[3]

THIS book presents the material given in a course for graduate students on the treatment of experimental data. A large part of it will be of aid to students and engineers engaged in work involving measurements of any sort. As a reference book it should be useful to engineers in general. The material is presented in a clear lucid style. The many diagrams and numerical examples, which were evidently selected with great care, enhance the value of the book.

[2] Electro-Physics Department, Westinghouse Research Laboratories, East Pittsburgh, Pa.

[3] Instructor in Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts. Mem. A.S.M.E.

The scope of the book is quite large, particularly from the standpoint of the beginner in the subject. Starting with the simple elementary methods of presenting data in tables, smoothing of tables, interpolation, etc., the authors proceed logically to the representation of data by graphs, by equations, and then to tabular and graphical differentiation and integration. The method of representing a function by Fourier series is discussed next and includes a description of various types of analyzers. The normal frequency distribution is clarified for the beginner. Considerable attention is given to the computation of precision indexes for measurements of equal and unequal weights. The method of least squares is made comprehensible; in addition, short cuts are given for avoiding lengthy numerical work and the pitfalls are indicated clearly. The authors present the various tests used by statisticians in the correlation of data; these tests though relatively new in engineering are quite important. The text ends with a discussion of the analysis of nonharmonic periodic functions. The appendix has several tables and includes a brief discussion of determinants. A useful index is provided.

At the bottom of page 95 it is stated erroneously that Simpson's three-eighths rule will usually give better results than Simpson's one-third rule. On page 155 of Scarborough—it is regrettable that the bibliography does not include the excellent work of J. B. Scarborough, "Numerical Mathematical Analysis," the Johns Hopkins Press, Baltimore, Md., 1930—it is shown analytically that the inherent error in the former is always greater than that in the latter. This can be verified by numerical examples. Hence Simpson's three-eighths rule should never be used in numerical calculations.

In the discussion of least squares it should have been noted that the solution of the normal equations may occasionally lead to erroneous values of the constants of the desired equations. The error arises from the disappearance of several significant figures in the course of the solution. A sufficient number of significant figures can be retained in most cases if calculations are made with seven-place logarithms or an eight-bank calculating machine.

Lubrication

LUBRICATION. By Arthur Edwin Norton, Late Gordon McKay Professor of Applied Mechanics, Harvard University. Edited by J. R. Munger. First edition. McGraw-Hill Book Company, Inc., 1942. Cloth, 6 × 9 in., xi and 244 pp., 115 illustrations, $3.

REVIEWED BY BURT L. NEWKIRK[4]

THERE is perhaps no field that includes so many highly specialized divisions as that of lubrication. The book "Lubrication" by the late Prof. Arthur Edwin Norton of Harvard University (edited by J. R. Munger, his assistant of 1939–1940) covers this field rather inclusively in textbook style. It is an outgrowth of the courses formerly given by Professor Norton.

The introductory chapter is short, but comprehensive, calculated to arouse the interest as well as give a general orientation. Students will do well to reread this chapter at intervals during a course on lubrication.

The next three chapters deal with the mechanics of fluids as it applies to bearing performance, the phenomena of thin film lubrication and oiliness, and the chemical and physical properties of lubricating oils and greases. This whole field is treated concisely but with many important details in 55 pages.

The main portion of the book, chapters five to ten, inclusive, deals with theories of bearing design, including thrust (slider) and journal bearings, and calculation of the various factors of performance.

The first two chapters of this section deal with slider bearings, first with constant and then variable viscosity and no side leakage. The next two chapters cover full and partial journal bearings, including fitted bearings, without side leakage, and the last two chapters of the section take up effects of side leakage on the theory of the slider bearing and the journal bearing, respectively. This section contains charts, numerical tables, and worked-out numerical examples.

The last three chapters deal broadly with practice in the field of bearings and lubrication. They may be understood without previous mastery of chapters 5 to 10. These discussions give a scholarly appraisal of various phases of practice, some of which have grown up, without sufficient comprehension of the physical basis of design. The grooving of bearing surfaces is a case in point. Design should provide for admission and distribution of the lubricant in regions of low pressure, as indicated by hydrodynamic theory, and grooves should be avoided that connect such regions with those of high pressure. The important feature of thermal equilibrium and viscosity-temperature relationships is discussed. Means for applying the lubricant, oil seals and oil cleaners, bearing materials, and other miscellaneous matters essential to successful performance are treated in this section.

The last chapter discusses the fields of application, and relative advantages of ball, roller, and needle bearings, and their lubrication.

The book closes with a table of notation, a list of 63 references, and a very short index.

There seems to be no mention of pivot bearings of electrical instruments and meters, which are interesting because, in instruments with total loads of a few grams, the unit loads are the heaviest in bearing practice, 10 to 30 tons per square inch. Some of these run without lubrication. In meters, even though the bearing contact areas are minute, and normal speeds low, moderately abnormal rotation speeds shorten the life of the bearing.

The tapered land thrust bearing designed by E. G. Gilson and reported on by Linn and Shepard in *Mechanical Engineering* is of interest also, because it was developed in view of hydrodynamic theory, but with surfaces at fixed angles, sacrificing some theoretical hydrodynamic advantages for the sake of mechanical simplicity. A thrust bearing with fixed shoes is shown in chapter one. The Gilson design is undoubtedly of more value and interest than other thrust bearings discussed in chapter 12.

The Reist thrust bearing is understood to carry the heaviest total loads in bearing practice. This design is not based primarily on hydrodynamic theory, but it is used successfully for large water-turbine generators.

The subject of instability of the fluid film, vibration resulting therefrom, and design of rotor and bearings to avoid such disturbances might also have been discussed without very great extension of the scope of the book.

The items just referred to serve further to illustrate the breadth and diversity of the lubrication field. This text should be a very acceptable basis for courses in lubrication, for which a place should be found in engineering curricula. Various phases of this field are developing on a scientific basis, in much too great variety and extent for adequate treatment as a chapter in some other course such as fluid mechanics. In his perception of the need of engineering courses in lubrication, and his development of the course represented by this book, Professor Norton has done pioneering work. It is fortunate that Mr. Munger was sufficiently familiar with the course and able to prepare it promptly for publication.

The Bending of the Cylindrically Aeolotropic Plate

By G. F. CARRIER,[1] ITHACA, N. Y.

In this paper, the small-deflection theory, applicable to plates of cylindrically aeolotropic material,[2] is presented, and expressions are obtained for the moments and deflections produced by the following combinations of loading and boundary conditions: The disk clamped along its circumference and loaded by a uniform lateral pressure; the clamped disk loaded by a central concentrated force; the simply supported disk loaded by uniform edge moment; the disk with a rigid core clamped along its circumference and loaded by a central concentrated force; the ring clamped along its outer edge and loaded by a uniform shear distribution along the inner edge; the simply supported disk with an elastic isotropic core loaded by a uniform edge moment; and the disk under the loading given by $p = p_0 r \cos\theta$. The six symmetrical problems of this group were chosen for evaluation since they and their linear combinations comprise a large part of the total set of such problems. Curves are included showing, for three of the foregoing problems, the effect of the degree of anisotropy on the stresses. The practical application of solutions obtained by the following theory might lie, for example, in design problems involving circular plates which are built up of laminas of radial symmetry with different tangential and radial stiffnesses.[3] The theory could also be applied to the design of circular concrete slabs with different amounts of reinforcing steel in the radial and tangential directions.

Nomenclature

The following nomenclature is used in this paper:

r, θ, z = cylindrical co-ordinates
$e_r, e_\theta, \gamma_{r\theta}$ = normal and shearing strains
u, v, w = radial, tangential, and axial displacements
$\sigma_r, \sigma_\theta, \tau_{r\theta}$ = normal and shearing stresses
$M_r, M_\theta, M_{r\theta}, M_{\theta r}$ = couples per unit length, as defined in Fig. 1
Q_r, Q_θ = shear forces per unit length as defined in Fig. 1
p = applied lateral pressure
a_{ij} = elastic constants of aeolotropic material (referred to cylindrical co-ords)
$E\mu$ = elastic constants of isotropic material
$c = a_{11}/a_{22}$
$b = \dfrac{2(a_{11}a_{22} - a_{12}^2) - a_{12}a_{66}}{a_{22}a_{66}}$
$\nu = -a_{12}/a_{11}$
r_1, r_2 = inner and outer radii of plate
h = thickness of plate
$\epsilon = r_1/r_2$
$\alpha = \sqrt{1/c}$
$k_1 = \sqrt{\dfrac{c + 1 + 2b}{2c}}$
$D = \dfrac{h^3 a_{22}}{12(a_{11}a_{22} - a_{12})}$
$F = \dfrac{Eh^3}{12(1 - \mu^2)}$
$K = [(1 - \alpha^2\nu^2) + (1 + \alpha\nu)(1 + \mu)\alpha F/D]\,\epsilon^{-\alpha} - [(1 - \alpha^2\nu^2) - (1 - \alpha\nu)(1 + \mu)\alpha F/D]\,\epsilon^{\alpha}$

The Bending Theory

The assumptions made in developing this theory are the same as those of the isotropic theory,[4] namely: (1) The effects of

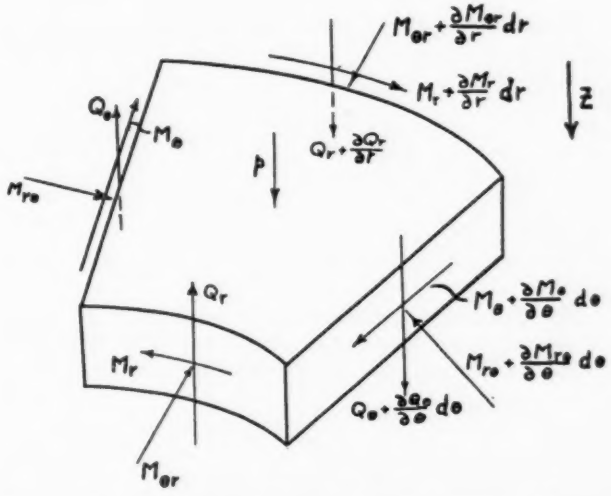

FIG. 1 SECTORIAL ELEMENT UNDER GENERAL LOADING, AS QUALIFIED BY ASSUMPTIONS (1) AND (3)
(The directions of the moment vectors are defined by the conventional "right-hand rule.")

τ_{rz}, $\tau_{\theta z}$, and σ_z on the deflection are negligible; (2) Lines which in the unloaded position are parallel to the z axis remain straight; (3) The forces per unit length defined by the integrals

$$\int_{-h/2}^{h/2} \sigma_r dz, \qquad \int_{-h/2}^{h/2} \sigma_\theta\, dz, \qquad \int_{-h/2}^{h/2} \tau_{r\theta} dz$$

vanish.

[2] "Stress Distributions in Cylindrically Aeolotropic Plates," by G. F. Carrier, JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 65, 1943, p. A-117.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[3] For example, the laminas (parallel to the r,θ plane) might be radially symmetrical wire meshes.

[4] "Theory of Plates and Shells," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., 1940, p. 257.

Under these assumptions, the only expressions from the Hooke's law relating to cylindrically aeolotropic materials which are necessary in developing the small bending theory are the following

$$\left.\begin{aligned} e_\theta &= a_{11}\sigma_\theta + a_{12}\sigma_r \\ e_r &= a_{12}\sigma_\theta + a_{22}\sigma_r \\ \gamma_{r\theta} &= a_{66}\tau_{r\theta} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [1]$$

The couples per unit length, as defined in Fig. 1, are given by

$$\left.\begin{aligned} M_r &= + \int_{-h/2}^{h/2} \sigma_r z\, dz \\ M_\theta &= + \int_{-h/2}^{h/2} \sigma_\theta z\, dz \\ M_{r\theta} &= -M_{\sigma r} \int_{-h/2}^{h/2} \tau_{r\theta} z\, dz \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [2]$$

Since the neutral surface ($z = 0$) remains undisplaced horizontally, as implied by assumption (3), the values of u and v at any point z are given by

$$\left.\begin{aligned} u &= -z\,\partial w/\partial r \\ v &= -(z/r)\partial w/\partial\theta \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [3]$$

The strains are defined in the conventional manner as

$$\left.\begin{aligned} e_r &= \partial u/\partial r \\ e_\theta &= u/r + 1/r\,\partial v/\partial\theta \\ \gamma_{r\theta} &= 1/r\,\partial u/\partial\theta + \partial v/\partial r - v/r \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [4]$$

Equations [1], [2], [3], and [4] may be combined to give the following expressions for the couples in terms of w and the elastic constants

$$\left.\begin{aligned} M_r &= -D\left[C\frac{\partial^2 w}{\partial r^2} + \nu\left(\frac{1}{r}\frac{\partial w}{\partial r} + \frac{1}{r^2}\frac{\partial^2 w}{\partial\theta^2}\right)\right] \\ M_\theta &= -D\left[\frac{1}{r}\frac{\partial w}{\partial r} + \frac{1}{r^2}\frac{\partial^2 w}{\partial\theta^2} + \nu\frac{\partial^2 w}{\partial r^2}\right] \\ M_{r\theta} &= -M_{\theta r} = D(b-\nu)\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial w}{\partial\theta}\right) \end{aligned}\right\} \quad \ldots [5]$$

The equations of equilibrium are derived from a consideration of the couples and forces acting on the sectorial element shown in Fig. 1. They are, as in the isotropic case

$$\left.\begin{aligned} &\frac{\partial M_r}{\partial r} - \frac{1}{r}\frac{\partial M_{r\theta}}{\partial\theta} + \frac{1}{r}(M_r - M_\theta) - Q_r = 0 \\ &\frac{1}{r}\frac{\partial M_\theta}{\partial\theta} - \frac{\partial M_{r\theta}}{\partial r} - \frac{2}{r}M_{r\theta} - Q_\theta = 0 \\ &\frac{\partial}{\partial r}(rQ_r) + \frac{\partial Q_\theta}{\partial\theta} + rp = 0 \end{aligned}\right\} \quad \ldots [6]$$

These equations together with relations, Equations [5], produce the following differential equation

$$\left\{\frac{1}{r^4}\frac{\partial^4}{\partial\theta^4} + \frac{2b}{r^2}\frac{\partial^4}{\partial r^2\partial\theta^2} - \frac{2b}{r^2}\frac{\partial^3}{\partial\theta^2\partial r} + \frac{2(1+b)}{r^4}\frac{\partial^2}{\partial\theta^2} + C\frac{\partial^4}{\partial r^4} + \frac{2c}{r}\frac{\partial^3}{\partial r^3} - \frac{1}{r^2}\frac{\partial^2}{\partial r^2} + \frac{1}{r^3}\frac{\partial}{\partial r}\right\} W = \frac{p}{D} \quad \ldots [7]$$

It is interesting to note that the differential operator in this equation is identical with that occurring in the plane-stress theory[2] applying to this type of material, although the constant b is a different combination of elastic constants from the corresponding term in the plane-stress problem.

The particular integral of Equation [7] will depend upon the form of the load p. Some terms of the complementary solution are given by[5]

$$w = a_1 r^{1+\alpha} + a_2 r^{1-\alpha} + a_3 r^2 + a_4 + (Ar^{1+k_1} + Br + Cr^{1-k_1} + Dr\ln r)\cos\theta \quad \ldots [8]$$

The boundary conditions of any problem, when applied to the particular integral and the general complementary solution, will give all equations needed to produce a solution to that problem.

Limitations of the Theory

In applying this theory to plates composed of laminas, in and parallel to the $r\theta$ plane, it is essential to note that, in addition to limiting its application to cases where the deflections are small, it is necessary to consider the values of a_{44} and a_{55},[6] the reciprocals of the shearing moduli associated with the elements cut, respectively, from the rz plane and from the cylindrical surface defined by r = const. In these cases, when the shearing resistance of the impregnating material is very small, that is, when a_{44} and a_{55} approach infinity, it is intuitively clear that the laminas will behave like individual membranes and that the bending theory will not be applicable. This condition, of course, invalidates the assumption (3) previously used in developing this theory.

In the solution of problem (5) which appears in a later section of this paper, infinite values for the bending moments are obtained when ν is such that

$$\nu = \frac{1}{\alpha}\frac{1+\epsilon^{2\alpha}}{1-\epsilon^{2\alpha}}$$

This suggests a limitation to the possible values of the elastic constant ν, a number corresponding to the Poisson's ratio appearing in the isotropic theory.

Unfortunately very little experimental data have been published on the values of elastic constants of aeolotropic materials, other than moduli of elasticity,[7] so that the arguments used here must be based upon the probability that certain properties observed in isotropic materials will be retained by the aeolotropic material, and hence these arguments are of a hypothetical nature.

It seems logical to assume that, in general, the strain in a direction normal to an applied tensile stress will be negative, and that the change in the volume of an element subjected to a tensile stress will be positive. That is to say, a_{12}, a_{13}, and a_{23} will be negative and such that the change in an element of volume V_0, under tensile stress, will obey the inequality

$$V_0(e_r + e_\theta + e_z) > 0$$

When this tensile stress is of the type σ_r, the latter condition becomes

$$V_0\sigma_r(a_{12} + a_{22} + a_{23}) > 0$$

and when the stress is of the type σ_θ

$$V_0\sigma_\theta(a_{11} + a_{12} + a_{13}) > 0$$

Dividing these relations by $V_0\sigma_r a_{22}$ and $V_0\sigma_\theta a_{11}$, respectively, we obtain

$$-\frac{a_{12}}{a_{22}} - \frac{a_{23}}{a_{22}} < 1$$

$$-\frac{a_{12}}{a_{11}} - \frac{a_{13}}{a_{11}} < 1$$

[5] The general complementary solution is given in Ref. 2, but only the terms reproduced here are needed for the subsequent work.

[6] These constants appear in the Hooke's law for this material (see ref. 2).

[7] Plastics Catalog, 1943, Plastics Catalogue Corporation, New York, N. Y.

where, under the former of the two assumptions just made, each of the left-hand terms is positive. This restricts $-a_{12}/a_{22}$ and $-a_{12}/a_{11}$ to be between 0 and 1, or we may write

$$\nu = -a_{12}/a_{22} < 1$$

$$\alpha^2\nu = -a_{12}/a_{11} < 1$$

These then become the restrictions on the possible values of ν. On the strength of this hypothesis, the values of ν used in the following problems have been taken as

$$\nu = 1/2, \quad 0 \leq \alpha \leq 1$$

$$\alpha^2\nu = 1/2, \quad 1 \leq \alpha$$

Note that in the evaluation of these problems, the peaks at the value of α corresponding to isotropy (namely $\alpha = 1$) are caused by this method of choosing ν. Since the values of ν, occurring in any given type of material, would probably have a more uniform variation with α, there is no reason to believe, in general, that actual materials will display such a marked effect at the transition point between radially stiff and tangentially stiff plates.

Some Symmetrical Bending Problems

For those problems where p and w are functions of r only, Equation [7] reduces to the form

$$\left[c\frac{\partial^4}{\partial r^4} + \frac{2c}{r}\frac{\partial^3}{\partial r^3} - \frac{1}{r^2}\frac{\partial^2}{\partial r^2} + \frac{1}{r^3}\frac{\partial}{\partial r}\right]w = \frac{p}{D}$$

for which the general complementary solution is

$$w = a_1 r^{1+\alpha} + a_2 r^{1-\alpha} + a_3 r^2 + a_4$$

When p is a constant (the problem of uniform lateral load), the particular integral becomes

$$w = \frac{pr^4}{(72c - 8)D}$$

The following problems have been solved by applying the boundary conditions of each to the foregoing solutions of Equation [7]:

1 The disk with clamped edge, uniform lateral load.
2 The disk with clamped edge, central concentrated load.
3 The disk, simply supported, under uniform edge moment.
4 The disk with a rigid core of radius r_1 and clamped edge, central concentrated force.
5 The ring with clamped outer edge, loaded by uniform shear on the inner edge.
6 The disk with an elastic, isotropic core, simply supported, under uniform edge moment.

The problems of the bending of the simply supported plates under the loadings of problems (1) and (2) may be solved by combining the solutions of (1) and (2) with that of problem (3), evaluating the edge moment of problem (3) to satisfy the simple-support boundary condition. The simple-support problems, corresponding to problems (4) and (5), may also be solved by combining the clamped-edge solutions with the results of problem (6), wherein the stiffness of the core should be taken as vanishing for the ring problem and should be considered as infinite for the rigid-core problem.

Since no further considerations are necessary, the algebraic statements of the boundary conditions, and the corresponding solutions for the displacements and moments, will now be tabulated.

1 *Uniform Lateral Load, Clamped Edge:*

$$w = \partial w/\partial r = 0 \quad \text{at} \quad r = r_2$$

$$\partial w/\partial r = 0 \quad \text{at} \quad r = 0$$

$$Q_r = -pr/2$$

$$w = \frac{pr_2^4}{(72c-8)D}\left[\left(\frac{r}{r_2}\right)^4 - \frac{4}{1+\alpha}\left(\frac{r}{r_2}\right)^{1+\alpha} + \frac{3-\alpha}{1+\alpha}\right]$$

$$M_r = \frac{-pr_2^2}{18c-2}\left[(3c+\nu)\left(\frac{r}{r_2}\right)^2 - \frac{1+\alpha\nu}{\alpha}\left(\frac{r}{r_2}\right)^{\alpha-1}\right]$$

$$M_\theta = \frac{-pr_2^2}{18c-2}\left[(3\nu+1)\left(\frac{r}{r_2}\right)^2 - (1+\alpha\nu)\left(\frac{r}{r_2}\right)^{\alpha-1}\right]$$

2 *Concentrated Load, Clamped Edge:*

$$w = \partial w/\partial r = 0 \quad \text{at} \quad r = r_2$$

$$\partial w/\partial r = 0 \quad \text{at} \quad r = 0$$

$$Q_r = -P/2\pi r$$

$$w = \frac{-P\alpha^2 r_2^2}{4\pi D(\alpha^2-1)}\left[\left(\frac{r}{r_2}\right)^2 - \frac{2}{\alpha+1}\left(\frac{r}{r_2}\right)^{\alpha+1} - \frac{\alpha-1}{\alpha+1}\right]$$

$$M_r = \frac{P\alpha^2}{2\pi(\alpha^2-1)}\left[(c+\nu) - \frac{1+\alpha\nu}{\alpha}\left(\frac{r}{r_2}\right)^{\alpha-1}\right]$$

$$M_\theta = \frac{P\alpha^2}{2\pi(\alpha^2-1)}\left[1+\nu-(1+\alpha\nu)\left(\frac{r}{r_2}\right)^{\alpha-1}\right]$$

3 M_0 *Applied at Outer Edge, Simple Support:*

$$w = 0, \quad M_r = M_0 \quad \text{at} \quad r = r_2$$

$$\partial w/\partial r = 0 \qquad \text{at} \quad r = 0$$

$$Q_r = 0$$

$$w = \frac{M_0 r_2^2}{D}\,\frac{\alpha}{(\alpha+1)(\alpha\nu+1)}\left[1 - \left(\frac{r}{r_2}\right)^{\alpha+1}\right]$$

$$M_r = M_0\left(\frac{r}{r_2}\right)^{\alpha-1}, \quad M_\theta = \alpha M_0\left(\frac{r}{r_2}\right)^{\alpha-1}$$

4 *Disk With Rigid Core, Clamped Edge, Concentrated Load P:*

$$w = \partial w/\partial r = 0 \quad \text{at} \quad r = r_2$$

$$\partial w/\partial r = 0 \quad \text{at} \quad r = r_1$$

$$Q_r = -P/2\pi r$$

$$w = \frac{-Pr_2^2\alpha^2}{4\pi D(\alpha^2-1)}\left[\left(\frac{r}{r_2}\right)^2 - \frac{2}{1+\alpha}\,\frac{1-\epsilon^{1+\alpha}}{1-\epsilon^{2\alpha}}\left(\frac{r}{r_2}\right)^{1+\alpha} - \frac{2}{1-\alpha}\,\frac{\epsilon^{\alpha+1}-\epsilon^{2\alpha}}{1-\epsilon^{2\alpha}}\left(\frac{r}{r_2}\right)^{1-\alpha} + \frac{(\alpha-1)^2-(\alpha+1)^2\epsilon^{2\alpha}+4\alpha\epsilon^{\alpha+1}}{(1-\alpha^2)(1-\epsilon^{2\alpha})}\right]$$

$$M_r = \frac{P\alpha}{2\pi(\alpha^2-1)}\left[\frac{1+\alpha^2\nu}{\alpha} - (1+\alpha\nu)\,\frac{1-\epsilon^{\alpha+1}}{1-\epsilon^{2\alpha}}\left(\frac{r}{r_2}\right)^{\alpha-1} + (1-\alpha\nu)\,\frac{\epsilon^{\alpha+1}-\epsilon^{2\alpha}}{1-\epsilon^{2\alpha}}\left(\frac{r}{r_2}\right)^{-\alpha-1}\right]$$

$$M_\theta = \frac{P\alpha^2}{2\pi(\alpha^2-1)}\left[(1+\nu) - (1+\alpha\nu)\,\frac{1-\epsilon^{\alpha+1}}{1-\epsilon^{2\alpha}}\left(\frac{r}{r_2}\right)^{\alpha-1} - (1-\alpha\nu)\,\frac{\epsilon^{\alpha+1}-\epsilon^{2\alpha}}{1-\epsilon^{2\alpha}}\left(\frac{r}{r_2}\right)^{-\alpha-1}\right]$$

5 *Ring Clamped at r_2, Shear on Inner Edge:*

$$w = \partial w/\partial r = 0 \quad \text{at} \quad r = r_2$$

$$Q_r = Q_0, \quad M_r = 0, \quad \text{at} \quad r = r_1$$

$$w = \frac{Q_0 r_1^2}{(\alpha^2-1)D}\left[\frac{\alpha^2}{2}\left(\frac{r}{r_1}\right)^2 - \frac{\alpha}{\alpha+1}\,\frac{(1+\alpha^2\nu)\epsilon^{2\alpha}+\alpha(1-\alpha\nu)\epsilon^{\alpha-1}}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}}\left(\frac{r}{r_1}\right)^{\alpha+1} - \frac{\alpha}{\alpha-1}\,\frac{(1+\alpha^2\nu)-\alpha(1+\alpha\nu)\epsilon^{\alpha-1}}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}}\left(\frac{r}{r_1}\right)^{1-\alpha} - \frac{1}{\epsilon^2}\left\{\frac{\alpha^2}{2} - \frac{\alpha}{\alpha+1}\,\frac{(1+\alpha^2\nu)\epsilon^{\alpha+1}+\alpha(1-\alpha\nu)}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}} + \frac{\alpha}{\alpha-1}\,\frac{-(1+\alpha^2\nu)\epsilon^{\alpha-1}+\alpha(1+\alpha\nu)}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}}\right\}\right]$$

$$M_r = \frac{Q_0 r_1}{\alpha^2-1}\left[-(1+\alpha^2\nu)+(1+\alpha\nu) \times \frac{(1+\alpha^2\nu)\epsilon^{2\alpha}+\alpha(1-\alpha\nu)\epsilon^{\alpha-1}}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}}\left(\frac{r}{r_1}\right)^{\alpha-1} + (1-\alpha\nu)\,\frac{(1+\alpha^2\nu)-\alpha(1+\alpha\nu)\epsilon^{\alpha-1}}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}}\left(\frac{r}{r_1}\right)^{-\alpha-1}\right]$$

$$M_\theta = \frac{Q_0 r_1 \alpha}{\alpha^2-1}\left[-\alpha(1+\nu)+(1+\alpha\nu) \times \frac{(1+\alpha^2\nu)\epsilon^{2\alpha}+\alpha(1-\alpha\nu)\epsilon^{\alpha-1}}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}}\left(\frac{r}{r_1}\right)^{\alpha-1} -(1-\alpha\nu)\,\frac{(1+\alpha^2\nu)-\alpha(1+\alpha\nu)\epsilon^{\alpha-1}}{(1-\alpha\nu)+(1+\alpha\nu)\epsilon^{2\alpha}}\left(\frac{r}{r_1}\right)^{-\alpha-1}\right]$$

6 *Disk With Isotropic Elastic Core, Loaded by Uniform Edge Moment M_0:*

The boundary conditions for this problem are formulated by noting that, for the isotropic core, the following relation holds

$$M_r = -F(1+\mu)\partial w/\partial r, \quad \text{at} \quad r = r_1$$

This is true provided the loading is independent of θ. Noting also that M_r and $\partial w/\partial r$ must be continuous at the boundary between the two materials, the boundary conditions corresponding to the problem of applied edge moment become

$$M_r = -F(1+\mu)\,\partial w/\partial r, \quad Q_r = 0, \quad \text{at} \quad r = r_1$$

$$M_r = M_0, \qquad w = 0, \qquad r = r_2$$

$$w = \frac{M_0 r_1^2}{\epsilon DK}\left[\frac{(1+\alpha\nu)-(F/D)\,\alpha(1+\mu)}{\alpha(\alpha-1)}\left(\frac{r}{r_1}\right)^{1-\alpha} - \frac{1-\alpha\nu+(F/D)\alpha(1+\mu)}{\alpha(\alpha+1)}\left(\frac{r}{r_1}\right)^{1+\alpha} + \frac{(1-\alpha\nu)+(F/D)\,\alpha(1+\mu)}{\alpha(\alpha+1)}\,\epsilon^{-\alpha-1} - \frac{1+\alpha\nu-(F/D)\,\alpha(1+\mu)}{\alpha(\alpha-1)}\,\epsilon^{\alpha-1}\right]$$

$$M_r = \frac{M_0}{\epsilon K}\left[\left\{\frac{1-\alpha^2\nu^2}{\alpha^2}+\frac{F}{D}(1+\mu)\,\frac{1+\alpha\nu}{\alpha}\right\}\left(\frac{r}{r_1}\right)^{\alpha-1} - \left\{\frac{1-\alpha^2\nu^2}{\alpha^2}-\frac{F}{D}(1+\mu)\,\frac{1-\alpha\nu}{\alpha}\right\}\left(\frac{r}{r_1}\right)^{-\alpha-1}\right]$$

$$M_\theta = \frac{M_0}{\epsilon K}\left[\left\{\frac{1-\alpha^2\nu^2}{\alpha}+\frac{F}{D}(1+\mu)(1+\alpha\nu)\right\}\left(\frac{r}{r_1}\right)^{\alpha-1} + \frac{1-\alpha^2\nu^2}{\alpha}-\frac{F}{D}(1+\mu)(1-\alpha\nu)\left(\frac{r}{r_1}\right)^{-\alpha-1}\right]$$

An Unsymmetrical Bending Problem

The circular plate loaded by a distribution of pressure of the form $p = p_0(r/r_2)\cos\theta$ is a problem in unsymmetrical loading which has a very simple solution.

The particular integral of Equation [7] corresponding to this loading is given by

$$w = \frac{p_0 r^5}{16(15c - 2b - 1)Dr_2}\cos\theta$$

The corresponding complementary solution has the form

$$w = (Ar^{1+k} + Br + Cr^{1-k} + Dr\ln r)\cos\theta$$

When the boundary conditions for the clamped plate are applied to these expressions, the equations giving the deflection and moments are derived. These boundary conditions and solutions are

$$w = \partial w/\partial r = 0 \quad \text{at} \quad r = r_2$$

$$w \text{ and } M_r \text{ finite} \quad \text{at} \quad r = 0$$

$$w = \frac{p_0 r_2^4}{16(15c - 2b - 1)D}\left[\left(\frac{r}{r_2}\right)^5 - \frac{4}{k_1}\left(\frac{r}{r_2}\right)^{1+k_1} + \frac{4 - k_1}{k_1}\left(\frac{r}{r_2}\right)\right]\cos\theta$$

$$M_r = \frac{-p_0 r_2^2}{4(15c - 2b - 1)}\left[(5c + \nu)\left(\frac{r}{r_2}\right)^3 - (ck_1 + c + \nu)\left(\frac{r}{r_2}\right)^{k_1-1}\right]\cos\theta$$

$$M_\theta = \frac{-p_0 r_2^2}{4(15c - 2b - 1)}\left[(5\nu + 1)\left(\frac{r}{r_2}\right)^3 - (1 + k_1\nu + \nu)\left(\frac{r}{r_2}\right)^{k_1-1}\right]\cos\theta$$

$$M_{r\theta} = \frac{-p_0 r_2^2(b - \nu)}{4(15c - 2b - 1)}\left[\left(\frac{r}{r_2}\right)^3 - \left(\frac{r}{r_2}\right)^{k_1-1}\right]\sin\theta$$

Arbitrary Distribution of Lateral Pressure

The problem of the ring or disk with an arbitrary distribution of lateral pressure may be solved by one of the following:

If the pressure is a function of θ alone, expand it in a Fourier series and obtain the particular integral of Equation [7] for this loading. Choose the terms of the complementary solution which contain the same trigonometric terms as are found in the particular integral and evaluate the constants in such a manner as to satisfy the boundary conditions.

If the loading is made up of isolated concentric rings of force (per unit length), solve the problem as a group of simultaneous ring problems with uniformly applied shear forces and edge moments of undetermined magnitude.

If p is a function of r, the complementary solution of Equation [7] containing terms which are trigonometric functions of $\ln r$ must be found. This solution is very complex algebraically and, in general, the solution to a problem of this type will be tedious to evaluate.

The Bending of the Clamped Sectorial Plate

By G. F. CARRIER,[1] ITHACA, N. Y.

The problem of evaluating the bending moments, existing in a uniformly loaded clamped plate having the form of a sector of a ring, is one which arises in connection with the stress analysis of reinforced piston heads and in other design problems. In this paper, expressions are derived for the bending moments along the edges of such a plate. Similar problems, i.e., those of the clamped rectangular plate under uniform pressure,[2] under a central concentrated load,[3] and that of the simply supported sector of a disk under uniform pressure,[4] have been discussed by previous authors. The general approach used in the foregoing problems is adopted in the present case; a considerable reduction in the computational work is achieved, however, by the use of an integral-equation method of solving the boundary-condition equations. Numerical results are obtained for plates of various dimensions, and the edge moment distributions are plotted for these cases. Curves are also plotted which indicate the relationship existing between the maximum bending moments derived for sectorial plates and those previously obtained for clamped rectangular plates of similar size.

The Simply Supported Plate

IN the consideration of the bending of the sectorial plate (Fig. 1), the assumptions of the small bending theory are adopted, and the problem is reduced to one of finding that solution of the equation

$$\left(\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}+\frac{1}{r^2}\frac{\partial^2}{\partial\theta^2}\right)^2 W=\frac{q(r,\theta)}{D} \quad \ldots\ldots\ldots [1]$$

which satisfies a given set of boundary conditions.[5] (W is the deflection; D is the modulus of rigidity.)

The uniform lateral pressure, q_0, which is to be applied to the plate, may be expressed in the form

$$q_0=\frac{4q_0}{\pi}\sum_{m=1,3,5}^{\infty}\frac{(-1)^{\frac{(m-1)}{2}}}{m}\cos\frac{mk}{2}\theta \quad \ldots\ldots\ldots [2]$$

in the region, $-\frac{\pi}{k}<\theta<\frac{\pi}{k}$. ($k$ and several other symbols are defined in Fig. 1.)

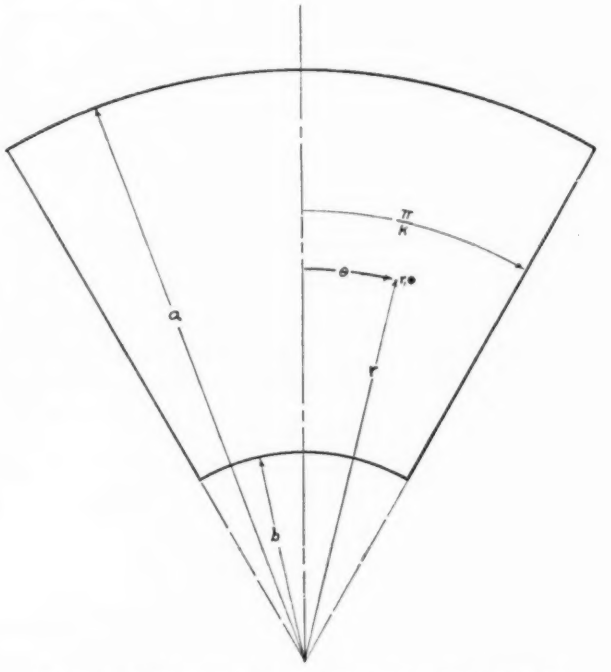

FIG. 1 THE SECTORIAL PLATE INVOLVED IN THE PROBLEM

In terms of the dimensionless forms defined later in Equations [4], Equation [1] may be written

$$\left(\frac{\partial^2}{\partial\rho^2}+\frac{1}{\rho}\frac{\partial}{\partial\rho}+\frac{1}{\rho^2}\frac{\partial^2}{\partial\theta^2}\right)^2 w=\sum_{m=1,3}^{\infty}\frac{(-1)^{\frac{m-1}{2}}}{m}\cos u\theta \quad \ldots\ldots [3]$$

where

$$\left.\begin{aligned}\rho&=\frac{r}{b},\quad u=\frac{mk}{2},\quad w=\frac{\pi DW}{4q_0b^4},\quad \epsilon=\frac{a}{b}\\ m_r&=\frac{\pi M_r}{4q_0b^2}=\left[\frac{\partial^2}{\partial\rho^2}+\nu\left(\frac{1}{\rho}\frac{\partial}{\partial\rho}+\frac{1}{\rho^2}\frac{\partial^2}{\partial\theta^2}\right)\right]w\\ m_\theta&=\frac{\pi M_\theta}{4q_0b^2}=\left[\frac{1}{\rho^2}\frac{\partial^2}{\partial\theta^2}+\frac{1}{\rho}\frac{\partial}{\partial\rho}+\nu\frac{\partial^2}{\partial\rho^2}\right]w\end{aligned}\right\} \quad \ldots [4]$$

A particular integral of Equation [3] is

$$\left.\begin{aligned}w_0&=\sum_{m=1,3}^{\infty}(-1)^{\frac{m-1}{2}}\rho^4\frac{\cos u\theta}{m(u^2-4)(u^2-16)},\\ &\qquad\qquad \text{for } u\neq 2,\ u\neq 4,\\ \text{or, for } u&=\begin{cases}2;\ w_0=(-1)^{\frac{m-1}{2}}\dfrac{\rho^4\ln\rho}{48m}\cos 2\theta,\\ 4;\ w_0=(-1)^{\frac{m-1}{2}}\dfrac{\rho^4\ln\rho}{96m}\cos 4\theta,\end{cases}\end{aligned}\right\} \quad \ldots [5]$$

and a complementary solution of similar form is given by

Presented at the National Meeting of the Applied Mechanics Division, Chicago, Ill., June 16-17, 1944, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

$$w_1 = \sum_{m=1,3}^{\infty} (-1)^{\frac{m-1}{2}} \left\{ A_m \left(\frac{\rho}{\epsilon}\right)^u + B_m \rho^{-u} + C_m \left(\frac{\rho}{\epsilon}\right)^{2+u} + D_m \rho^{2-u} \right\} \cos u\theta \quad \ldots\ldots [6]$$

Four of the boundary conditions of the simply supported plate, namely

$$w = m_\theta = 0, \text{ at } \theta = \pm \pi/k$$

are satisfied by the solution, $w_0 + w_1$, regardless of the values assigned to $A_m, \ldots D_m$. The remaining four conditions are satisfied by setting

$$w_0 + w_1 = 0, \text{ and } m_r = 0, \text{ at } \rho = 1, \text{ and at } \rho = \epsilon$$

This determines uniquely the $A_m, \ldots D_m$, since it produces four simultaneous equations in the four coefficients corresponding to each m. The expressions for the $A_m, \ldots D_m$, and those for several other coefficients which will be encountered, are not written out explicitly in this paper since they are very long and are of direct use only as they appear in combinations which are quoted in a subsequent section.

The bending moments may of course be found immediately in terms of these coefficients by application of Equations [4].

The slopes at the edges, to be used in satisfying the boundary conditions for the clamped plate, are found by differentiation, and are denoted as follows

$$\left.\begin{aligned} \text{at } \rho = \epsilon, \ \frac{\partial}{\partial \rho}(w_0 + w_1) &= \sum_{m=1,3}^{\infty} P_m \cos u\theta \\ \text{at } \rho = 1, \ \frac{\partial}{\partial \rho}(w_0 + w_1) &= \sum_{m=1,3}^{\infty} Q_m \cos u\theta \\ \text{at } \theta = \pm \frac{\pi}{k}, \ \frac{\partial}{\partial \theta}(w_0 + w_1) &= \sum_{m=1,3}^{\infty} \rho \mathcal{L}_m(p\xi) \end{aligned}\right\} \ldots [7]$$

where $p = \pi/\ln \epsilon$ and $\xi = \ln \rho$.

The symbols, P_m, Q_m, and $\mathcal{L}_m$, introduced here, are self-defining in terms of the parameters, $A_m, \ldots D_m$, k, and ϵ. Symbol $\mathcal{L}$ is defined as a function of ξ, rather than one of ρ, to avoid the necessity of redefining the notation in the treatment of Equations [11].

The Clamped Plate

The bending of the clamped plate will be treated by superimposing on the solution for the simply supported plate two solutions of the differential equation

$$\left(\frac{\partial^2}{\partial \rho^2} + \frac{1}{\rho}\frac{\partial}{\partial \rho} + \frac{1}{\rho^2}\frac{\partial^2}{\partial \theta^2}\right)^2 w = 0$$

namely

$$\left.\begin{aligned} w_2 &= \sum_{m=1,3}^{\infty} (-1)^{\frac{m-1}{2}} \left\{ E_m \left(\frac{\rho}{\epsilon}\right)^u + F_m \rho^{-u} + G_m \left(\frac{\rho}{\epsilon}\right)^{2+u} + H_m \rho^{2-u} \right\} \cos u\theta \\ \text{and} \quad w_3 &= \sum_{n=1,2}^{\infty} \rho \frac{\cos \theta_0}{\sinh \varphi_n} (I_n \cos\theta \cosh np\theta + J_n \sin\theta \sinh np\theta) \sin np\xi \end{aligned}\right\} \ldots [8]$$

where $\theta_0 = \dfrac{\pi}{k}, \quad \varphi_n = \dfrac{np\pi}{k}$

These solutions are easily obtained by considering solutions of the form

$$w = R(\rho)\Theta(\theta)$$

This superposition corresponds, of course, to applying edge moments to the plate, whose distributions depend upon the values of the coefficients, $E_m, \ldots J_n$, which must be evaluated to make the displacements and slopes vanish on the four edges. By virtue of the fact that $w_0 + w_1$ vanishes at all four edges, w_2 at the radial edges, and w_3 along the circular edges, w (henceforth implying $w = w_0 + w_1 + w_2 + w_3$) will itself vanish on all four edges if

$$\left.\begin{aligned} E_m &= G_m \frac{\epsilon^{-2-2u} - 1}{1 - \epsilon^{-2u}} + H_m \frac{\epsilon^{-u} - \epsilon^{2-u}}{1 - \epsilon^{-2u}} \\ F_m &= G_m \frac{\epsilon^{-u} - \epsilon^{-2-u}}{1 - \epsilon^{-2u}} + H_m \frac{\epsilon^{2-2u} - 1}{1 - \epsilon^{-2u}} \\ I_n &= -J_n \tan\theta_0 \tanh \varphi_n \end{aligned}\right\} \ldots [8a]$$

The contributions of w_2 to the slopes are now given by

$$\left.\begin{aligned} \text{at } \rho = \epsilon, \ \frac{\partial w_2}{\partial \rho} &= \sum_{m=1,3}^{\infty} (a_{1m} G_m + b_{1m} H_m) \cos u\theta \\ \text{at } \rho = 1, \ \frac{\partial w_2}{\partial \rho} &= \sum_{m=1,3}^{\infty} (a_{2m} G_m + b_{2m} H_m) \cos u\theta \\ \text{at } \theta = \frac{\pi}{k}, \ \frac{\partial w_2}{\partial \theta} &= \sum_{m=1,3}^{\infty} \rho[\alpha_m(p\xi) G_m + \beta_m(p\xi) H_m] \end{aligned}\right\} \ldots [9]$$

where a_{im}, b_{im}, are constants, and α_m, β_m, are functions, each defined by the indicated differentiations and the preceding equalities. They are not quoted explicitly since again they are of importance only as they occur in combinations which arise later in the analysis.

From w_3, we obtain

$$\left.\begin{aligned} \text{at } \rho = \epsilon, \ \frac{\partial w_3}{\partial \rho} &= \sum_{n=1}^{\infty} (-1)^n np J_n \left[\sin\theta \cos\theta_0 \frac{\sinh np\theta}{\sinh \varphi_n} - \cos\theta \sin\theta_0 \frac{\cosh np\theta}{\cosh \varphi_n} \right] \\ &= \sum_{n=1}^{\infty} J_n \gamma_n' \left(\frac{k\theta}{2}\right) = \sum_{n=1}^{\infty} (-1)^n J_n \sum_{m=1,3}^{\infty} Y_{mn} \cos u\theta \\ \text{at } \rho = 1, \ \frac{\partial w_3}{\partial \rho} &= \sum_{n=1}^{\infty} J_n \gamma_n \left(\frac{k\theta}{2}\right) = \sum_{n=1}^{\infty} J_n \sum_{m=1}^{\infty} Y'_{mn} \cos u\theta \\ \text{at } \theta = \frac{\pi}{k}, \ \frac{\partial w_3}{\partial \theta} &= \sum_{n=1}^{\infty} \rho J_n \left[1 + \frac{np \sin 2\theta_0}{\sinh 2\varphi_n} \right] \sin np\xi \\ &= \sum_{n=1}^{\infty} C_n J_n \rho \sin np\xi \end{aligned}\right\} \ldots [10]$$

where[6]

$$Y_{mn} = -(-1)^{\frac{m-1}{2}} \frac{4}{\pi} \frac{\cosh 2\varphi_n + \cos 2\theta_0}{\sinh 2\varphi_n} \frac{kun^2p^2}{[(u+1)^2 + n^2p^2][(u-1)^2 + n^2p^2]}$$

The only boundary conditions remaining to be satisfied are

$$\frac{\partial w}{\partial \rho} = \frac{\partial w}{\partial \theta} = 0$$

at the four edges.

Since all terms in $\frac{\partial w}{\partial \theta}$ are odd in θ, the conditions on the radial edges are identical, and only one need be considered.

If we now utilize the foregoing expressions for the slopes and formulate the three remaining boundary conditions, we obtain

$$\left.\begin{aligned}
&\sum_m a_{1m}G_m \cos u\theta + \sum_m b_{1m}H_m \cos u\theta \\
&\qquad + \sum_n \gamma'_n \left(\frac{k\theta}{2}\right) J_n = -\sum_m P_m \cos u\theta \\
&\sum_m a_{2m}G_m \cos u\theta + \sum_m b_{2m}H_m \cos u\theta \\
&\qquad + \sum_n \gamma_n \left(\frac{k\theta}{2}\right) J_n = -\sum_m Q_m \cos u\theta \\
&\sum_m \alpha_m(p\xi)G_m + \sum_m \beta_m(p\xi)H_m \\
&\qquad + \sum_n c_n J_n \sin np\xi = -\sum_m \mathfrak{L}_m(p\xi)
\end{aligned}\right\} \quad . . [11]$$

The reduction of these equations to those in J_n only, and the method of evaluation of these coefficients, is carried out in detail in the Appendix. With the determination of the values of the J_n, the deflection may be considered as known since the G_m and H_m have been expressed in terms of the J_n during the reduction of Equations [11].

[6] This Fourier coefficient arises in the expansions of γ and γ' into their cosine series, in the interval, $-\frac{\pi}{k} < \theta < \frac{\pi}{k}$.

The Bending Moments

The bending moments along the radial edge can occur only from the terms in w_3, since all other terms in w have a factor of $\cos u\theta$, which vanishes at this edge. Hence the expression for m_θ, quoted in Equations [4], when applied to w_3, yields the following formula for moment distribution along the radial edge

$$m_\theta = \frac{2p}{\rho} \sum_{n=1}^{\infty} nJ_n \sin np\xi \frac{\cosh 2\varphi_n + \cos 2\theta_0}{\sinh 2\varphi_n}$$

In order to evaluate the bending moments along the circular edges, both w_2 and w_3 must be considered. If G_m and H_m are expressed in terms of the J_i (essentially Equations [14] of the Appendix), and if the equation for m_r (Equation [4]) is applied to $w_2 + w_3$, the formulas at the bottom of this page for m_r are obtained:[7]

When, in the foregoing equations, each J_i is given the value zero, the bending moments become those for the sectorial plate, simply supported on the radial edges and clamped along the circular edges.

It is interesting to note that although P_m, Q_m, and other expressions occurring in the development of this problem depend upon the Poisson's ratio ν, of the material, the final equations for the J_i and those for the bending moments along the edges are independent of the value of this quantity. This provides a partial check on the algebraic work (which is involved enough to make a check desirable) since this result can be shown to be a necessary one. Except as this quantity appears in the constant D, the solution for the deflection cannot depend upon ν, since it occurs neither in the differential equation nor in the boundary conditions. Furthermore, this number appears in the moment expressions only as a coefficient of the radial slope which vanishes on all four edges, and as a coefficient of the curvature, tangent to the edge at which the moment is being evaluated, and this term also vanishes.

The bending moments in a complete ring under uniform lateral

[7] λ_m, μ_m are defined in the Appendix where they occur in Equations [17].

$$m_r = \sum_{(\rho=\epsilon)} \sum_m (-1)^{\frac{m-1}{2}} \frac{\mu_m}{\lambda_m} \left\{ \begin{array}{l} (u-4)(u-2)\epsilon^2 - 2u(u-1)(u+4)\epsilon^{-u} + 2u(u+1)(u+2)\epsilon^{-2-u} \\ -2(u^2-8)(u^2-1)\epsilon^{2-2u} + u^2(u^2-4)\epsilon^{4-2u} + u^2(u^2-16)\epsilon^{-2u} \\ +2u(u+1)(u-4)\epsilon^{-3u} - 2u(u-1)(u-2)\epsilon^{-2-3u} + (u+2)(u+4)\epsilon^{2-4u} \end{array} \right\} \cos u\theta$$

$$- \sum_m \frac{2u}{\epsilon} \left\{ \begin{array}{l} \left[(1-\epsilon^{-4u}) + u\epsilon^{-2u}\left(\epsilon^2 - \frac{1}{\epsilon^2}\right)\right] \sum_n (-1)^n Y_{mn} J_n \\ + \left[(u-1)(\epsilon^{1-u} - \epsilon^{-1-3u}) - (u+1)(\epsilon^{-1-u} - \epsilon^{1-3u})\right] \sum_n Y_{mn} J_n \end{array} \right\} \cos u\theta$$

$$m_r = \sum_{(\rho=1)} \sum_m (-1)^{\frac{m-1}{2}} \frac{\mu_m}{m\lambda_m} \left\{ \begin{array}{l} (u+2)(u+4) - 2u(u-1)(u-2)\epsilon^{4-u} + 2u(u+1)(u-4)\epsilon^{2-u} \\ + u^2(u^2-16)\epsilon^{2-2u} - 2(u^2-8)(u^2-16)\epsilon^{-1u} + u^2(u^2-4)\epsilon^{-2-2u} \\ + 2u(u+2)(u+1)\epsilon^{4-3u} - 2u(u+4)(u-1)\epsilon^{2-3u} + (u-4)(u-2)\epsilon^{-4u} \end{array} \right\} \cos u\theta$$

$$+ \sum_m 2u \left\{ \begin{array}{l} \left[(1-\epsilon^{-4u}) + u\epsilon^{-2u}\left(\epsilon^2 - \frac{1}{\epsilon^2}\right)\right] \sum_n Y_{mn} J_n \\ + \left[(u-1)(\epsilon^{1-u} - \epsilon^{-1-3u}) - (u+1)(\epsilon^{-1-u} - \epsilon^{1-3u})\right] \sum_n (-1)^n Y_{mn} J_n \end{array} \right\} \cos u\theta$$

load and clamped on both edges, to be used in Fig. 5 for comparative purposes, are found by obtaining that solution of Equation [1] which is independent of θ and which has zero displacement and slope along the edges. The maximum bending moment (along the inner edge) becomes

$$m_r = \frac{\epsilon^4 + 4\ln\epsilon - 1}{4\ln\epsilon} - \frac{(\epsilon^2 + 2\ln\epsilon - 1)(\epsilon^4 - 4\epsilon^2\ln\epsilon - 1)}{(4\ln\epsilon)[(\epsilon^2-1)^2 - 4\epsilon^2(\ln\epsilon)^2]}$$

Numerical Results

Computations have been carried out in detail for three cases. In each of these, k was taken as 6, that is, the angle of the sector was taken as 60 deg. The values of ϵ were taken as, 2.0, 2.85, and 4.81, the latter two chosen to make the corresponding values of p, which occurs very frequently in the computations, equal to 3 and 2, respectively. Following this discussion, a set of equations for J_i (those for $\epsilon = 4.81$) are included to illustrate the method used in the evaluation of these numbers. Referring to these, the first approximations to the J_i were found by solving those equations (or parts thereof) which lie to the left of the dotted line, substituting previously found values when necessary. The second approximations are found by substituting those values obtained in the first step into the first equation and finding the new J_1. Then this and the first approximations to the other J_i are used to find J_2, and the method is continued. The accuracy of this second group of values, estimated by noting the difference between them and the previously found values, is considered sufficient to justify their use in the computation of the moments, as the values are certainly as accurate as those found for the R_{mi}, and the K_{imn}.[8] Using values of m ranging from 1 to 11, the K_{imn} for the higher i and n are probably not accurate within 10 per cent, but the effect of these terms is small and the accuracy of the final results should be well within this limit. The values of the J_i, for i less than 6, should be accurate to within 2 per cent, barring computational error, but the higher J_i are probably not as good, owing both to the fact that the R_{mi} in this range are small differences of comparatively large numbers, and to the comparative inaccuracy of the K_{imn}. The effect of these higher J_i is, however, negligible (they could actually have been dispensed with in these three cases), except near the corners where the stresses are very small.

The bending moments occurring in these three cases have been plotted in two different manners. Figs. 2, 3, 4 show, respectively, the bending-moment distributions along the inner, outer, and radial edges. The dimensionless moments plotted are not the m_r and m_θ, but are quantities based upon plates with the same outer radii. Fig. 4 shows superimposed views of the three plates, and inspection of this diagram, in conjunction with Figs. 2 and 3, should easily convince one that an extrapolation from the plate corresponding to $\epsilon = 4.81$ to a plate extending to the center would produce no great change in the magnitude of the moments

[8] These quantities appear in the expressions for the J_i, see the Appendix.

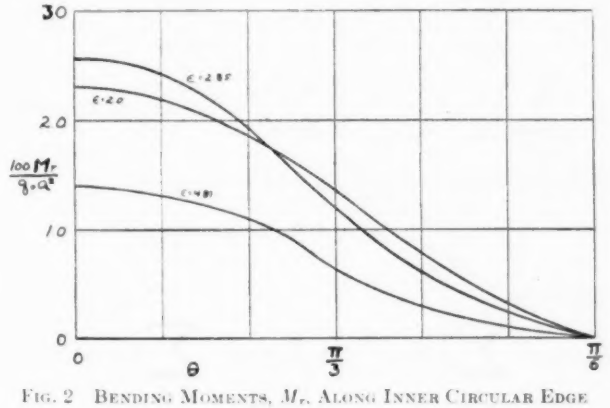

Fig. 2 Bending Moments, M_r, Along Inner Circular Edge

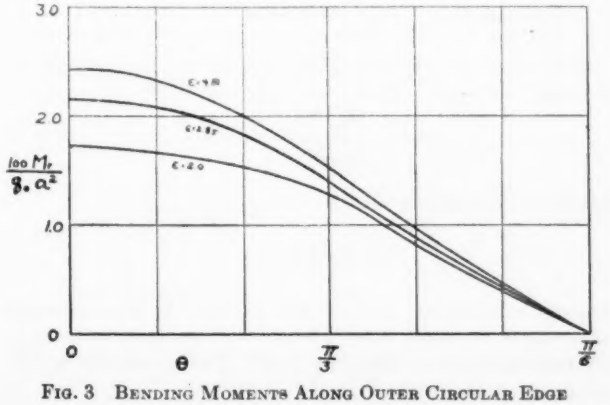

Fig. 3 Bending Moments Along Outer Circular Edge

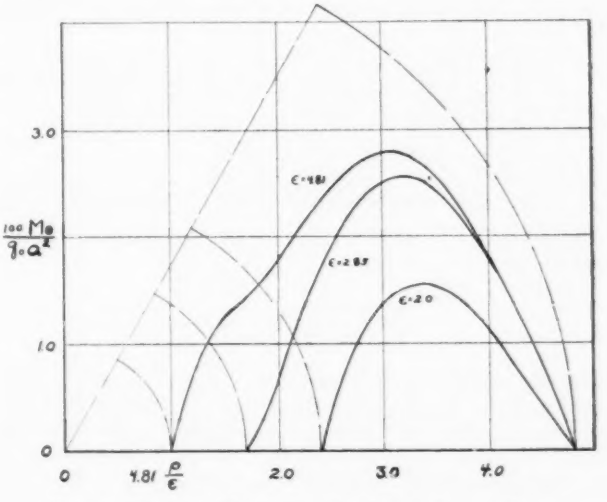

Fig. 4 Bending Moments, M_θ, Along Radial Edge

$\alpha = (\epsilon - 1)b$ $\qquad \frac{\beta = \pi(\epsilon+1)}{k} b$

(k taken as 6.0 in each case.)

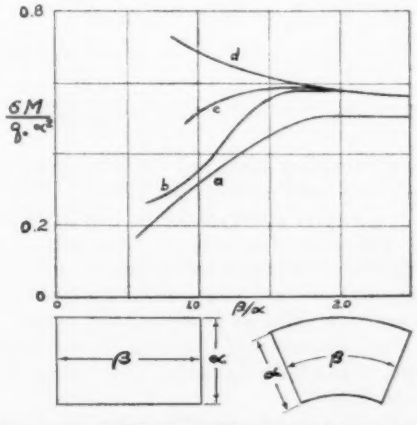

Fig. 5 Comparison of Maximum Bending Moments for Various Shapes and Boundary Conditions

(*a*, Clamped rectangular plate. *b*, Clamped sectorial plate. *c*, Sectorial plate, clamped on circular edges, simply supported on radial edges. *d*, Complete ring, clamped edges.)

occurring along the outer circular edge and along the outer part of the radial edge.

In Fig. 5 are plotted four curves: (*a*) is a plot of the maximum bending moment in a clamped rectangular plate, plotted against the ratio of the lengths of the sides,[9] (*b*) is a curve of maximum bending moment in the clamped sectorial plate, plotted against a similar parameter which is defined in the figure; (*c*) is a curve of maximum moment in the sectorial plate which is simply supported on the radial edges and clamped along the circular ones; (*d*) is the corresponding curve for the complete ring with clamped edges. These last two curves have the same abscissa as (*b*).

For those values of ϵ and k which were used, there seems to be a close analogy between the stresses induced in a sectorial plate and those in a rectangular plate of similar size, when they are similarly loaded and clamped.

TABLE 1 EQUATIONS FOR THE J_i ($\epsilon = 4.81$)

$$
\begin{aligned}
1.077\,J_1 &= +0.239 + 0.237\,J_3 + 0.130\,J_5 + 0.085\,J_7\\
0.967\,J_3 &= +0.00065 + 0.090\,J_1 + 0.070\,J_5 + 0.062\,J_7\\
0.951\,J_5 &= -0.00577 + 0.030\,J_1 + 0.047\,J_3 + 0.048\,J_7\\
0.963\,J_7 &= -0.00261 + 0.014\,J_1 + 0.028\,J_3 + 0.035\,J_5\\
0.975\,J_9 &= -0.00143 + 0.008\,J_1 + 0.017\,J_3 + 0.024\,J_5\\
0.985\,J_{11} &= -0.00072 + 0.005\,J_1 + 0.012\,J_3 + 0.018\,J_5
\end{aligned}
$$

These and a similar set of equations for the even J_i produce the following results:

$$
\begin{aligned}
J_1 &= 0.228 & J_2 &= -0.0703\\
J_3 &= 0.0221 & J_4 &= -0.00433\\
J_5 &= 0.00230 & J_6 &= -0.00186\\
J_7 &= 0.00131 & J_8 &= -0.00111\\
J_9 &= 0.00089 & J_{10} &= -0.00075\\
J_{11} &= 0.00069
\end{aligned}
$$

Appendix

Equations [11] must be satisfied for all values of θ and ξ in the regions

$$-\frac{\pi}{2} < \frac{k\theta}{2} < \frac{\pi}{2};\ 0 < p\xi < \pi$$

Since the solution of these equations is purely a mathematical problem, they may be rewritten in terms of dummy variables (in order to obtain a maximum of simplicity in the following work), provided it is understood that the functions are defined over the corresponding regions of these variables. We write then

$$\sum_m a_{1m}G_m \cos mx + \sum_m b_{1m}H_m \cos mx + \sum_n J_n\gamma_n'(x) = -\sum_m P_m \cos mx \ldots [11a]$$

$$\sum_m a_{2m}G_m \cos my + \sum_m b_{2m}H_m \cos my + \sum_n J_n\gamma_n(y) = -\sum_m Q_m \cos my \ldots [11b]$$

$$\sum_m G_m\alpha_m(Z) + \sum_m H_m\beta_m(Z) + \sum_n c_nJ_n \sin nZ = -\sum_m \mathfrak{L}_m(Z) \ldots\ldots [11c]$$

A previously developed method by which the values of G_m, H_m, and J_n may be found, proceeds as follows:[3] The functions α_m, β_m, γ_m, γ'_m and $\mathfrak{L}_m$ are expanded in Fourier series, thereby producing an infinite set of equations in the unknown coefficients. These may be solved by any of the variations on the method of successive approximations. This method has efficiently yielded the desired results in previous problems,[3] but in the present instance, the computational work is greatly reduced by the following procedure, in which Equations [11] are reduced to a set of equations in J_n only.

It is desirable, first, to solve simultaneously Equations [11*a*, *b*] in such a way as to obtain an equation for the G_m (or the equivalent thereof) from which the H_m have been eliminated. To facilitate this, we define the functions

$$G(x) = \sum_m \frac{a_{1m}b_{2m} - a_{2m}b_{1m}}{b_{2m}} G_m \cos mx \ldots\ldots [12a]$$

$$H'(y) = \sum_m b_{2m}H_m \cos my \ldots\ldots [12b]$$

These expressions imply that

$$G_m = \frac{2b_{2m}}{\pi(a_{1m}b_{2m} - a_{2m}b_{1m})} \int_{-\pi/2}^{\pi/2} G(x) \cos mx dx \ldots [13a]$$

$$H_m = \frac{2}{\pi b_{2m}} \int_{-\pi/2}^{\pi/2} H'(y) \cos my dy \ldots\ldots [13b]$$

The substitution of Equations [12*a*] and [13*b*] into [11*a*], and of [12*b*] into [11*b*] produces the following pair of equations

$$G(x) = -\sum_m P_m \cos mx - \sum_n \gamma_n'(x)J_n - \sum_m \frac{a_{2m}b_{1m}}{b_{2m}} G_m \cos mx - \sum_m \frac{2b_{1m}}{\pi b_{2m}} \cos mx \int_0^\pi H'(y) \cos my dy$$

$$H'(y) = -\sum_m Q_m \cos my - \sum_n J_n\gamma_n(y) - \sum_m a_{2m}G_m \cos my$$

The further substitution of the latter of these into the former, followed by some of the indicated integrations, produces the desired equation for $G(x)$. This has the form

$$G(x) = -\sum_m \left(P_m - \frac{b_{1m}}{b_{2m}} Q_m\right) \cos mx - \sum_n J_n\gamma_n'(x) + \frac{2}{\pi} \sum_m \frac{b_{1m}}{b_{2m}} \cos mx \int_{-\pi/2}^{\pi/2} \sum_n J_n\gamma_n(y) \cos my dy \ldots [14a]$$

After a similar procedure, $H(x)$ which is defined as

$$H(x) = \frac{a_{1m}b_{2m} - a_{2m}b_{1m}}{a_{1m}} H_m \cos mx$$

is given by

$$H(x) = -\sum_m \left(Q_m - \frac{a_{2m}}{a_{1m}} P_m\right) \cos mx - \sum_n J_n\gamma_n(x) + \frac{2}{\pi} \sum_m \frac{a_{2m}}{a_{1m}} \cos mx \int_{-\pi/2}^{\pi/2} \sum_n J_n\gamma'_n(y) \cos my dy \ldots [14b]$$

The process of eliminating the G_m and H_m is continued by defining

$$J(\varphi) = \sum_n c_nJ_n \sin n\varphi$$

and the accompanying relation

$$J_n = \frac{2}{\pi c_n} \int_0^\pi J(Z) \sin nZ dZ \quad \ldots\ldots [15]$$

The G_m in Equation [11*c*] are now replaced by the expression occurring in Equation [13*a*], wherein $G(x)$ has been replaced by the right-hand side of Equation [14*a*]. The corresponding substitution is made for the H_m and $J(\varphi)$ becomes

[9] "Stress and Deflection of Rectangular Plates," by I. A. Wojtassak, Trans. A.S.M.E., vol. 58, 1936, pp. A-71 to A-73.

$$J(\varphi) = -\sum_m \left\{ \mathfrak{L}_m(\varphi) - \frac{(b_{2m}P_m - b_{1m}Q_m)\alpha_m(\varphi) + (a_{1m}Q_m - a_{2m}P_m)\beta_m(\varphi)}{a_{1m}b_{2m} - a_{2m}b_{1m}} \right\}$$

$$+ \frac{4}{\pi^2}\int_0^\pi \sum_n \frac{1}{c_n} J(Z)\sin nZ\,dZ \left\{ \sum_m \int_{-\pi/2}^{\pi/2} \frac{[b_{2m}\gamma_n(y) - b_{1m}\gamma_n'(y)]\alpha_m(\varphi) + [a_{1m}\gamma_n'(y) - a_{2m}\gamma_n(y)]\beta_m(\varphi)}{a_{1m}b_{2m} - a_{2m}b_{1m}} \cos my\,dy \right\} \quad [16]$$

After performing the integration over y, and after considerable algebraic simplification, this may be written

$$J(\varphi) = -\sum_m R_m(\varphi) + \int_0^\pi \sum_{m,n} K_{mn}(\varphi, Z)J(Z)dZ \quad \ldots\ldots [17]$$

where

$$R_m(\varphi) = \frac{k\mu_m}{4\lambda_m}\left\{ \begin{array}{l} [(u-2)(\epsilon^3 + \epsilon^{-1-3u}) - u(u+4)(\epsilon^{1-u} + \epsilon^{1-2u}) + (u+1)(u+2)(\epsilon^{-1-u} + \epsilon^{3-2u})]e^{(u-1)\frac{\varphi-\pi}{p}} \\ + [-(u+2)(1+\epsilon^{4-3u}) + (u-1)(u-2)(\epsilon^{4-u} + \epsilon^{-2u}) - (u)(u-4)(\epsilon^{2-u} + \epsilon^{2-2u})]e^{-(u+1)\frac{\varphi}{p}} \\ + [-(u-4)(\epsilon^3 + \epsilon^{1-3u}) + (u-1)(u+4)(\epsilon^{1-u} + \epsilon^{3-2u}) - u(u+2)(\epsilon^{-1-u} + \epsilon^{5-2u})]e^{(u+1)\frac{\varphi-\pi}{p}} \\ + [(u+4)(1+\epsilon^{2-3u}) - u(u-2)(\epsilon^{4-u} + \epsilon^{-2-2u}) + (u+1)(u-4)(\epsilon^{-2u} + \epsilon^{3-u})]e^{-(u-1)\frac{\varphi}{p}} \\ -2\lambda_m e^{3\frac{\varphi}{p}} \end{array} \right\}$$

$$K_{mn}(\varphi, Z) = -\frac{Y_{mn}}{c_n} u \sin nZ \, \frac{\sinh\frac{\varphi}{p}\sinh u\left(\frac{\pi-\varphi}{p}\right) + (-1)^{n-1}\sinh\frac{\pi-\varphi}{p}\sinh u\frac{\varphi}{p}}{\sinh u\frac{\pi}{p} + (-1)^{n-1}u\sinh\frac{\pi}{p}}$$

$$\mu_m = \frac{1}{(u^2-4)(u^2-16)} \qquad \lambda_m = (1-\epsilon^{-2u})^2 - u^2\epsilon^{-2u}\left(\epsilon - \frac{1}{\epsilon}\right)^2$$

The foregoing Fredholm equation may now be solved by expanding $J(\varphi)$, $K_{mn}(\varphi, t)$, $R(\varphi)$, in Fourier series, integrating, and obtaining

$$J_i = \sum_m R_{mi} + \sum_{m,n} K_{imn}J_n \quad \ldots\ldots\ldots\ldots [18]$$

where

$$R_{mi} = \frac{kip^2[1 + (-1)^{i-1}\epsilon^3]}{\pi(9 + i^2p^2)[(u+1)^2 + p^2i^2](2+u)(4-u)}$$

$$+ \frac{p^2k^2im\mu_m}{\pi\lambda_m T_{mi}}\left\{ \begin{array}{l} (-1)^{i-1}[(u-2)\epsilon^3 - (u-1)(u+4)\epsilon^{1-u} + (u+1)(u+2)\epsilon^{-1-u} - u(u-2)\epsilon^{5-2u} + 2(u^2-1)\epsilon^{3-2u} \\ \quad - u(u+4)\epsilon^{1-2u} + (u+1)(u-4)\epsilon^{1-3u} + (u-1)(u-2)\epsilon^{-1-3u} + (u+4)\epsilon^{3-4u}] \\ + [(u+4) - (u-1)(u-2)\epsilon^{4-u} + (u+1)(u-4)\epsilon^{2-u} - u(u+4)\epsilon^{2-2u} + 2(u^2-1)\epsilon^{-2u} \\ \quad - u(u-2)\epsilon^{-2-2u} - (u-1)(u+4)\epsilon^{2-3u} + (u+1)(u+2)\epsilon^{4-3u} + (u-2)\epsilon^{-4u}] \end{array} \right\} \quad [18a]$$

$$K_{imn} = [(-1)^{i-n} + 1]\frac{\cosh 2\varphi_n + \cos 2\theta_0}{\sinh 2\varphi_n} \cdot \frac{\cosh\frac{m\pi k}{2p} + (-1)^{i-1}\cosh\frac{\pi}{p}}{\sinh\frac{m\pi k}{2p} + (-1)^{i-1}u\sinh\frac{\pi}{p}} \cdot \frac{2in^2m^3p^4k^4}{\pi^2 T_{mi}T_{mn}}$$

$$T_{mn} = [(u+1)^2 + n^2p^2][(u-1)^2 + n^2p^2]$$

The J_i may now be found by the method of successive approximations with considerably less labor than by the procedure mentioned previously. It can easily be seen that the introduction of the function $J(\varphi)$ was unnecessary. However, this function was introduced both for the sake of consistency of procedure, and to note that in those analogous problems where $J(\varphi)$ might be the desired result (this would have been the case in the corresponding problem on the rectangular plate), and where $K_{mn}(\varphi, Z)$ could be summed to a sufficient degree of accuracy, the Fredholm equation might be of more use than those equations given by Equations [18].

A completely equivalent method of obtaining Equations [18] would be to continue the process outlined at the beginning of this section, by solving simultaneously the equations obtained therein and again eliminating the G_m and H_m. The difficulty here arises in the algebraic work required to obtain a simple form for R_{mi}. This was so involved in the present problem that it is doubtful if the comparatively simple form found, Equation [18a], would have been obtained by the latter procedure.

Since Equations [14] essentially determine the G_m and H_m, there remains only the obvious but tedious task of evaluating the R_{mi} and the K_{imn}, and applying the method of successive approximations to Equations [18]. The bending moments are found as outlined in the foregoing section.

ACKNOWLEDGMENT

The author is indebted to Prof. J. N. Goodier of Cornell University for suggesting this problem, and for his valuable criticisms during the conduct of the work.

Strengthening of Circular Holes in Plates Under Edge Loads

By LEON BESKIN,[1] ALLENTOWN, PA.

In this paper, stress distributions are determined around strengthened circular holes in plates submitted to edge loads at infinity. Various proportions of circular strengthenings are considered, and three conditions of applied edge loads are investigated; uniform hydrostatic stress, uniform shearing stress, uniform axial stress. Stress distributions are found by methods of theory of elasticity, and the results are given in the form of stress-concentration factors. In order to reduce the results to a common basis, the stress-concentration factors have been defined by the ratio of the critical stress, computed by the distortion-energy theory, to the critical stress at infinity, which is the critical stress in the plate without hole.

Nomenclature

The following nomenclature is used in the paper:

Dimensions, Co-Ordinates, Displacements

t = plate thickness
t' = ring thickness
R = radius of hole and of rim
R' = outer radius of ring
A = area of rim section

$x = \frac{R'}{R}; \quad y = \frac{A}{tR}; \quad y' = \frac{A}{t'R}; \quad z = \frac{t'}{t}$

$h = y + (z-1)(x-1)$ = (area of reinforcement): Rt

$M = 2y + (z-1)(x^2-1) = \frac{\text{weight of reinforcement}}{\text{weight corresponding to hole}}$

u, v = components of displacement
r, θ = polar co-ordinates

Stresses

$\sigma_r, \sigma_\theta, \tau_{r\theta}$ = normal and shearing stresses in plate related to polar co-ordinates
$\sigma'_r, \sigma'_\theta, \tau'_{r\theta}$ = corresponding stresses in ring
σ_1 = normal stress in rim
i = index for inner edge of plate or of ring
2 = index for circumference $r = 2R$
e = index for outer edge of ring
1 = index for rim ($r = R$)
E = modulus of elasticity
ν = Poisson's ratio (value 0.3)
p = uniform hydrostatic stress at infinity
$\sigma_r^*, \sigma_\theta^*$ = corresponding normal stresses
q = uniform shearing stress at infinity
$\bar{\sigma}_r, \bar{\sigma}_\theta, \bar{\tau}_{r\theta}$ = corresponding maximum normal and shearing stresses for given r

$\left.\begin{aligned}\sigma &= p + q\\ \sigma' &= p - q\end{aligned}\right\}$ = principal stresses at infinity

$a, m, K; a', m', K'$ = coefficients in plate and in ring, corresponding to hydrostatic stress at infinity
$b, c, d, f; b', c', d', f'$ = coefficients in plate and in ring, corresponding to shearing stress at infinity

$B = \bar{\sigma}_r^2 + \bar{\sigma}_\theta^2 - \bar{\sigma}_r\bar{\sigma}_\theta - 3\bar{\tau}_{r\theta}^2$

$C = \sigma_r^*\bar{\sigma}_r + \sigma_\theta^*\bar{\sigma}_\theta - \frac{1}{2}(\sigma_r^*\bar{\sigma}_\theta + \sigma_\theta^*\bar{\sigma}_r)$

$D = \sigma_r^{*2} + \sigma_\theta^{*2} - \sigma_r^*\sigma_\theta^* + 3\bar{\tau}_{r\theta r}^2$

N = critical-stress combination (*distortion theory*[2])

$N^2 = \sigma_r^2 + \sigma_\theta^2 - \sigma_r\sigma_\theta + 3\tau_{r\theta}^2$

N_0 = critical stress at infinity

$N_0^2 = p^2 + 3q^2$

$j = \frac{N}{N_0}$ stress-concentration factor

N, j can be affected with indices i, 2, e, 1 for corresponding parts of plate.

$j(0), j(45), j(90)$ = values of j along a radius forming an angle $\theta = 0, 45, 90$ deg with the direction of the stress at infinity.

Introduction

It is well known that if a circular hole is made in a plate submitted to given stresses, the distribution of stresses is very much altered in the vicinity of the hole, and the stresses are greatly increased in the region surrounding the hole.

In the following, the plate is supposed to be in a state of uniform plane stress at great distances from a hole, and the influence of circular beads around the hole is investigated.

Two basic solutions are examined: (1) Uniform stress acting in all directions (hydrostatic stress); and (2) uniform shearing stress. Any other uniform stress can be considered as a superposition of the two basic solutions, and the condition of a uniform tensile stress acting in one direction is investigated (designated as "axial stress").

It is well known that around a hole, the ratio of the maximum stress to the uniform stress at a great distance from the hole has the following values:

Condition	Ratio
Hydrostatic stress	2
Shearing stress	4
Tensile stress	3

The influence of the dimensions and shape of the section of the beads on the stress concentration will be investigated hereafter. The beads are divided into two parts, a rim and a ring, and the notations are shown in Fig. 1. The ring is constituted by an in-

[2] "Theory of Elasticity," by S. Timoshenko, first edition, McGraw-Hill Book Company, Inc., New York, N. Y., 1934; Equation [84], p. 137.

crease of the thickness of the plate, and the rim is a section considered as being concentrated around the hole. For various proportions of ring and rim, the stress distribution in elastic condition is examined, and the critical stress is computed by the *distortion-energy theory* of Huber and von Mises.

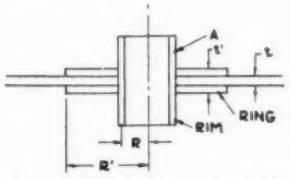

FIG. 1 SECTION OF BEADS, SHOWING NOTATIONS

It is assumed that the problem can be considered as a plane-stress problem, the thicknesses being considered as infinitely small in comparison with the plane dimensions, but questions connected with elastic stability are excluded. All stresses are supposed inferior to the yield point, and conventional expressions of theory of elasticity are used.

MATHEMATICAL DEVELOPMENTS

SOLUTION 1 HYDROSTATIC STRESS

The distribution has a circular symmetry, and the following solution can be used[3]
In the plate

$$\sigma_r = \frac{a}{r^2} + p; \quad \sigma_\theta = -\frac{a}{r^2} + p; \quad \tau_{r\theta} = 0 \dots\dots [1]$$

In the ring

$$\sigma'_r = \frac{a'}{r^2} + p'; \quad \sigma'_\theta = -\frac{a'}{r^2} + p'; \quad \tau_{r\theta}' = 0 \dots\dots [2]$$

The unknowns are p', a', a and the stress n_1 in the rim. Four equations of equilibrium and of equality of strain can be written at the outer and the inner edges of the ring as follows
Equilibrium of normal forces along radius

$$\frac{a}{R'^2} + p = z\left(\frac{a}{R'^2} + p'\right) \dots\dots [3]$$

$$\frac{a'}{R'^2} + p' = y'\sigma_1 \dots\dots [4]$$

Equality of strain along circumference

$$\left(-\frac{a}{R'^2} + p\right) - \nu\left(\frac{a}{R'^2} + p\right) = \left(-\frac{a'}{R'^2} + p'\right) - \nu\left(\frac{a'}{R'^2} + p'\right) \dots\dots [5]$$

$$\sigma_1 = \left(-\frac{a'}{R^2} + p'\right) - \nu\left(\frac{a'}{R^2} + p'\right) \dots\dots [6]$$

The solution of Equations [3] to [6] yields the values

$$p' = \frac{p}{z}\frac{1+m}{1+m'}; \quad a = R^2x^2mp; \quad a' = R^2x^2m'p' \dots\dots [7]$$

in which the quantities m and m' have the following values

$$m' = \frac{1}{x^2}\left[\frac{2y'}{y'(1+\nu)+1} - 1\right]; \quad W = \frac{1-m'}{1+m'};$$

$$m = \frac{2z}{(z-1)\nu + z + W} - 1 \dots\dots [8]$$

[3] "Theory of Elasticity," by S. Timoshenko, first edition, McGraw-Hill Book Company, Inc., New York, N. Y., 1934, p. 55.

The critical values of stress are as follows:
Along the hole

$$\sigma'_{ri} = p'(1 + x^2m'); \quad \sigma'_{\theta i} = p'(1 - x^2m') \dots\dots [9]$$

$$\sigma_1 = \sigma'_{ri}:y' \dots\dots [10]$$

Along the outer edge of the ring

$$\sigma'_{re} = p'(1 + m'); \quad \sigma'_{\theta e} = p'(1 - m') \dots\dots [11]$$

$$\sigma_{ri} = p(1 + m); \quad \sigma_{\theta i} = p(1 - m) \dots\dots [12]$$

The distribution of stress is represented by diagrams of the type shown in Fig. 2.

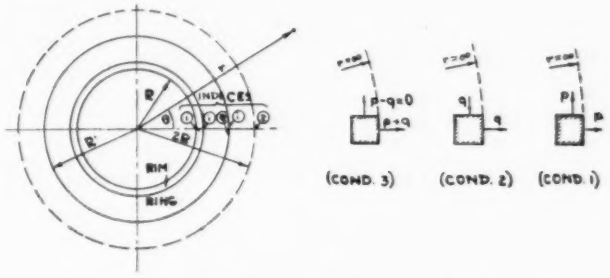

FIG. 2 DIAGRAM SHOWING DISTRIBUTION OF STRESS

When there is no ring, Equations [7] to [12] become

$$\left.\begin{aligned} a &= R^2mp; \quad m = \frac{2y}{y(1+\nu)+1} - 1 \\ \sigma_1 &= \sigma_{ri}:y; \quad \sigma_{ri} = p(1+m); \quad \sigma_{\theta i} = p(1-m) \end{aligned}\right\} \dots\dots [13]$$

When there is no rim, the value of m' is

$$m' = -1:x^2 \dots\dots [14]$$

For two principal stresses of the type

$$p(1 + K), \quad p(1 - K) \text{ or } p'(1 + K'), \quad p'(1 - K') \dots\dots [15]$$

the critical stress and the stress-concentration factors are equal to

$$\left.\begin{aligned} N &= p\sqrt{1+3K^2} \quad \text{or} \quad N = p'\sqrt{1+3K'^2} \\ j &= \sqrt{1+3K^2} \quad \text{or} \quad j = (p':p)\sqrt{1+3K'^2} \end{aligned}\right\} \dots\dots [16]$$

in which

$$K = \frac{R^2}{r^2}x^2m; \quad K' = \frac{R^2}{r^2}x^2m' \dots\dots [17]$$

The best strengthenings will fulfill the following conditions:
Stress in plate unchanged $m = 0$
Stresses in ring and rim not overstress in plate

$$p'\sqrt{1+3x^4m'^2} \le p; \qquad p'(1+x^2m'):y' \le p \dots\dots [18]$$

Thus there will be no overstressed region.
The condition $m = 0$ yields

$$z = \frac{1 - m'(1+\nu):(1-\nu)}{1+m'} \dots\dots [19]$$

For small values of y' the two conditions [18] are almost identical, and for values of y' greater than 0.5, the first condition is the most critical and is chosen as unique condition. For the two limit conditions, rim without ring and ring without rim, the amount of reinforcement is the same and is equal to $2:(1 - \nu) = 2.85714$ times the amount of material corresponding to the hole. A minimum of that amount appears for

$$y' = 0.6; \quad x = 2; \quad y = 1.2; \quad z = 1.25$$

and is equal to 2.30 times the material of the hole.

The general expression for the ratio of the additional material to the material corresponding to the hole is

$$2y'z + (z - 1)(x^2 - 1) = M$$

Table 1 gives the proportions for the optimum strengthenings.

TABLE 1 OPTIMUM STRENGTHENING IN HYDROSTATIC-STRESS CONDITION

y'	x	z	y	M
0	1.363	4.333	0	2.857

Solution 2 Pure Shearing Stress

The following solution corresponds to the symmetry of the problem[4]

$$\left.\begin{aligned} \sigma_r &= -\left(b + \frac{c}{r^4} + \frac{2d}{r^2}\right)\cos 2\theta \\ \sigma_\theta &= \left(b + \frac{c}{r^4} + 2fr^2\right)\cos 2\theta \\ \tau_{r\theta} &= \left(b - \frac{c}{r^4} - \frac{d}{r^2} + fr^2\right)\sin 2\theta \end{aligned}\right\} \quad \ldots [20]$$

There are 8 constants, 4 for each region of the plate, the constants in the ring are affected with the index prime ($'$). The differential equations for displacements[5] yield the following solution

$$\left.\begin{aligned} Eu &= \cos 2\theta\left[-b(1+\nu)r + \frac{c(1+\nu)}{3r^3} + \frac{2d}{r} - \frac{2\nu fr^3}{3}\right] \\ Ev &= \sin 2\theta\left[b(1+\nu)r + \frac{c(1+\nu)}{3r^3} - \frac{d(1-\nu)}{r} + \frac{(3+\nu)fr^3}{3}\right] \end{aligned}\right\} \quad \ldots [21]$$

The conditions at infinity yield $b = -q$; $f = 0$. The conditions at the outer edge of the ring express the equilibrium of normal and tangential stresses, and the equality of displacements u and v. They are

$$\left.\begin{aligned} -q + \frac{c}{R'^4} + \frac{2d}{R'^2} &= z\left(b' + \frac{c'}{R'^4} + \frac{2d'}{R'^2}\right) \\ -q - \frac{c}{R'^4} - \frac{d}{R'^2} &= z\left(b' - \frac{c'}{R'^4} - \frac{d'}{R'^2} + fR'^2\right) \\ \left(q + \frac{c}{3R'^4}\right)(1+\nu) + \frac{2d}{R'^2} &= \left(-b' + \frac{c'}{3R'^4}\right)(1+\nu) + \frac{2d'}{R'^2} - \frac{2\nu}{3}f'R'^2 \\ \left(-q + \frac{c}{3R'^4}\right)(1+\nu) - \frac{d(1-\nu)}{R'^2} &= \left(b' + \frac{c'}{3R'^4}\right)(1+\nu) - \frac{d'(1-\nu)}{R'^2} - \frac{3+\nu}{3}f'R'^2 \end{aligned}\right\} \quad \ldots [22]$$

[4] "Theory of Elasticity," by S. Timoshenko, first edition, McGraw-Hill Book Company, Inc., New York, N. Y., 1934, p. 75.

[5] Ibid., pp. 62–63.

Along the rim, there are three relations; one of strain, two of equilibrium

$$\sigma_1 = \sigma_{\theta_i} - \nu\sigma_{r_i}; \quad \sigma_1 y' = \sigma'_{r_i}; \quad y'\frac{d\sigma_1}{d\theta} + \tau_{r\theta_i}' = 0 \ldots\ldots [23]$$

Eliminating σ_1, the two remaining equations are

$$\left.\begin{aligned} \left(b' + \frac{c'}{R^4}\right)[1 + (\nu+1)y'] + \frac{2d'}{R^2}(1+\nu y') + 2f'R^2y' &= 0 \\ b' - \frac{c'}{R^4} - 2\left(b' + \frac{c'}{R^4}\right)(1+\nu)y' - \frac{d'}{R^2}(1+4\nu y') + f'R^2(1-4y') &= 0 \end{aligned}\right\} \quad \ldots [24]$$

The six Equations [22] and [24] yield the following solution: Calling

$$\delta = \frac{1+\nu y'}{1+(1+\nu)y'}; \quad \varphi = \frac{(z-1)(3-\nu)}{4+(z-1)(3-\nu)};$$

$$\psi = 1 + \frac{4}{(z-1)(1+\nu)} \ldots\ldots [25a]$$

$$\lambda = \frac{8:[4+(z-1)(3-\nu)]}{2x^6\psi(2\delta-3) + 2x^4(\varphi\psi+3) - 12x^2(2\delta-1) + 8(4\delta-3) - \frac{2\varphi}{x^2}(6\delta-5)} \ldots\ldots [25b]$$

The constants are

$$\left.\begin{aligned} b' &= q\lambda[4(3-4\delta) + 3x^2(2\delta-1) - \psi x^6(2\delta-3)] \\ \frac{c'}{R'^4} &= -3q\lambda\left[\frac{6\delta-5}{x^2} - \psi x^2(2\delta-1)\right] \\ \frac{d'}{R'^2} &= 2q\lambda\left[\frac{6\delta-5}{x^2} - \psi x^4\right] \\ f'R'^2 &= -6q\lambda x^2[1 - 2\delta + x^2] \\ \frac{c}{R'^4} &= -3q - z\left[3b' - \frac{c'}{R'^4} + 2f'R'^2\right] \\ \frac{d}{R'^2} &= 2q + z\left[2b' + \frac{d'}{R'^2} + f'R'^2\right] \\ b &= -q \end{aligned}\right\} \quad \ldots [26]$$

In the case where there is no ring, the equations simplify

$$b = -q; \quad c = -3R^4q\frac{1-y(1-\nu)}{1+y(3+\nu)};$$

$$d = 2R^2q\frac{1+y(1+\nu)}{1+y(3+\mu)} \ldots\ldots [26a]$$

In the case when there is no rim, $\delta = 1$, which simplifies the Equations [25], [26].

Calling $\bar{\sigma}_r$, $\bar{\sigma}_\theta$, $\bar{\tau}_{r\theta}$ the maximum values of σ_r, σ_θ, $\tau_{r\theta}$ for a given radius (corresponding to $\theta = 0$ or $\theta = \pi:4$), the stresses at any point of the circumference are

$$\sigma_r = \bar{\sigma}_r\cos 2\theta; \quad \sigma_\theta = \bar{\sigma}_\theta\cos 2\theta; \quad \tau_{r\theta} = \bar{\tau}_{r\theta}\sin 2\theta \ldots\ldots [27]$$

The critical-stress combination is N

$$\left.\begin{aligned} N^2 &= \sigma_r^2 + \sigma_\theta^2 - \sigma_r\sigma_\theta + 3\tau_{r\theta}^2 \\ &= (\bar{\sigma}_r^2 + \bar{\sigma}_\theta^2 - \bar{\sigma}_r\bar{\sigma}_\theta)\cos^2 2\theta + 3\bar{\tau}_{r\theta}^2\sin^2 2\theta \end{aligned}\right\} \quad [28]$$

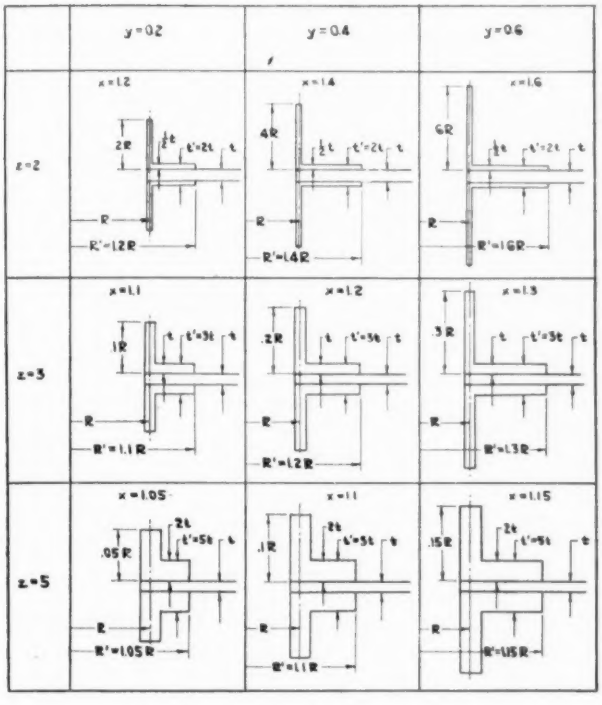

FIG. 3 RING AND RIM COMBINATIONS

The maximum occurs for $\theta = 0$ or $\theta = \pi{:}4$. Thus the two combinations of load must be calculated

$$\bar{\sigma}_r^2 + \bar{\sigma}_\theta^2 - \bar{\sigma}_r\bar{\sigma}_\theta;\ 3\bar{\tau}^2_{r\theta} \qquad [29]$$

and the larger quantity will determine the stress-concentration factor j. It is easily seen that the combination of normal stresses is always a decreasing function of the radius, thus its maximum occurs for the minimum radius. On the contrary, the shear may pass by a maximum, which must be determined.

SOLUTION 3 PURE TENSILE STRESS, I.E., AXIAL STRESS

The solutions corresponding to a stress of given direction at infinity can be determined by addition of solutions 1 and 2, in which $p = q$. Calling σ_r^* and σ_θ^* the solution under hydrostatic stress, the resultant stress is

$$\sigma_r = \bar{\sigma}_r \cos 2\theta + \sigma_r^*;\ \sigma_\theta = \bar{\sigma}_\theta \cos 2\theta + \sigma_\theta^*;\ \tau_{r\theta} = \bar{\tau}_{r\theta} \sin 2\theta \qquad [30]$$

The critical combination of stress is

$$\left.\begin{aligned} N^2 &= \cos^2 2\theta(\bar{\sigma}_r^2 + \bar{\sigma}_\theta^2 - \bar{\sigma}_r\bar{\sigma}_\theta - 3\bar{\tau}^2_{r\theta}) \\ &+ 2\cos 2\theta\left(\sigma_r^*\bar{\sigma}_r + \sigma_\theta^*\bar{\sigma}_\theta - \frac{\sigma^*\bar{\sigma}_\theta + \sigma^*\bar{\sigma}_r}{2}\right) \\ &+ (\sigma^{*2}_r + \sigma^{*2}_\theta - \sigma^*_r\sigma^*_\theta + 3\bar{\tau}^2_{r\theta}) \\ N^2 &= B\cos^2 2\theta + 2C\cos 2\theta + D \end{aligned}\right\} \qquad [31]$$

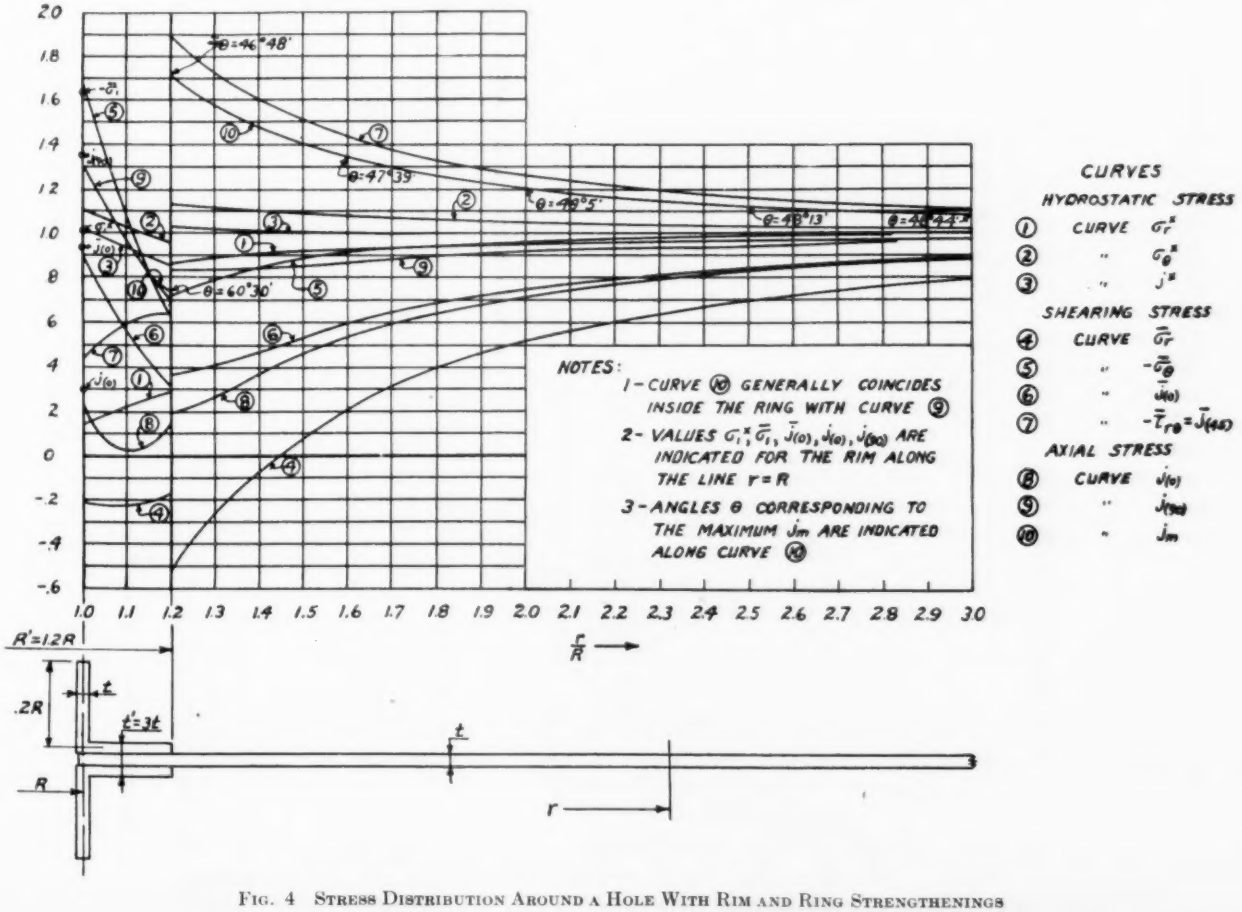

FIG. 4 STRESS DISTRIBUTION AROUND A HOLE WITH RIM AND RING STRENGTHENINGS

(Condition $\frac{R'}{R} = x = 1.2$; $\frac{t'}{t} = z = 3$; $y = \frac{A}{Rt} = 0.40$.)

The maximum of N as a function of α is determined as follows:

$$\left.\begin{array}{ll} 1 & B>0;\ N^2=B+2|C|+D,\ \theta=0 \text{ or } \pi \\ 2 & B<0 \text{ and } |C:B|\geq 1; \\ & \qquad N^2=B+2|C|+D,\ \theta=0 \text{ or } \pi \\ 3 & B<0 \text{ and } |C:B|<1; \\ & \qquad N^2=D-\frac{C^2}{B},\ \cos 2\theta=-\frac{C}{B} \end{array}\right\} \quad \ldots[32]$$

With the knowledge of solutions 1 and 2, the stress-concentration factor can be determined. The maximum always appears for the minimum radius.

Numerical Results

The following types of strengthening are investigated:

(*a*) Rim without ring, defined by the quantity $y = A:(tR)$ for 13 values of y (0; 0.1; 0.2; 0.3; 0.4; 0.6; 0.8; 1.0; 1.2; $1:[1-\nu]$; 2; 3; ∞).

(*b*) Ring without rim, defined by the quantities $x = R':R$ and $z = t':t$, for 3 values of z (2, 3, 5), and 7 values of x (1.1; 1.2; 1.3; 1.4; 1.6; 1.8; 2) (total of 16 combinations); and for an infinitely rigid hub of outer radius R.

(*c*) Combinations of ring and rim, corresponding to angles with equal legs assembled to the plate; this corresponds to the condition

$$y = (z - 1)(x - 1)$$

calculated for the following values (9 combinations) (see Fig. 3)

z	x		
2	1.2	1.4	1.6
3	1.1	1.2	1.3
5	1.05	1.10	1.15
y	0.2	0.4	0.6

Tables 2, 3, and 4 give the results for the two basic solutions (hydrostatic stress and pure shear), and for the combination tensile stress in one direction (axial stress).

Fig. 4 shows a stress-distribution diagram for the condition $z = 3$; $x = 1.2$. The curves in Fig. 5 give a summary of the results of the tables, showing the values of the stress-concentration factors (maximum value and value for $z = 2R$).

Conclusions

Examination of the curves in Fig. 5, and Tables 2, 3, and 4, leads to the following conclusions:

1 *Hole in Plate Under Hydrostatic Stress.* A rim strengthening (flanged hole) gives the smallest stress-concentration factor for a given weight of material. With an area equal or superior to Rt, a flange will give a stress-concentration factor practically equal to 1. For $A = 0.4Rt$, the stress concentration is equal to 1.3.

Thin ring strengthenings (doubler plate) are to be rejected, as the stress concentration in the doubler is high. Thick ring strengthenings can be successfully used; for instance with $t' = 5t$, $R' = 1.2R$, $h = 0.8$, it is found that $j = 1.08$.

Ring-rim combinations (angle around the hole) with thick flanges, give low stress concentration; for instance, with $t' = 5t$, $R' = 1.1R$, $h = 0.8$, it is found that $j = 1.04$.

TABLE 5 STRESS-CONCENTRATION FACTORS

Condition	Stress-concentration factor j: Without reinforcement	With reinforcement	Reinforcement factor h*
Hydrostatic stress	2	1.3	.4
Shearing stress	2.3	1.35	.2
Axial stress	3	1.5	.4

* $h = \frac{A}{Rt} + \left(\frac{t'}{t} - 1\right)\left(\frac{R'}{R} - 1\right)$

Generally speaking, any reinforcement with thick flanges, having an area such as $h = 0.8$, will give negligible stress concentrations under hydrostatic stress.

2 *Hole in Plate Under Shearing Stress.* In this condition the stress-concentration factor is always above 1.35. That minimum is reached with a flanged hole corresponding to $A = 0.2Rt$. Comparable values of j can be obtained with thick doublers, for instance with $t' = 5t$, $R' = 1.08$, $h = 0.32$, a value of $j = 1.4$ is obtained. Due to high stress concentration in thin doublers, the latter give high values of j. Thick angles give values of j comparable to that of a flanged hole, with a somewhat increased area; for instance with $t' = 5t$, $R' = 1.04$, $h = 0.32$ corresponds to $j = 1.35$.

3 *Hole in a Plate Under Axial Stress.* In this condition, the stress-concentration factor is always above 1.5. That minimum is obtained with a flanged hole such as $A = 0.4Rt$. Thick doublers ($t' = 5t$) may give $j = 1.75$, for $h = 0.6$. Thin doublers, as in the previous conditions, are to be rejected. Thin reinforcing angles are nearly as efficient as thick angles: for $t':t = 5$, and $h = 0.5$, the value of j is 1.55, while for $t':t = 2$, and $h = 0.6$ the value of j is 1.60.

4 *General Conclusions.* Thin doublers are generally inefficient in respect to their effect on the stress-concentration factor. Generally, the best strengthenings are obtained with flanged holes or reinforcing angles with thick legs. An average value of 0.2 to 0.4 for the ratio h = (area of reinforcement):Rt will give the best results, bringing the stress-concentration factors to the values given in Table 5.

Equivalent Circuits of the Elastic Field

By GABRIEL KRON,[1] SCHENECTADY, N. Y.

This paper presents equivalent circuits representing the partial differential equations of the theory of elasticity for bodies of arbitrary shapes. Transient, steady-state, or sinusoidally oscillating elastic-field phenomena may now be studied, within any desired degree of accuracy, either by a "network analyzer," or by numerical- and analytical-circuit methods. Such problems are the propagation of elastic waves, determination of the natural frequencies of vibration of elastic bodies, or of stresses and strains in steady-stressed states. The elastic body may be non-homogeneous, may have arbitrary shape and arbitrary boundary conditions, it may rotate at a uniform angular velocity and may, for representation, be divided into blocks of uneven length in different directions. The circuits are developed to handle both two- and three-dimensional phenomena. They are expressed in all types of orthogonal curvilinear reference frames in order to simplify the boundary relations and to allow the solution of three-dimensional problems with axial and other symmetry by the use of only a two-dimensional network. Detailed circuits are given for the important cases of axial symmetry, cylindrical co-ordinates (two-dimensional) and rectangular co-ordinates (two- and three-dimensional). Nonlinear stress-strain relations in the plastic range may be handled by a step-by-step variation of the circuit constants. Nonisotropic bodies and nonorthogonal reference frames, however, require an extension of the circuits given. The circuits for steady-state stress and small oscillation phenomena require only inductances and capacitors, while the circuits for transients require also standard (not ideal) transformers. A companion paper[2] deals in detail with numerical and experimental methods to solve the equivalent circuits.

Equations of Elasticity

An equivalent circuit must satisfy each and all of the forms in which the equations of the elastic field may be expressed. Some of these forms are as follows:

1 Integral equations
2 Differential equations
3 Finite-difference equations.

To establish the network pattern, this paper will use the integral approach to the physical problem, while to find the network constants, the differential equations will be employed. However, most engineers will undoubtedly prefer to replace first the differential equations by the finite-difference equations and to use for all analysis the resulting set of linear algebraic equations. While this last method offers the path of least resistance, it is thought to be the longest, most tedious, and least fruitful of attacks.

The equivalent circuit must satisfy three sets of elasticity equations, which are as follows:

1 "Hooke's law," representing six relations between the stresses and strains.

2 The "equations of equilibrium," representing three relations between the stresses.

3 The "conditions of compatibility," representing six relations between the strains.

Since the stresses will be represented by currents and the strains by voltages, the electrical equivalents of the foregoing three sets of equations are as follows:

1 Hooke's law corresponds to Ohm's law, $I = YE$, determining the value of the "admittances" Y of the circuit elements.

2 The equations of equilibrium correspond to Kirchhoff's second law, stating that the sum of the "currents" I, entering each junction, is zero.

3 The conditions of compatibility correspond to Kirchhoff's first law, stating that the sum of the "voltages" E, around each mesh, is zero.

Equations of Equilibrium

Assuming orthogonal curvilinear co-ordinates, and no body forces, let the co-ordinate surfaces cut the three-dimensional elastic body into infinitesimal blocks, such as shown in Fig. 1. On each of the six surfaces, stresses act in a general direction. These stresses will be expressed here as components of a vector F^{α}. If each of the stresses is projected along the three tangent lines drawn to the co-ordinate lines passing through the centers of the six walls, the resultant stresses are eighteen in number, nine of which define a set of three new vectors. Each arrow in Fig. 1 will be assumed to represent the surface integral of the particular stress $\sigma'^{\alpha\beta}$ on its own wall.

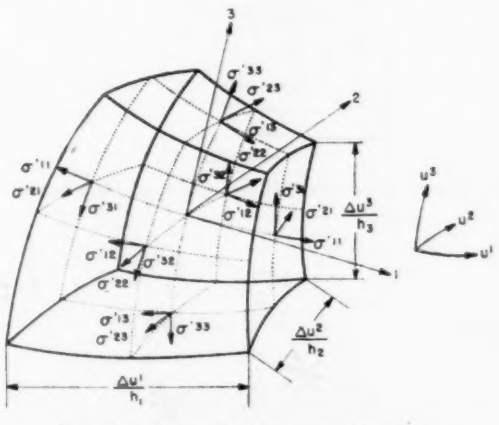

Fig. 1 Surface Integrals of Stresses

Next, at the center of the block, let a tangent line be drawn to the u^1 co-ordinate line, and let the eighteen different stresses be projected along this line. (Because of the orthogonality of the axes, the projections of σ'^{23} and σ'^{32} are zero.)

It is intended to represent these stresses by six currents entering the center of the block along the co-ordinate lines, as shown

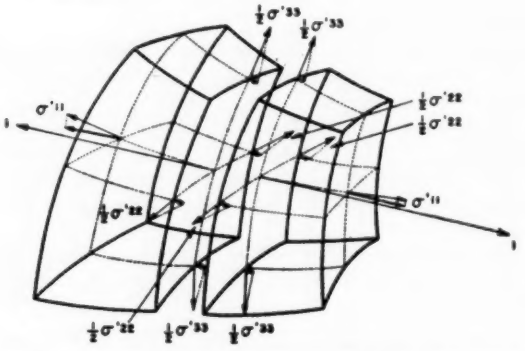

FIG. 3 (*a*) PROJECTION OF DIRECT STRESSES ALONG u^1

FIG. 3 (*b*) THEIR REPRESENTATION BY CURRENTS

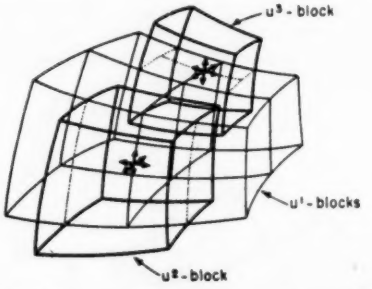

FIG. 4 THREE SUCCESSIVE SUBDIVISIONS OF THE ELASTIC BODY

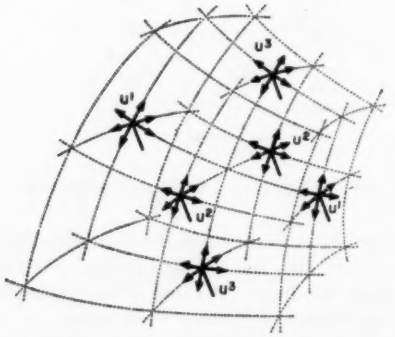

FIG. 5 SPATIAL ARRANGEMENTS OF CURRENTS

in Fig. 2. For this purpose the stresses are divided into three groups as follows:

1 The block is divided into two halves along axis u^1, Fig. 3 (*a*). On each half-block the u^1 projections of the direct stresses σ'^{11}, σ'^{22}, and σ'^{33} are added, and their sum is represented by currents in the u^1 direction, as shown in Fig. 3(*b*).

2 The block is now divided into two parts along axis u^2. On each half-block the u^1 projections of the shear stresses σ'^{12} and σ'^{21} are added, and their sum is represented by currents along the u^2 direction.

3 The same block is finally divided into two parts along the u^3 axis and the projections of the shear stresses σ'^{13} and σ'^{31} on each half-block are represented by currents along the u^3 direction.

The resultant of all the u^1 projections of the stresses on the block is represented by the six currents in Fig. 2, at the center of the block, adding up to zero. When a body force exists, then the six currents do not add up to zero but to a seventh current representing the body forces in the u^1 direction.

In order to represent next the projections of the stresses upon the tangent line drawn at the center of a block to the u^2 co-ordinate line, the whole elastic body is divided all over again into blocks, in the manner shown in Fig. 4. The u^2 blocks are shifted half a block on the u^1–u^2 surface from the u^1 blocks. In each of these u^2 blocks, the stresses are projected along the u^2 tangent line, then are divided again into three groups and represented by six currents as before. The previous reasoning is repeated with a cyclic variation of u^1–u^2–u^3.

Finally the whole elastic body is subdivided for the third time into u^3 blocks (Fig. 4), shifted half a block on the u^1-u^3 surface from the u^1 blocks. The stresses are projected upon the tangent line to the u^3 axis at the center of the block and again represented by six currents entering a junction.

As a result of three successive subdivisions, the stress representations are arranged in space as shown in Fig. 5, that is, the equivalent circuit does not represent the "total" stresses acting upon an infinitesimal block of the elastic body. The circuit represents only the projections of the stresses either along the u^1 or along the u^2 or u^3 axes. But these blocks with the different projections are so interspersed with each other that the resultant stresses on each block are known within a half-block accuracy.

HOOKE'S LAW

The absolute potential (above ground) of a u^1 (or u^2, u^3) junction represents the total displacement $s_{(1)}$ of that particular point of the elastic body in the u^1 (or u^2, u^3) direction if rectangular co-ordinates are used. (In curvilinear co-ordinates, the absolute potential represents s_1 which is equal to $s_{(1)}/h_1$.) The difference of potential between two u^1 junctions, say, along the u^2 axis, represents $(\partial s_1/\partial u^2)\,\Delta u^2$. Hence, each strain $e_{\alpha\beta}$ is represented as the sum of several voltage drops across coils connecting either two u^1 (or u^2, u^3) points, or each u^1 (or u^2, u^3) point to the ground.

(Theoretically, it is possible to have any of three different grounds, one for each type of junction, or one common ground. In numerical calculations one ground is sufficient, but in using the "network analyzer," the availability of three different grounds has been found to be of advantage.)

To find the coil impedances in transient problems, the equation of equilibrium has to be divided by $p = \partial/\partial t$; then:

1 All coils that represent stresses are inductances.

2 All ground coils that represent the mass of the elastic body are capacitors.

3 The forces f^α applied on the elastic body appear on the equivalent network as impressed currents of the form

$$\rho' f^\alpha / p = \rho' \int f^\alpha dt$$

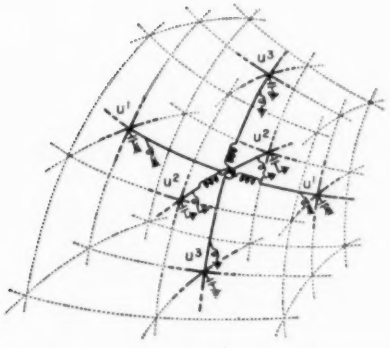

FIG. 6 TRANSIENT EQUIVALENT NETWORK

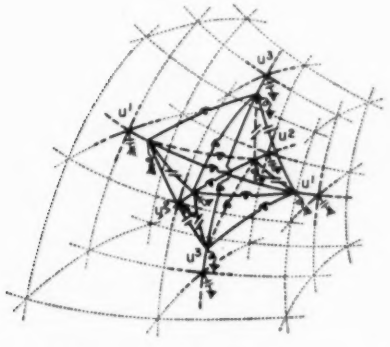

FIG. 7 NETWORK FOR SMALL OSCILLATIONS

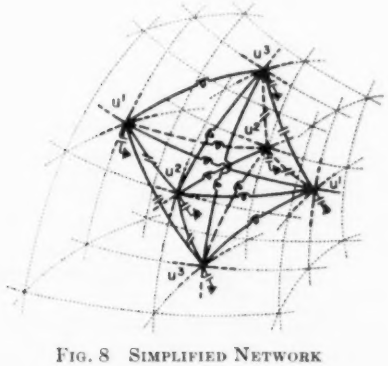

FIG. 8 SIMPLIFIED NETWORK

Hence in the "transient" equivalent circuit, the admittances are arranged as shown in Fig. 6, where mutual couplings exist between the three central inductances as dictated by Hooke's law. In curvilinear axes, mutual coupling exists also between a central and a ground coil. All central coils are assumed to lie in space at points half-way between the junctions, where the total displacements s_α are measured.

In steady-state ($p = 0$), and small-oscillation ($p = j\omega$) problems, the mutual couplings may be replaced, if so desired, by well-known methods with straight inductances and capacitors between the entrance points of the transformers, as shown in Fig. 7. In other words, in these problems the equation of equilibrium is satisfied also by a network containing only positive and negative resistances. Since no negative resistances are available in the d-c network analyzer, the two types of resistances are replaced by the inductances and capacitors of the a-c analyzer.

The difference between a network used for sinusoidally oscillating elastic-field problems and one used for steady-state problems is merely the presence or absence of the ground condensers representing the mass of the elastic body. As the frequency of mechanical oscillation varies, the magnitude of the ground condensers on the constant-frequency a-c analyzer also is varied (leaving the rest of the network admittances unchanged). At zero frequency (steady state), the condenser admittances become zero and they can be removed. It should be expressly noted that the transient network containing transformers may also be used for oscillating and steady-state problems as well, and without the necessity of changing the condenser admittances with the frequency of oscillations.

Since, in the last network, two diagonal and several ground coils are everywhere in parallel, for purposes of practical analysis the network may be simplified as shown in Fig. 8.

CONDITIONS OF COMPATIBILITY

When an electrical network has been developed in which the currents entering each of the junctions satisfy some one of the three equations of equilibrium, the network performance still may not correspond to the behavior of an elastic body; that is, numerous networks may be developed which satisfy merely the

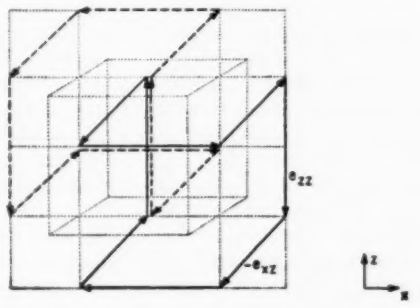

FIG. 9 EQUATION OF COMPATIBILITY, $K_{zzzz} = 0$

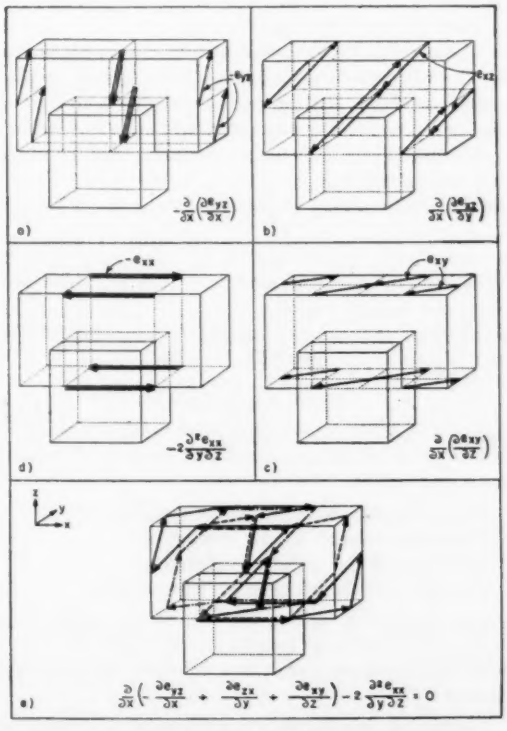

FIG. 10 EQUATION OF COMPATIBILITY $K_{zyzx} = 0$

equations of equilibrium. It is yet necessary that the voltage drops (strains) should satisfy six conditions of compatibility by being added up to zero in closed meshes that conform to a definite prescribed pattern.

In rectangular co-ordinates, each of the six equations represents two or four simultaneously closed meshes, as shown in Figs. 9 and 10. (There are two other figures similar to each of these, differing only by a cyclic interchange of indices.) It should be noted that each line passes through actual coils. In representing the strains say e_{zz} by two lines, they may be either both diagonal (as shown) or one horizontal and the other vertical, ending in the same points as before.

In curvilinear co-ordinates, each equation of compatibility is satisfied simultaneously by the meshes mentioned plus additional meshes formed by the additional ground coils. An example is given in Fig. 24.

Boundary Conditions

Consider the two-dimensional network in Fig. 11. At point u^1, the horizontal currents represent the horizontal direct stresses and the vertical currents the shear stresses upon a half-block of elastic material. At the u^3 point, the role of the currents is interchanged.

At a vertical boundary in the u^3 direction, the resultant direct stresses along u^1, namely, $\sigma'^{11}+\ldots$. are zero, also the shear stresses σ'^{13} (but not the vertical direct stresses $\sigma'^{33}+\ldots$.). Hence by cutting the network along the vertical wavy line indicated and removing the right-hand portion, a boundary is formed parallel to u^3. This representation assumes that only one half of a u^1 block (but the whole of a u^3 block) is retained at the vertical boundary, as shown in Fig. 12.

At a horizontal boundary in the u^1 direction, the resultant direct stresses along u^3, namely $\sigma'^{33}+\ldots$ are zero, also the shear stresses σ'^{31} (but not the horizontal direct stresses $\sigma'^{11}+\ldots$). Hence by cutting the network along the horizontal wavy line indicated, a boundary is formed parallel to u^1. Now only one half of the u^3 block (but the whole of the u^1 block) is retained at the horizontal boundary, Fig. 12.

It is also possible to cut the network by a diagonal line as shown in Fig. 11, or by other zig-zag lines. This method of establishing boundaries by simply cutting the network opens up the possibility of building a permanently connected network analyzer for elastic-field problems, in which the boundaries are varied merely by opening and closing switches.

The three-dimensional network is similarly cut by wavy surfaces.

If on a boundary surface applied forces (direct and shear) exist, they take the place of the boundary stresses which previously were equated to zero, Fig. 13.

Body forces (such as centrifugal forces) are applied as currents entering the respective junctions.

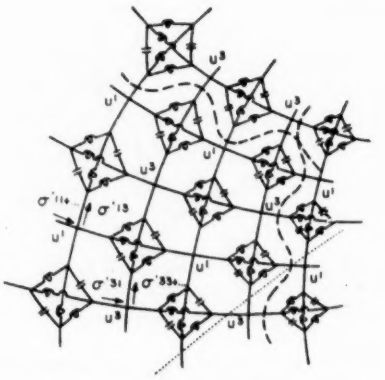

Fig. 11 Cutting Along Boundaries

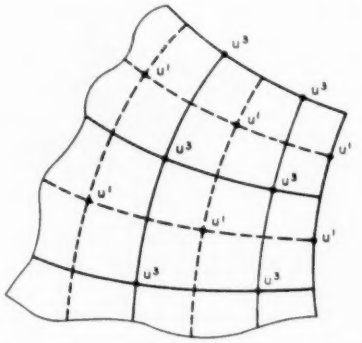

Fig. 12 Boundaries of the Elastic Body

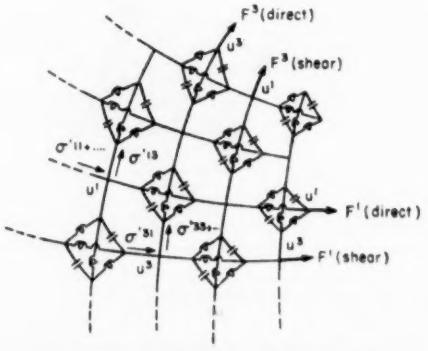

Fig. 13 Applied Boundary Forces

Equivalent Circuits

Examples of networks along four different reference frames are given in Figs. 14 to 23, inclusive, and Table 1. These reference frames are as follows:

1 Three-dimensional, rectangular co-ordinates.
2 Three-dimensional, axially symmetric.
3 Two-dimensional, polar co-ordinates.
4 Two-dimensional, rectangular co-ordinates.

In each frame, the blocks, into which the elastic body is divided, may have different lengths in different directions.

Along each reference frame, two different networks may exist, as follows:

1 Containing transformers (all transient networks must employ them).

2 Containing only inductances and capacitors.

Each of these networks may assume two different forms:

1 They correspond to the assumed physical picture. They give the stresses, the strains (as the sum of several voltages), and the total displacements.

2 The networks are simplified to contain the minimum number of coils. The stresses now have to be calculated from the measured strains.

For each reference frame either two or three of the possible four networks are shown. The two-dimensional networks are the same for both the plane-stress and the plane-strain cases, but the coil admittances assume different values for the two cases. In Table 1, the admittances are given for the plane-strain cases.

LIMITATION OF CONVENTIONAL EQUATIONS

In formulating and manipulating the equations of physical phenomena, the engineer or physicist is likely to perform certain algebraic operations that mathematically are allowable, but from purely physical considerations are not so. Such operations are for instance:

1 Canceling plus and minus terms

$$(A + C) + (B - C) = A + B$$

If $A + C$ and $B - C$ are measurable physical entities, then usually neither A nor B and often not even $A + B$ are measurable entities.

2 Canceling terms in numerator and denominator

$$(AC)(C^{-1}B) = AB$$

Here again if (AC) and $(C^{-1}B)$ are actually existing physical entities, then often A, B, or AB are not.

3 Dividing both sides of an equation by the same term, as replacing

$$DA + DB = DC$$

by

$$A + B = C$$

where, again, none of the resulting expressions may be a measurable physical entity.

Examples of such mathematical manipulations are the partial differential equations of the electromagnetic field and of the elastic field, when expressed along curvilinear co-ordinates. Luckily, the dynamical equations of Lagrange have not been subjected to such changes, but the conventional equations of small oscillations, derived from the Lagrangian equations, are perfect examples of physically deficient mathematical descriptions of physical phenomena. Also in a great number of the so-called "practical" approaches to the mathematical solution of mechanical and electrical engineering problems, the physical picture has been subordinated to mathematical simplicity.

The engineer becomes conscious of this tampering with the physical picture especially when he attempts to set up a physical model, say an electrical equivalent circuit, to simulate a physical phenomenon. He finds that there are some extra terms in the equations that somehow do not fit into any kind of a model he can think of, or that an otherwise satisfactory model calls for extra expressions that are absent from the equations. Even a mental model may run into similar difficulties.

Of course mathematicians and physicists have long since become aware of these diverging interests of the two sciences (whenever they have attempted to set up geometrical models for physical problems) and, accordingly, mathematicians have developed and physicists have adapted various techniques to keep the mathematical symbol and the corresponding physical entity in one-to-one correspondence throughout the analysis. A branch of the mathematical theory of "invariants," under the name of "vector analysis" for problems in three-dimensional rectangular reference frames, and of "tensor analysis" for problems in curvilinear and generalized co-ordinates, is the outgrowth of such attempts.

By the use of the methods of tensor analysis, the engineer is enabled to keep his physical picture unmutilated while formulating and simplifying his equations. Hence by setting up his equations in a tensorial form instead of any haphazard manner, the engineer gets more clues on how to establish a model (physical, geometrical, or mental) for his problem. Other by-products of

the use of tensors, such as a "shorthand" representation of long and numerous equations, or the systematic "bookkeeping" of otherwise unmanageable terms, are purely incidental to the primary advantage of keeping the physical reasoning straightforward and the physical picture of the phenomenon undistorted.

Of course, most of the time the engineer does employ the method of tensors without being aware of doing so. However, in more complex problems, a conscious use of routine tensorial procedures will save him much time and effort to avoid the numerous pitfalls awaiting him.

A Principle to Establish Models for Physical Systems

In setting up stationary electrical networks to simulate the performance of rotating electrical machinery, dynamical systems and various field phenomena, the following principle serves as an indispensable guide:

"A set of equations, representing the performance of any physical system (be it mechanical, thermal, or any other system) may be represented by a physical model (equivalent circuit) only if the set of equations is a tensor equation. The invariance of the set of equations is a necessary, but not a sufficient condition."

In other words, before the engineer attempts to set up a physical model whose performance follows term by term a given set of algebraic, differential, or integral equations, his first step is to change his equations into a form in which each symbol is a measurable quantity, a "tensor." By making this first step, he maneuvers himself into a favorable position to enjoy, unencumbered by irrelevant expressions, all the headaches that still lie ahead of him.

The next step is to decide what forms of the numerous possibilities the tensorial equation should assume. This depends upon the type of model to be attempted. In the present paper the model is a stationary electrical network, the tensorial equation of which is known to be

$$e_\alpha = z_{\alpha\beta} i^\beta \qquad \text{or} \qquad i^\alpha = y^{\alpha\beta} e_\beta$$

It is intended to represent displacement by voltages, hence the displacement vector s_α must be a "covariant" tensor, just as the voltage vector e_α is. Also, it is intended to represent forces by currents, hence the force vector f^α must be a "contravariant" tensor, just as the current vector i^α is. (There is a great difference between the covariant and contravariant components of the same vector. Assuming, say, cylindrical co-ordinates, s^θ represents angular displacement along s_θ, but s_θ stands for a linear displacement times the radius. Both the covariant and contravariant components of a vector, s_θ and s^θ, also differ from what conventional vector analysis calls the components $s_{(\theta)}$ of a vector.) This selection of the force and displacement vectors immediately compells the engineer to assume the stress tensor as a "twice" contravariant tensor $\sigma^{\alpha\beta}$ just as $y^{\alpha\beta}$ is. (There are seven varieties of stresses to select the right one from, namely $\sigma_{\alpha\beta}$, $\sigma_\alpha{}^\beta$, $\sigma^\alpha{}_\beta$, $\sigma^{\alpha\beta}$, $\sigma_{(\alpha)\beta}$, $\sigma_{(\alpha)}{}^\beta$, and $\sigma_{(\alpha)(\beta)}$, each one being different.)

Since a field problem is represented by considering forces acting not at a "point" in space but upon the surfaces of a finite block cut out of space, the final step is known to be a change from the tensorial into a tensor-density form of equation, in which some of the contravariant tensors, say $\sigma^{\alpha\beta}$, must also become tensor densities $\sigma'^{\alpha\beta}$ (denoted by a prime).

Once the desired tensorial form has been fixed, then ingenuity must be resorted to in finding a correct network pattern that allows the employment of nine current differentials (stress differentials) to add up to zero at three different space points (three differentials at each point), corresponding to the three equations of equilibrium (and subject to the six conditions of compatibility). With the correct network pattern established, the determination of the network constants for the various types of reference frames is mere routine work.

Tensorial Equation of Equilibrium

The conventional form of the equations of equilibrium for orthogonal curvilinear axes is given by Love as

$$h_1h_2h_3\left(\frac{\partial}{\partial u^1}\frac{\sigma_{(1)(1)}}{h_2h_3}+\frac{\partial}{\partial u^2}\frac{\sigma_{(1)(2)}}{h_3h_1}+\frac{\partial}{\partial u^3}\frac{\sigma_{(1)(3)}}{h_1h_2}\right)$$
$$+h_1h_2\frac{\partial}{\partial u^2}\left(\frac{1}{h_1}\right)\sigma_{(1)(2)}+h_1h_3\frac{\partial}{\partial u^3}\left(\frac{1}{h_1}\right)\sigma_{(1)(3)}$$
$$-h_1h_2\frac{\partial}{\partial u^1}\left(\frac{1}{h_2}\right)\sigma_{(2)(2)}-h_1h_3\frac{\partial}{\partial u^1}\left(\frac{1}{h_3}\right)\sigma_{(3)(3)}+\rho f_{(1)}$$
$$=\rho\frac{\partial^2 s_{(1)}}{\partial t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The other two equations follow in a cyclical order.

These conventional equations are not in a form in which they may correspond to a physical model. They are changed to a suitable tensor-density form by the following steps:

1 The nontensor stresses $\sigma_{(\alpha)(\beta)}$ (stresses at a point) are replaced by the tensor densities $\sigma'^{\alpha\beta}$ (surface integral of contravariant point stresses) according to Equations [15].

2 The nontensor displacements $s_{(\alpha)}$ are replaced by the covariant displacements s_α by Equation [11].

3 The nontensor forces $f_{(\alpha)}$ are replaced by the contravariant forces f^α by Equation [13].

4 The nontensor density ρ is replaced by the tensor density ρ' by Equation [16].

5 The first equation is multiplied by h_1, the second by h_2, the third by h_3.

6 All three equations are divided by $h_1h_2h_3$.

Performing the operations, the resultant tensor-density equations are as follows

$$\frac{\partial\sigma'^{11}}{\partial u^1}+\frac{\partial\sigma'^{12}}{\partial u^2}+\frac{\partial\sigma'^{13}}{\partial u^3}-\frac{1}{h_1}\frac{\partial h_1}{\partial u^1}\sigma'^{11}-\frac{2}{h_1}\frac{\partial h_1}{\partial u^2}\sigma'^{12}$$
$$-\frac{2}{h_1}\frac{\partial h_1}{\partial u^3}\sigma'^{13}+\frac{(h_1)^2}{(h_2)^3}\frac{\partial h_2}{\partial u^1}\sigma'^{22}+\frac{(h_1)^2}{(h_3)^2}\frac{\partial h_3}{\partial u^1}\sigma'^{33}$$
$$+\rho' f^1=(h_1)^2\rho'\frac{\partial^2 s_1}{\partial t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

The other two equations follow in a cyclical order.

These last equations correspond to the tensorial form

$$\frac{\delta\sigma'^{\alpha\beta}}{\delta u^\beta}+\rho' f^\alpha=\rho' g^{\alpha\beta}\frac{\partial^2 s_\beta}{\partial t^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

or

$$\frac{\partial\sigma'^{\alpha\beta}}{\partial u^\beta}+\left\{\begin{matrix}\alpha\\ \beta\gamma\end{matrix}\right\}\sigma'^{\beta\gamma}+\rho' f^\alpha=\rho' g^{\alpha\beta}\frac{\partial^2 s_\beta}{\partial t^2} \quad \ldots\ldots\ldots [4]$$

When the free index $\alpha = 1$, the first equation is

$$\frac{\partial\sigma'^{11}}{\partial u^1}+\frac{\partial\sigma'^{12}}{\partial u^2}+\frac{\partial\sigma'^{13}}{\partial u^3}+\left\{\begin{matrix}1\\ 11\end{matrix}\right\}\sigma'^{11}+2\left\{\begin{matrix}1\\ 12\end{matrix}\right\}\sigma'^{12}$$
$$+2\left\{\begin{matrix}1\\ 13\end{matrix}\right\}\sigma'^{13}+\left\{\begin{matrix}1\\ 22\end{matrix}\right\}\sigma'^{22}+\left\{\begin{matrix}1\\ 33\end{matrix}\right\}\sigma'^{33}+\rho' f^1=\rho' g^{11}\frac{\partial^2 s_1}{\partial t^2} \quad [5]$$

where the Christoffel symbols are defined as

$$\left.\begin{aligned} \left\{\begin{matrix}1\\11\end{matrix}\right\} &= -\frac{1}{h_1}\frac{\partial h_1}{\partial u^{1'}} \qquad \left\{\begin{matrix}1\\12\end{matrix}\right\} = -\frac{1}{h_1}\frac{\partial h_1}{\partial u^{2'}} \qquad \left\{\begin{matrix}1\\13\end{matrix}\right\} = \\ &\qquad\qquad -\frac{1}{h_1}\frac{\partial h_1}{\partial u^{3}} \\ \left\{\begin{matrix}1\\22\end{matrix}\right\} &= \frac{(h_1)^2}{(h_2)^3}\frac{\partial h_2}{\partial u^{1'}} \qquad \left\{\begin{matrix}1\\23\end{matrix}\right\} = 0, \qquad \left\{\begin{matrix}1\\33\end{matrix}\right\} = \frac{(h_1)^2}{(h_3)^3}\frac{\partial h_3}{\partial u^{1}} \end{aligned}\right\} \quad \ldots [6]$$

The other two equations follow in cyclical order.

Relations Between Tensorial and Conventional Quantities

The tensorial quantities (open indices) are defined in terms of conventional quantities (closed indices) in the following manner:

The variables u^α and the metrical coefficients h are given in Table 2 for the three most common orthogonal reference frames. Their values in other reference frames (such as elliptical, spheroidal, etc., frames) are found in texts on applied mathematics.

TABLE 2 VALUES OF $u\alpha$ AND h

	u^1	u^2	u^3	$\frac{1}{h_1}$	$\frac{1}{h_2}$	$\frac{1}{h_3}$
Cartesian.....	x	y	z	1	1	1
Cylindrical.....	r	θ	z	1	r	1
Spherical.....	r	θ	ψ	1	r	$r\sin\theta$

The set of vectors $\epsilon_\alpha{}^{(\beta)}$ changing projections along a tangent line (nontensorial quantities) to components along the reference frames (tensors) are defined by

$\epsilon_\alpha{}^{(\beta)} =$

α \ (β)	(1)	(2)	(3)
1	$1/h_1$		
2		$1/h_2$	
3			$1/h_3$

..... [7]

The metric tensor is

$g_{\alpha\beta} =$

α \	1	2	3
1	$1/(h_1)^2$		
2		$1/(h_2)^2$	
3			$1/(h_3)^2$

..... [8]

$$g = 1/(h_1h_2h_3)^2 \ldots [9]$$

The displacement vector is

$$s_\alpha = \epsilon_\alpha{}^{(\beta)}s_{(\beta)} \ldots [10]$$

$s_\alpha =$

α	1	2	3
	$s_{(1)}/h_1$	$s_{(2)}/h_2$	$s_{(3)}/h_3$

..... [11]

The force vector is

$$f^\alpha = \epsilon^\alpha{}_{(\beta)}f^{(\beta)} \ldots [12]$$

$f^\alpha =$

α	1	2	3
	$f_{(1)}h_1$	$f_{(2)}h_2$	$f_{(3)}h_3$

..... [13]

The stress tensor density is

$$\sigma'^{\alpha\beta} = \sqrt{g}\,\sigma^{\alpha\beta} = \sqrt{g}\,\epsilon^\alpha{}_{(\gamma)}\epsilon^\beta{}_{(\delta)}\sigma_{(\gamma)(\delta)} \ldots [14]$$

$\sigma'^{\alpha\beta} =$

α \ β	1	2	3
1	$\frac{h_1}{h_2h_3}\sigma_{(1)(1)}$	$\frac{1}{h_3}\sigma_{(1)(2)}$	$\frac{1}{h_2}\sigma_{(1)(3)}$
2	$\frac{1}{h_3}\sigma_{(2)(1)}$	$\frac{h_2}{h_1h_3}\sigma_{(2)(2)}$	$\frac{1}{h_1}\sigma_{(2)(3)}$
3	$\frac{1}{h_2}\sigma_{(3)(1)}$	$\frac{1}{h_1}\sigma_{(3)(2)}$	$\frac{h_3}{h_1h_2}\sigma_{(3)(3)}$

..... [15]

The mass tensor density is

$$\rho' = \sqrt{g}\,\rho = \frac{1}{h_1h_2h_3}\rho \ldots [16]$$

Example:

The tensorial equations of a two-dimensional example along cylindrical co-ordinates will be given in detail. The equivalent circuit may represent part of a rotating turbine rotor (plane-strain case of a rotating thick cylinder).

The equations of equilibrium are

$$\left.\begin{aligned} \left[\frac{\partial\sigma'^{rr}}{\partial r} + \frac{\partial\sigma'^{r\theta}}{\partial\sigma} - r\sigma'^{\theta\theta} + \rho r^2\omega^2\right]\Delta r\,\Delta\theta\,\Delta z &= 0 \\ \left[\frac{\partial\theta'^{r\theta}}{\partial\theta} + \frac{\partial\sigma'^{\theta r}}{\partial r} + \frac{2\sigma'^{r\theta}}{r}\right]\Delta r\,\Delta\theta\,\Delta z &= 0 \end{aligned}\right\} \ldots [17]$$

where ω = angular velocity of rotor.

The stresses are defined in terms of the displacements as

$$\left.\begin{aligned} \sigma'^{rr} &= (2\mu+\lambda)r\frac{\partial s_r}{\partial r} + \frac{\lambda}{r}\frac{\partial s_\theta}{\partial\theta} + \lambda s_r \\ \sigma'^{r\theta} &= \frac{\mu}{r}\frac{\partial s_r}{\partial\theta} + \frac{\mu}{r}\frac{\partial s_\theta}{\partial r} - \frac{2\mu}{r^2}s_\theta \\ \sigma'^{\theta\theta} &= \frac{\lambda}{r}\frac{\partial s_r}{\partial r} + \frac{2\mu+\lambda}{r^3}\frac{\partial s_\theta}{\partial\theta} + \frac{2\mu+\lambda}{r^2}s_r \end{aligned}\right\} \ldots [18]$$

The displacements are

$$s_r = s_{(r)} \text{ and } s_\theta = r\,s_{(\theta)} \ldots [19]$$

where $s_{(\theta)}$ is the linear displacement along θ.

The strains are

$$\left.\begin{aligned} \epsilon_{rr} &= \frac{\partial \delta_r}{\partial r} \\ \epsilon_{r\theta} &= \frac{\partial \delta_r}{\partial \theta} + \frac{\partial \delta_\theta}{\partial r} - \frac{2\delta_\theta}{r} \\ \epsilon_{\theta\theta} &= \frac{\partial \delta_\theta}{\partial \theta} + r\delta_r \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [20]$$

The condition of compatibility is

$$K_{r\theta r\theta} = \frac{\partial^2 \epsilon_{rr}}{\partial \theta^2} + \frac{\partial^2 \epsilon_{\theta\theta}}{\partial r^2} - \frac{\partial^2 \epsilon_{r\theta}}{\partial r \partial \theta} - r\frac{\partial \epsilon_{rr}}{\partial r} - \frac{2}{r}\frac{\partial \epsilon_{\theta\theta}}{\partial r} + \frac{2}{r^2}\epsilon_{\theta\theta} = 0 [21]$$

Fig. 24 shows that part of the first three terms not involving the ground becomes identically zero in the same two meshes as in the rectangular case (Fig. 9). The remaining part of the first three terms and the last three terms cover the meshes formed by the ground coils.

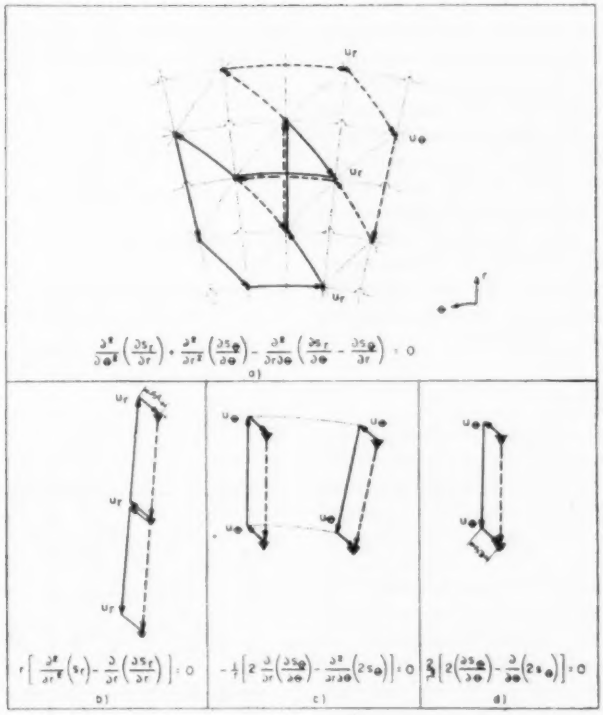

FIG. 24 EQUATION OF COMPATIBILITY $K_{r\theta r\theta} = 0$ IN POLAR CO-ORDINATES

Numerical and Network-Analyzer Solution of the Equivalent Circuits for the Elastic Field

By G. K. CARTER,[1] SCHENECTADY, N. Y.

This is a companion paper to one by Gabriel Kron.[2] Particular cases of circuits in two independent variables are used. Test of these circuits by numerical substitution of known simple solutions indicates that the mesh size in the circuits need not be excessively small in order to give a useful accuracy of results. By trial of the a-c network analyzer,[3] in similar cases, limitations on the use of the analyzer in its present form for the solution of elastic-field problems are studied. Finally, it is found by trial that solution of the circuits by hand, using a "relaxation" method,[4] is practicable; and in this way the desirable objective of a solution of the elastic-field problem directly from given boundary conditions is achieved.

Numerical Checks

As a preliminary to use of the equivalent circuits, it was thought desirable to become acquainted with the magnitudes of the quantities involved by substitution of certain known solutions. In the first place, the substitution was applied for the case of static plane strain in rectangular co-ordinates. The mesh system for this case, shown in Fig. 1, is that given in Fig. 22 of the companion paper,[2] with Δz set equal to unity; this circuit may be used also for the case of plane stress, of course, by a change of elastic constants, under the assumptions generally accepted for that purpose. The elastic constants assumed here and throughout the remainder of this paper are Young's modulus $E = 30{,}000{,}000$ psi and Poisson's ratio $\sigma = 0.28$; these give $\mu = 11{,}719{,}000$ psi and $\lambda = 14{,}914{,}000$ psi.

The simplest case of direct stress is that of simple tension, say, $\sigma_{yy} = K = 1000$ psi. Taking $u = 0$ at $x = 0$ and $v = 0$ at $y = 0$, the displacements in this case are easily found to be

$$\left.\begin{aligned} u &= -\frac{K\sigma}{E}(1+\sigma)x \\ v &= \frac{K}{E}(1-\sigma^2)y \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [1]$$

For the network, Fig. 2, in which $\Delta x = \Delta y = 1$ in., Equations [1] give the displacements, i.e., voltages, at any desired points. For instance at

$$\begin{aligned} y &= 5, & v &= 15.35 \times 10^{-5} \\ y &= 4, & v &= 12.28 \times 10^{-5} \\ x &= \pm 2, & u &= \mp 2.388 \times 10^{-5} \\ x &= \pm 1, & u &= \mp 1.194 \times 10^{-5} \end{aligned}$$

Thus current i_1 is

$$i_1 = (15.35 - 2.388)\,149.14 + (15.35 - 1.194)(-149.14) + (15.35 - 12.28)\,383.52 = -178.2 + 1178 = 1000 \text{ lb}$$

which is the load on the section Δx (= 1 in.) wide centered under i_1. Current i_3 is

Presented at the National Meeting of the Applied Mechanics Division, Chicago, Ill., June 16-17, 1944, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

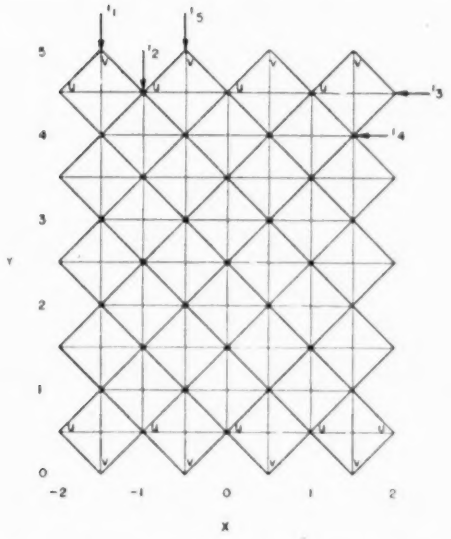

FIG. 2 NETWORK USED IN CALCULATIONS AND ANALYZER TESTS

$$i_3 = (-2.388 - 15.35)(-149.14) + (-2.388 - 12.28)\,149.14 + (-2.388 + 1.194)\,383.52 = 458 - 458 = 0$$

Currents of the type i_2 and i_4 are also seen to be zero. Since, in this simple case, the forces and displacements are linear in x and y, the results obtained in this way are independent of the size of the subdivisions, except that i_1 is proportional to Δx; this field is represented exactly by the network.

The equally simple case of uniform shear is that in which, say, $\sigma_{xy} = K = 1000$ psi. Then, if $u = v = 0$ along $y = 0$, the displacements are

$$\left.\begin{aligned} u &= \frac{2K(1+\sigma)}{E}\,y \\ v &= 0 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Applied to Fig. 2, these give at

$$y = 4.5, \qquad u = \frac{3.838}{10{,}000}$$

$$y = 3.5, \qquad u = \frac{2.983}{10{,}000}$$

Thus

$$i_1 = i_3 = 0$$

$$i_2 = (3.838 - 2.983)\,1171.9 = 1000 \text{ lb}$$

the shear force on the section Δx wide centered under i_2. The similar load represented by

$$i_4 = (0 - 3.838)\,1491.4 + (0 - 2.983)(-1491.4) + (0 - 3.838)(-2663.3) + (0 - 2.983)\,2663.3 = 1000 \text{ lb}$$

is on the section Δy high centered on i_4. Again, the field is represented exactly by the circuit, regardless of the mesh size.

Another case in which the solution is known is that of simple bending, assuming say, $\sigma_{xx} = 0$, $\sigma_{yy} = -Kx = -1000x$ psi. Taking $v = 0$ at $y = 0$ and $u = 0$ at $x = 0$, $y = 1/2$, the displacements are

$$\left.\begin{aligned} u &= \frac{K(1+\sigma)}{2E}\left[\sigma x^2 + (1-\sigma)y^2 - \frac{(1-\sigma)}{4}\right] \\ v &= \frac{K(1+\sigma)}{2E}\,[-2(1-\sigma)xy] \end{aligned}\right\} \quad \ldots\ldots [3]$$

Without listing all the calculations, which are similar to those already given, results of slide-rule computation are:

$i_1 = 1501$ lb, compared with 1500 lb actual load
$i_3 = 500$ lb, compared with 500 lb actual load
The other types of load currents are zero.

An additional type of check is that the sum of the currents flowing out of any junction point must be zero; for example, these currents at the points (—0.5, 4) and (—1, 3.5) are as follows:

(—0.5, 4)		(—1, 3.5)	
+	—	+	—
587	590	1080	1439
1440	1440	230	686
6690	3425	3427	160
3270	6530	1385	3835
11987	11985	6122	6120

Thus the applied loads and the sum of currents at the junctions check to slide-rule accuracy, despite the coarseness of the mesh used. A point of practical importance is to be noted in the currents tabulated here, i.e., that the individual currents in some of the circuit elements at a point may be considerably larger than the actual loads at that point.

The second circuit considered is that for plane strain in polar co-ordinates, given as Fig. 19 of the companion paper.[2] The particular case considered is that of a steel disk, 4 in. ID, 10 in. OD, rotating at 3600 rpm; on its inside surface is a uniform pressure of 10,000 psi; on its outside surface a radial stress which is of the amount 10,000 cos 2θ psi. The numerical checks in this case consisted only of calculating the current balance at a particular point for a u-type junction and for a v-type junction. The point chosen was $\left(7 \text{ in.}, \frac{\pi}{9}\right)$; the mesh size was $\Delta r = 0.5$ in., $\Delta\theta = \frac{\pi}{100}$. The current balance for the u-type point, using voltages from the exact solution, is as follows:

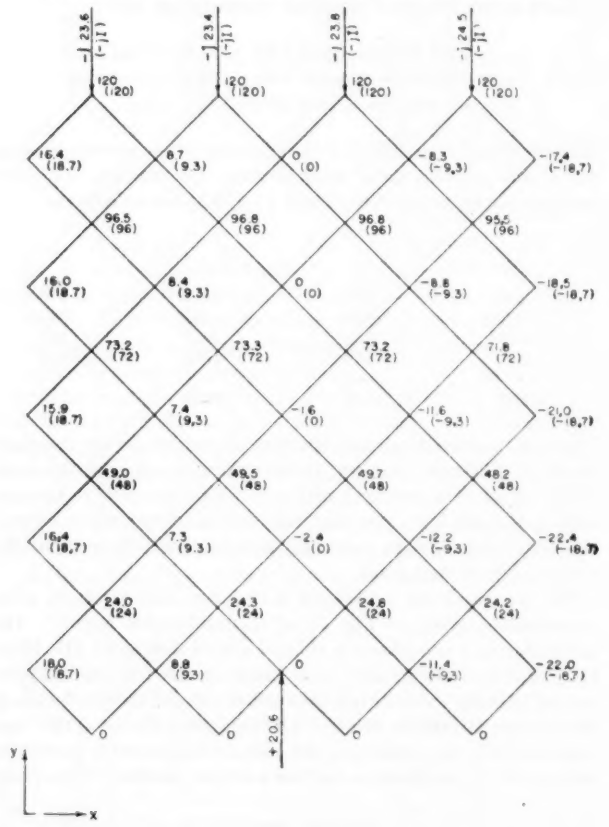
	(+)	(—)
Uniform pressure	1.039×10^3	1.162×10^3
	0.1216	
	1.161×10^3	1.162×10^3
Rotation	0.1298×10^3	0.1347×10^3
	0.0850	0.0803
	0.2148×10^3	0.2150×10^3
Varying pressure	6.04×10^3	7.51×10^3
	0.530	0.531
	0.810	
	0.661	
	8.041×10^3	8.041×10^3
Total	9.417×10^3	9.418×10^3

Similarly, for the v-type point, the current balance is as follows:

	(+)	(—)
Uniform pressure	0	0
Rotation	0	0
Varying pressure	0.0059×10^3	0.0523×10^3
	1.644	1.431
		0.1691
	1.650×10^3	1.652×10^3

These calculations therefore indicate (*a*) that the polar co-ordinate network is correct, and (*b*) that in polar co-ordinates also a moderate size mesh is adequate.

TABLE 1 DISPLACEMENTS IN A BAR IN TENSION



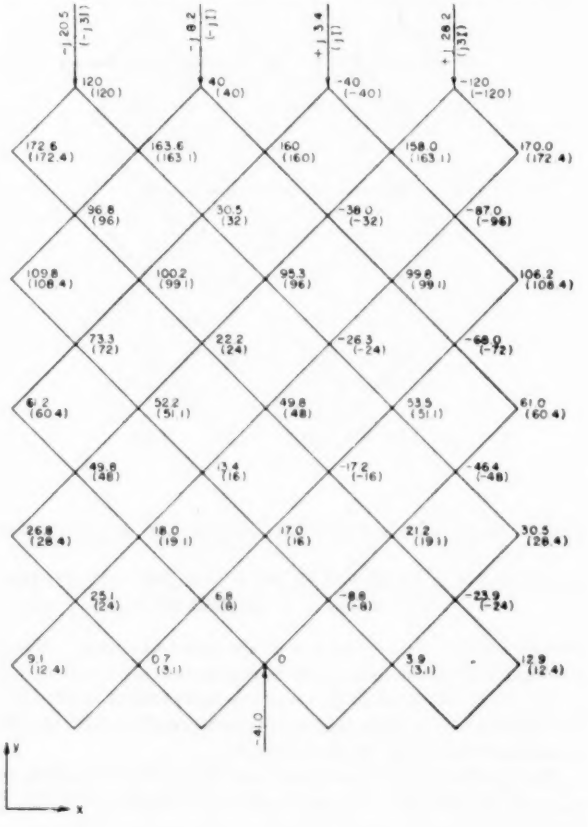


TABLE 2 DISPLACEMENTS IN A BAR IN BENDING

Network-Analyzer Tests

As part of the study of the equivalent circuits, certain cases were tried out on the a-c network analyzer.[3] For this purpose, positive admittances were generally represented by inductors and negative by capacitors. Real components of voltage were generally used for displacements, imaginary components of current for loads. Ideally the voltages and currents should be in time quadrature; divergence from this relationship, due to resistance in the analyzer elements, is exaggerated by the large component currents referred to in the preceding section and is a limitation in addition to those of precision in settings and measurements.

The circuit in rectangular co-ordinates, shown in Fig. 2, was tried first. For simple tension, as a matter of convenience, voltage was fixed at the top v points, the bottom v points being grounded (zero displacement). It should be observed that this simple elastic field corresponds to a condition in the electrical network which is quite startling to an electrical engineer at first glance, that is, the network is expected to produce two sets of equipotential lines at right angles to each other.

Various expedients were tried for the purpose of neutralizing the effects of the unavoidable resistance in the network. Negative-resistance units being impractical for any appreciable number of elements simultaneously, the most successful results were obtained simply by supplying loss components of current (real components) at other points than the load points. This method is illustrated by the results shown in Table 1, for which only one additional generator, supplying loss current at the middle bottom u point was used. The measured displacements are remarkably close to the theoretical values, which are given in parentheses. However, no simple and easily applied rule has yet been found to determine the optimum position and magnitude of the loss-supplying units.

The case of simple bending was next tried. Table 2 shows the result when supplying part of the losses from the single generator on the middle bottom u point; here again, the agreement with the calculated displacement distribution is remarkably close.

Attention was next turned to the circuit for the three-dimensional field having axial symmetry, shown in Fig. 18 of the companion paper.[2] The case of a cylinder with uniform external pressure, impressed here as a uniform radial displacement, is illustrated by Table 3; it has in addition a generator supplying losses through the middle point on the top boundary. The cylinder represented is 1 in. inside radius, 2 in. outside radius, and 0.8 in. long; calculated displacements are given in parentheses. Table 4 is for the same cylinder with uniform internal displacement.

Numerical Solution

The final step in this study of the equivalent circuits of the elastic field was the numerical solution of a particular case by hand. Such a procedure would be alternative to a direct solution of the differential equations; it is believed to offer some advantages in that Southwell's "relaxation" method of solution[4] is directly applicable, the unliquidated loads are always apparent, and any means whatever, from network-analyzer tests to ESP (mental telepathy), may be utilized in improving the solution.

The case chosen is a cantilever beam with the fixed end rigidly held both for axial and for vertical displacements; the beam is 1.2 in. long and 0.4 in. deep. Plane strain is assumed, and the loadings used are per inch of width. A mesh size of $\Delta x = .0.2$ in. and $\Delta y = 0.1$ in. is used. The load consists of 256 lb shear load distributed parabolically over the free-end cross section, and an

TABLE 3 DISPLACEMENTS IN A CYLINDER UNDER EXTERNAL PRESSURE (NEGATIVE)

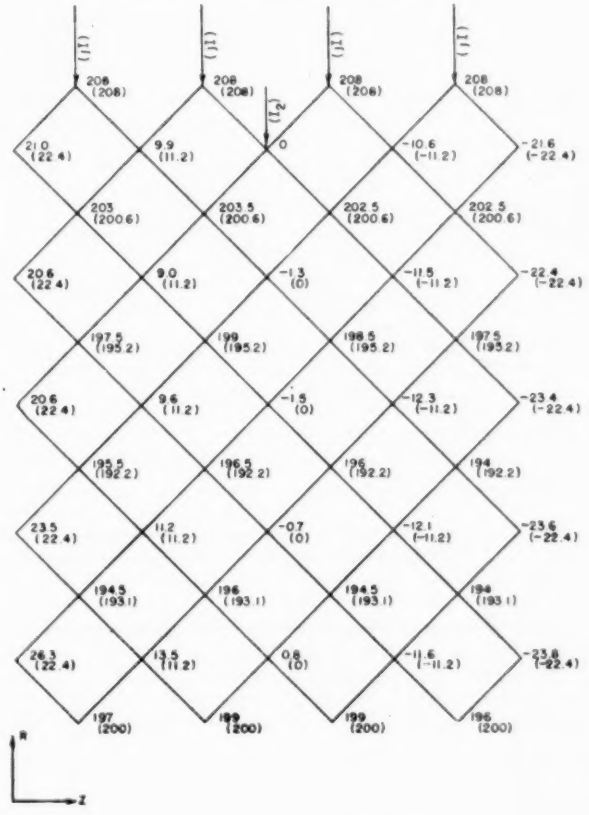

TABLE 4 DISPLACEMENTS IN A CYLINDER UNDER INTERNAL PRESSURE

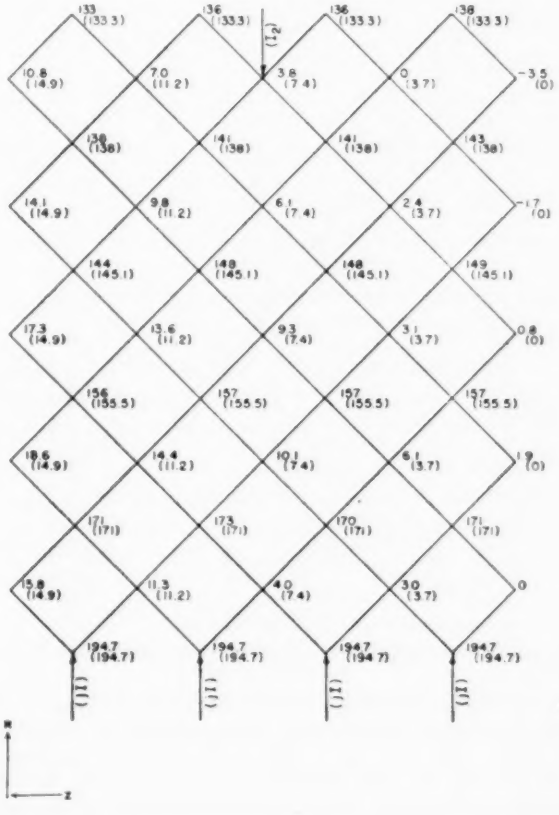

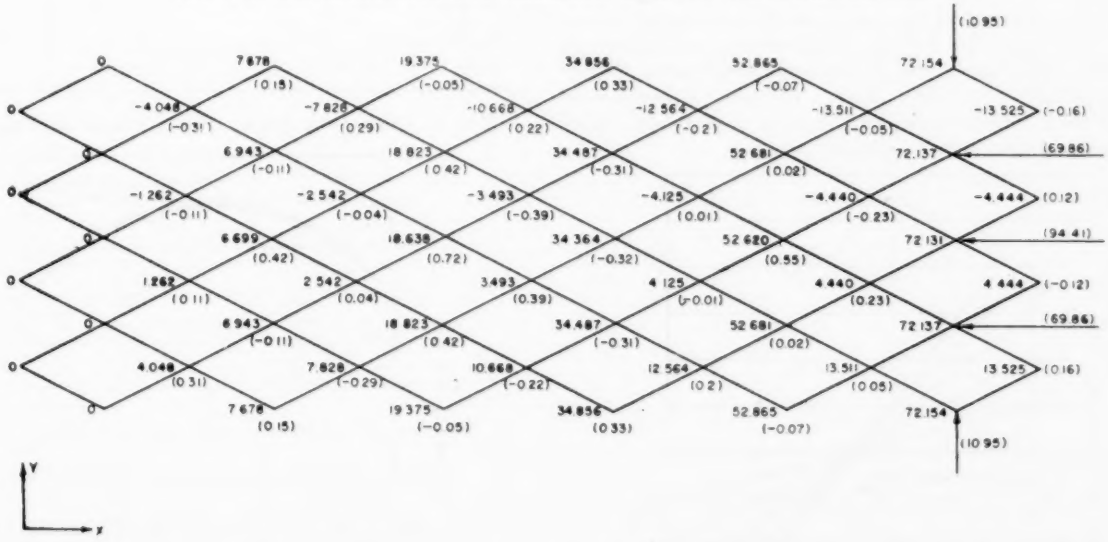

TABLE 5 DISPLACEMENTS AND RESIDUAL LOADS IN A CANTILEVER BEAM

additional concentrated load of 11 lb at the top and bottom edge of this cross section. The elastic moduli are divided by 100,000, so as to eliminate unnecessary zeros; this factor must be divided into the listed displacements to give results in inches.

The electric circuit for this case was solved by a relaxation method to five significant figures for the largest displacements, that is, a change of one unit in the last place of any of the displacement numbers would give a larger residual load at that point than existed before the change. Table 5 gives the displacements, with the residual loads in parentheses. The results are given graphically in Figs. 3 to 9, inclusive. Fig. 3 is a plot of the x displacements at several cross sections; there is only slight departure from the linear variation assumed in simple beam theory. The y displacement of the neutral surface of the beam is given in Fig. 4, along with the curve calculated from simple beam theory, including approximately the deflection due to shear. The smaller deflection obtained in the field solution can be attributed at least partially to the more restrictive boundary condition, since no

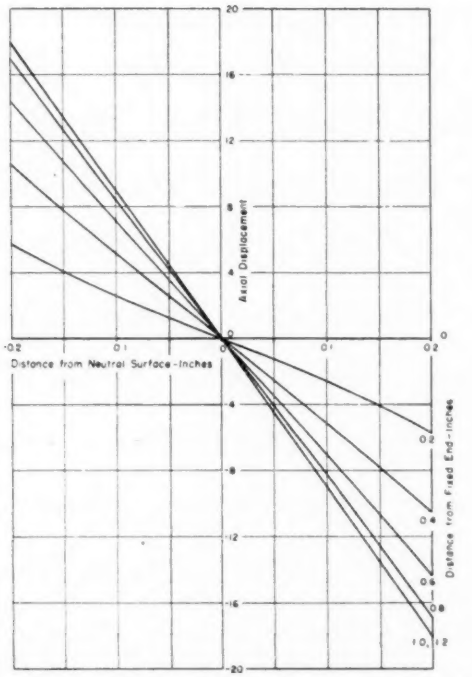

FIG. 3 CANTILEVER BEAM; AXIAL DISPLACEMENTS AT VARIOUS CROSS SECTIONS

vertical contraction is allowed at the fixed end in this case. The remaining figures are plots of the stress components. Fig. 5 gives the axial variation of shear stress; the variation vertically is shown in Fig. 6. The distribution is uniform along the beam and parabolic across it, except in the neighborhood of the applied forces. Fig. 7 shows that the direct stress in the axial direction varies practically linearly with depth, as assumed in simple beam theory; Fig. 8 shows that this stress is also linearly related to axial distance. Finally, Fig. 9 shows the distribution of the vertical direct-stress component; this is perceptible only in the vicinity of the applied vertical direct loads. The rapid attenuation of the end-stress concentrations with distance is of course simply another illustration of Saint Venant's principle.

SUMMARY

The purpose of the work reviewed in this paper was to study

the application of the equivalent circuit representation to the solution of elastic-field problems. This objective was sought in three ways: (1) Known solutions of certain field problems were used to give numerical checks on the validity of the circuit representation; these showed that the circuits are adequate for the

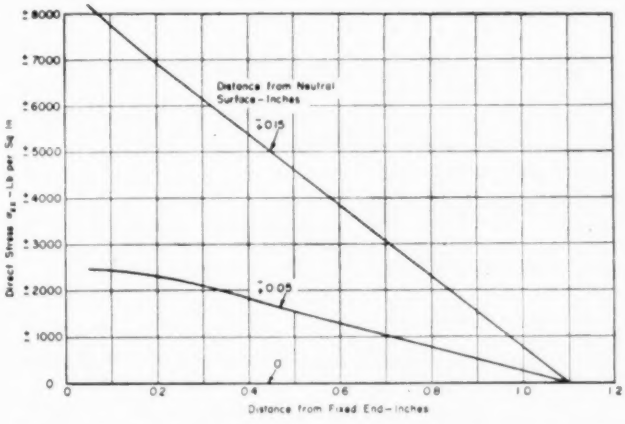

FIG. 8 CANTILEVER BEAM; DIRECT AXIAL STRESS AT VARIOUS LEVELS

purpose and suggested that only a moderately small mesh size is required. (2) Similar problems were set up on the a-c network analyzer to determine to what extent that instrument could be utilized in solving elastic-field problems; while good results could be obtained on the analyzer, the limited number of elements available and the unavoidable resistance effects offer some restriction to its usefulness. (3) A particular case was solved by hand, using the equivalent circuit as a framework for the calculations; this shows that it is feasible to solve elastic-field problems in this way directly from given boundary conditions. Application of the "relaxation" method in such a solution enables use to be made of analyzer results, approximate solutions, and intuition with respect to either the elastic field or the electric network; and there is indication at all times of the degree of approximation of the solution, in terms of the unliquidated loads (currents).

ACKNOWLEDGMENT

The author acknowledges with pleasure the co-operation of his associates in the General Electric Company in the work described in this paper; particularly valuable have been the advice received from Gabriel Kron and Charles Concordia, and the careful calculations contributed by Mrs. Mary Dyrkacz.

Basic Mechanics of the Metal-Cutting Process

By M. EUGENE MERCHANT,[1] CINCINNATI, OHIO

The author presents a mathematical analysis of the geometry and mechanics of the metal-cutting process, covering two common types of geometry which occur in cutting. This analysis offers a key for the study of engineering problems in the field of metal cutting in terms of such fundamental quantities as strain, rate of shear, friction between chip and tool, shear strength of the metal, work done in shearing the metal and in overcoming friction, etc. The two cases covered are, in essence, that of a straight-edged cutting tool moving relative to the workpiece in a direction perpendicular to its cutting edge, termed "orthogonal cutting," and that of a similar cutting tool so set that the cutting edge is oblique to the direction of relative motion of tool and work, termed "oblique cutting." Equations are developed which permit the calculation of such quantities as those just enumerated from readily observable values. The theoretical findings are particularly applicable and significant in the case of present-day high-speed machining operations with sintered-carbide tools.

Nomenclature

The following nomenclature is used in this paper:

A_0 = cross-sectional area of "chip" before removal from workpiece = $w_1 t_1$

A_c = cross-sectional area of chip after removal from workpiece = $w_2 t_2$

A_s = area of shear plane = $\dfrac{w_3 t_1}{\sin \phi}$

F = friction force; force component acting between tool face and sliding chip

F_c = cutting force; force component acting in direction of motion of tool relative to workpiece

F_l = lateral force; force component acting in direction perpendicular to F_c and parallel to surface generated

F_n = force component acting in direction perpendicular to shear plane

F_s = shearing force; force component acting in direction of shear of metal, in shear plane

F_t = thrust force; force component acting in direction perpendicular to F_c and to surface generated

L_1 = arbitrary distance measured in direction of relative motion of cutting tool and workpiece

L_2 = distance through which point on chip moves relative to cutting tool, when tool advances distance L_1

L_3 = distance through which point on chip moves relative to workpiece when tool advances distance L_1

N = normal force; force component acting perpendicular to tool face

R, R' = resultant forces; forces acting between chip and tool and between chip and workpiece

r_c = cutting ratio = r_L

r_L = chip length ratio = $\dfrac{L_2}{L_1}$

r_t = chip thickness ratio = $\dfrac{t_1}{t_2}$

r_w = chip width ratio = $\dfrac{w_1}{w_2}$

S_s = mean shear stress on shear plane; mean shear strength of metal being cut

t = conventional true rake angle; rake angle of tool as measured in plane parallel to direction of relative motion of work and tool and perpendicular to surface generated

t_1 = thickness of "chip" before removal from workpiece

t_2 = thickness of chip after removal from workpiece, as measured in direction perpendicular to face of cutting tool

V_c = cutting velocity; velocity of tool relative to workpiece

V_f = chip-flow velocity; velocity of chip relative to cutting tool

V_s = velocity of shear; velocity of chip relative to workpiece

w_1 = width of chip before removal from workpiece

w_2 = width of chip after removal from workpiece

w_3 = width of shear plane, as measured in direction parallel to cutting edge of tool

W_c = work done in cutting, per unit volume of metal removed

W_f = work done in overcoming friction between chip and tool, per unit volume of metal removed

W_s = work done in shearing of metal, per unit volume of metal removed

α = oblique rake angle; rake angle of tool as measured in plane perpendicular to its cutting edge

β = chip flow angle; angle between a perpendicular to cutting edge and the direction of chip flow over face of tool, as measured in plane of tool face

γ = angle of inclination of cutting edge; angle between direction of motion of tool relative to work and a perpendicular to cutting edge of tool, as measured in plane of surface generated

δ = angle between direction of shear of metal on shear plane and a perpendicular to cutting edge of tool, as measured in shear plane

ϵ = shearing strain undergone by chip during process of removal

μ = coefficient of friction acting between sliding chip and tool face = F/N

σ = angle defined in Fig. 10

τ = friction angle = arc tan μ

ϕ = shear angle; angle between shear plane and surface being generated, measured in plane perpendicular to cutting edge of tool

Introduction

A knowledge of the basic force relationships and the associated geometry occurring in the process of cutting metal is a necessity if the solution of engineering problems arising in that field is to be handled on anything other than an empirical basis. In this paper an analysis of the force systems and the geometry of chip formation occurring in two common types of cutting processes is presented.

The first and somewhat special case, considered in Part 1 of this paper, is that of a cutting tool having a plane face and a single straight cutting edge, generating a plane surface parallel to the original plane surface of the workpiece, and so set that the cutting edge is perpendicular to the direction of relative motion of tool and workpiece. In this case the force system can be considered to be two-dimensional. We shall characterize this type of cutting by the term "orthogonal cutting."

The second and quite general case, considered in Part 2 of this paper, is that of a tool similar to the preceding one, but with the cutting edge oblique to the direction of relative motion of tool and workpiece. This case involves a three-dimensional force system. This type of cutting is sometimes called a shearing cut. We shall, however, characterize this type of cutting by the term "oblique cutting," as actually all cutting involves a shearing of the material being cut.

The Geometry of Chip Formation

The type of chip formation dealt with in this analysis is that of a continuous chip with no built-up edge adjacent to the tool face, often designated as a type-2 chip.[2] Of interest is the fact that this is the type of chip obtained in machining operations employing sintered-carbide cutting tools with either negative or positive true rake angles, operating at relatively high cutting speeds; a type of operation which is playing such a large and important part in our present-day war production.

This type of chip formation is illustrated in Figs. 1 and 2. Fig. 1 is a photomicrograph of a chip obtained with a positive-rake-angle carbide tool cutting S.A.E. 1112 steel at a speed of 310 fpm, while Fig. 2 is a photomicrograph of a similar chip obtained with a negative-rake-angle tool cutting at a speed of 780 fpm.

It may be seen from either of these photomicrographs that a continuous chip is formed by a process of shear which is mainly confined to a single plane extending from the cutting edge to the work surface. That this is the general mechanism of the formation of a continuous chip was recognized at least as long ago as 1877 by J. Thime,[3] and many later workers have taken cognizance of this fact. However, the significance of the *variability* of the direction of shear has only recently been recognized by Ernst and Merchant.[4] In the present analysis still further significance is found to be attached to the direction of shear.

1 Orthogonal Cutting With a Straight-Edged Tool

Geometrical Relationships

In the case of orthogonal cutting, the tool is so set that its cut-

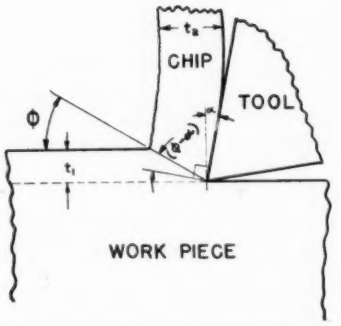

FIG. 3 SCHEMATIC REPRESENTATION OF GEOMETRY OF CHIP FORMATION IN CASE OF ORTHOGONAL CUTTING AND A CONTINUOUS CHIP WITHOUT BUILT-UP EDGE

ting edge is perpendicular to the direction of relative motion of tool and workpiece and generates a plane surface parallel to the original work surface. The geometry involved in this case is shown schematically in Fig. 3. The rake angle of the tool is designated by α, and the angle which the plane of shear makes with the surface generated is designated by ϕ. The thickness of the chip before removal is designated by t_1, and that after its removal by t_2. Knowing t_1, t_2, and α, ϕ can be determined from the following equation readily derivable from the geometry of Fig. 3

$$\tan \phi = \frac{t_1/t_2 \cos \alpha}{1 - t_1/t_2 \sin \alpha} \quad \ldots\ldots [1]$$

The ratio t_1/t_2 appearing in Equation [1] will be called the "chip thickness ratio" and designated by the symbol r_t. Then, from Equation [1]

$$r_t = \frac{t_1}{t_2} = \frac{\sin \phi}{\cos (\phi - \alpha)} \quad \ldots\ldots [1a]$$

If the small amount of side flow which occurs in the chip during removal is neglected, then in the case of orthogonal cutting the chip is the same width before removal as afterward. It follows from volume considerations that the "chip length ratio" r_L, which is found by dividing the length of the chip after removal by the length of the path from which it was cut, is equal to t_1/t_2. This chip length ratio will also be given the name "cutting ratio" here, for reasons which will become apparent later, and designated by the symbol r_c. Then

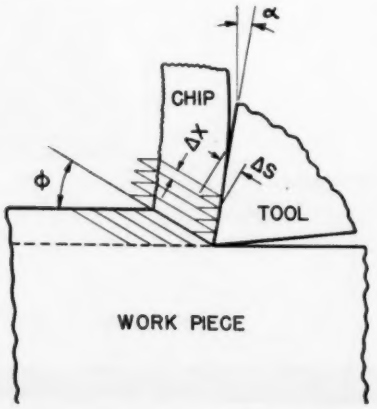

FIG. 4 SCHEMATIC REPRESENTATION OF THE PHYSICAL SIGNIFICANCE OF SHEARING STRAIN IN METAL-CUTTING PROCESS

$\left(\text{Strain} = \frac{\Delta S}{\Delta X}. \text{ In actual cutting } \Delta X \to 0.\right)$

$$r_c = r_L = \frac{L_2}{L_1} = \frac{t_1}{t_2} = r_t \quad \ldots\ldots [2]$$

In order to determine the shearing strain ϵ, which is undergone by the chip during its removal from the workpiece, the cutting process may for convenience be pictured as consisting of the displacement of a series of platelike elements of thickness ΔX through a distance ΔS relative to each other, as shown in Fig. 4. (In the actual process of cutting, ΔX of course approaches zero.) Then, from the geometry of Fig. 4

$$\text{Strain} = \epsilon = \frac{\Delta S}{\Delta X} = \cot \phi + \tan (\phi - \alpha) \quad \ldots\ldots [3]$$

As will be shown later, this is the true or natural strain in the chip, since the product of this quantity by the mean shear strength of the material gives the work done in shear per unit volume of metal removed.

In connection with Equation [3], it is of interest to investigate the value of ϕ which will make the strain a minimum for any given value of α. Thus

$$\frac{\partial \epsilon}{\partial \phi} = -\csc^2 \phi + \sec^2 (\phi - \alpha = 0$$

or

$$\phi = 90 - (\phi - \alpha)$$

$$[\phi]_{\epsilon = \min} = \frac{\alpha}{2} + 45 \text{ deg} \quad \ldots\ldots [4]$$

Substituting Equation [4] into Equation [1a], and bearing in mind Equation [2]

$$[r_c]_{\epsilon = \min} = \frac{\sin \left(45 + \frac{\alpha}{2}\right)}{\cos \left(45 - \frac{\alpha}{2}\right)} = 1 \quad \ldots\ldots [5]$$

or the cutting ratio must be unity in order for the strain to be a minimum.

The velocity relations for orthogonal cutting are shown in Fig.

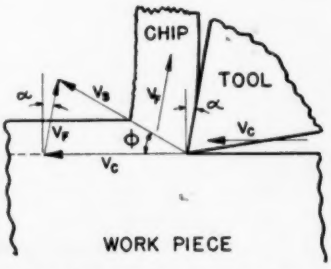

FIG. 5 VELOCITY RELATIONSHIPS IN CASE OF ORTHOGONAL CUTTING

5, where V_c is the cutting velocity, V_s the velocity of shear, and V_f the velocity of chip flow up the tool face. Fig. 5 is based upon the fact that the velocity of the chip relative to the workpiece (V_s) is equal to the vector sum of the velocity of the chip relative to the tool (V_f) and the velocity of the tool relative to the workpiece (V_c). It can be shown mathematically that the shearing velocity V_s is the actual velocity of the chip relative to the workpiece, but that will not be done here since the fact is fairly self-evident.

The following velocity relationships can evidently be derived from the geometry of Fig. 5

$$V_s = V_c \frac{\cos \alpha}{\cos (\phi - \alpha)} \quad \ldots\ldots [6]$$

$$Vf = V_c \frac{\sin \phi}{\cos (\phi - \alpha)} = V_e r_c \quad [7]$$

Force Relationships

Many previous investigators have attempted to make a theoretical analysis of the forces involved in cutting. Among these may be mentioned Thime,[3] Sellergren,[5] Stanton and Hyde,[6] Kronenberg,[7] and Gleboff-Heintz.[8]

However, these earlier workers apparently did not succeed in grasping the character of the force system involved in cutting,[9] probably because they failed to hit upon the useful device of considering the chip to be a "separate" body held in equilibrium by action of the force system. More recently, by use of this device, the author has developed a force system[10,4] for the case of

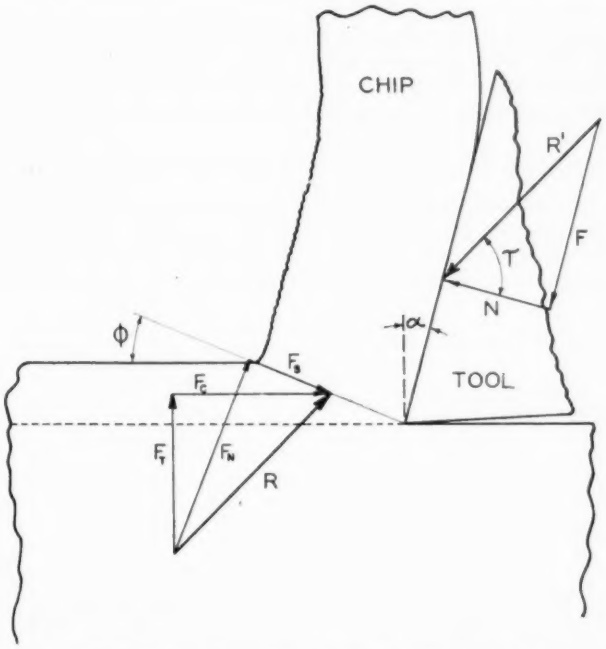

Fig. 6 Force System Acting in Case of Orthogonal Cutting, Showing Chip in Equilibrium Under Action of Equal and Opposite Resultant Forces R and R'

orthogonal cutting which appears to be physically consistent, judging by the results obtained with it to date in interpreting experimental data obtained from numerous cutting tests.

This force system is shown in Fig. 6. The chip may be considered as an independent body held in mechanical equilibrium by the action of the two equal and opposite resultant forces R and R' (neglecting a small couple arising from the fact that R and R' are not exactly collinear, which plays no part in the present discussion). Force R is the force which the workpiece exerts on the chip, while R' is the force which the tool exerts on the chip. The force R' may be resolved into a component F along the tool face, which is the force of friction acting between chip and tool, and a component N which is the force acting normal to the chip-tool interface. Thus the coefficient of friction μ acting between chip and tool is given by

$$\mu = \frac{F}{N} = \tan \tau \quad [8]$$

The force R in Fig. 6 may be resolved into a horizontal component F_c, the cutting force, which is responsible for the total work done in cutting, and into a component F_t, the thrust force, which does no work. Force R may also be resolved into a component along the shear plane F_s, the shearing force, which is responsible for the work done in shearing the metal, and into a component F_n normal to the shear plane.

Since R and R' are equal parallel forces, we may represent all their components as components of a single vector R, located for convenience at the tool point, as shown in Fig. 7. The relationships between the various components are readily perceived in this case.

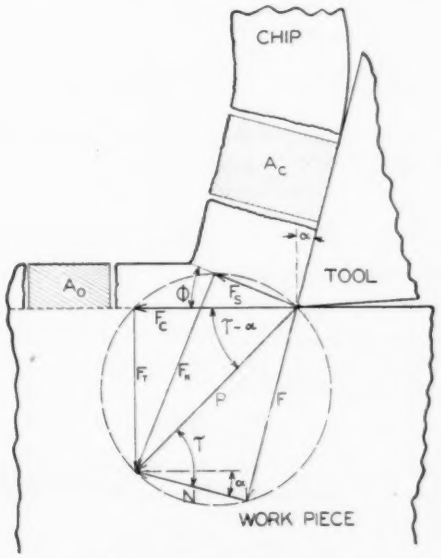

Fig. 7 Condensed Form of Force Diagram Derived From Fig. 6 Conveniently Indicating Geometrical Relationships Between Force Components

The directly measurable or readily obtainable quantities from among those shown in Fig. 7 are F_c, F_t, A_0, ϕ, and α. The remaining quantities shown, as well as other quantities of basic interest, can be calculated from these observables with the aid of the relationships now to be developed.

The equation for the coefficient of friction μ can be readily obtained as follows

$$\tan (\tau - \alpha) = \frac{Ft}{F_c} \quad [9]$$

thus

$$\mu = \tan \tau = \frac{F_t + F_c \tan \alpha}{F_c - F_t \tan \alpha} \quad [10]$$

[9] Since writing the foregoing, a Finnish paper has come to the attention of the author, "Lastunmuodostumisen Teoriaa," by Väinö Piispanen, *Teknillinen Aikakauslehti*, vol. 27, 1937, p. 315, in which a force system similar to that shown in Fig. 6 is proposed. Only orthogonal cutting is considered. Although a suitable translation of this Finnish paper has not been obtained as yet, it appears that Piispanen's ideas concerning the chip geometry and the force system in orthogonal cutting are similar, in many respects, to those developed independently by the author.

[10] "Theory of Friction in Metal Cutting," by M. E. Merchant, University of Cincinnati Thesis, D.Sc., 1940 (confidential).

It can be seen directly from Fig. 7 that the force of friction F is

$$F = F_t \cos \alpha + F_c \sin \alpha \quad [11]$$

Similarly, it can be seen directly from Fig. 7 that the shearing force F_s is

$$F_s = F_c \cos \phi - F_t \sin \phi \quad [12]$$

If the area of the shear plane be designated by A_s and the cross-sectional area of the chip before removal by A_0, then

$$A_s = \frac{A_0}{\sin \phi} \quad [13]$$

Therefore, the mean shear stress S_s on the shear plane, which is equal to the mean shear strength of the material, is given by

$$S_s = \frac{F_s}{A_s} = \frac{F_c \sin \phi \cos \phi - F_t \sin^2 \phi}{A_0} \quad [14]$$

by virtue of Equations [12] and [13].

The work done in overcoming friction between the chip and tool, per unit volume of metal removed, which we shall designate by W_f, is found by dividing the frictional work done per unit of time by the volume of metal removed per unit of time; thus

$$W_f = \frac{FV_f}{A_0 V_c}$$

then, from Equation [7]

$$W_f = F \frac{r_c}{A_0} = F/A_c \quad [15]$$

Similarly, the work done in shear, per unit volume of metal removed, designated by W_s, is given by

$$W_s = \frac{F_s V_s}{A_0 V_c}$$

or, applying Equations [6] and [13]

$$W_s = \frac{F_s}{A_s} \frac{\cos \alpha}{\sin \phi \cos (\phi - \alpha)} = S_s [\cot \phi + \tan (\phi - \alpha)] \quad [16]$$

and therefore from Equation [3]

$$W_s = S_s \epsilon \quad [16a]$$

For comparison, the total work done in cutting, per unit volume of metal removed, designated by W_c, may be found as follows

$$W_c = \frac{F_c V_c}{A_0 V_c}$$

and, bearing in mind that the work done depends only upon the relative lengths of the velocity vectors and not on their direction, then from the geometry of Fig. 5

$$W_c = \frac{F_c}{A_0 V_c} (V_s \cos \phi + V_f \sin \alpha)$$

Introducing Equations [6] and [7] then gives

$$W_c = \frac{F_c}{A_0} \left[\frac{\cos \phi \cos \alpha + \sin \phi \sin \alpha}{\cos (\phi - \alpha)} \right]$$

and, making use of the geometry of Fig. 7

$$W_c = \frac{R}{A_0} \left[\frac{\cos (\tau - \alpha) \cos \phi \cos \alpha + \cos (\tau - \alpha) \sin \phi \sin \alpha}{\cos (\phi - \alpha)} \right]$$

$$= \frac{R}{A_0} \left[\frac{\cos (\phi + \tau - \alpha) \cos \alpha + \sin (\tau - \alpha) \sin \phi \cos \alpha + \cos (\tau - \alpha) \sin \phi \sin \alpha}{\cos (\phi - \alpha)} \right]$$

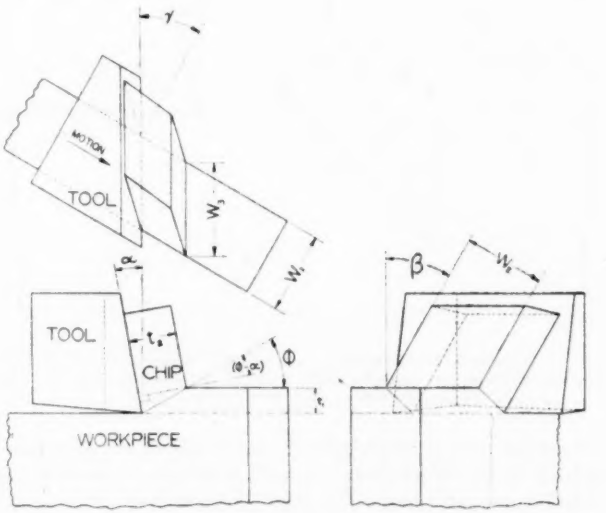
$$= \frac{F_s}{A_0} \frac{\cos \alpha}{\cos (\phi - \alpha)} + \frac{R}{A_0} \frac{\sin \phi}{\cos (\phi - \alpha)} \cdot [\sin (\tau - \alpha) \cos \alpha + \cos (\tau - \alpha) \sin \alpha]$$

Thus from Equations [13], [16], and [3] and the geometry of Fig. 7

$$W_c = S_s \epsilon + \frac{r_c}{A_0} (F_t \cos \alpha + F_c \sin \alpha)$$

and therefore from Equations [11] and [15]

$$W_c = S_s \epsilon + F/A_c$$



or, from Equations [15] and [16a]

$$W_c = W_s + W_f \quad [17]$$

Thus the total work done in cutting is equal to the sum of the work done in shearing the metal and the work done in overcoming friction between tool and chip. This result is one to be expected, but serves as a useful check on the logic employed.

2 OBLIQUE CUTTING WITH A STRAIGHT-EDGED TOOL

The formulas derived in Part 1 of this paper hold only for the case of orthogonal cutting (cutting edge perpendicular to direction of motion), and will be seen to be special cases of the more general formulas derived in this section for the case of oblique

NOTE: ANGLE β IS MEASURED IN PLANE OF TOOL FACE

FIG. 8 ORTHOGRAPHIC REPRESENTATION OF GEOMETRY OF OBLIQUE CUTTING

cutting. The idea that oblique cutting involved certain additional factors not present in orthogonal cutting was first expressed by Sellergren[5] in 1896, but apparently little further attention was given to this fact until now.

GEOMETRICAL RELATIONSHIPS

The three-dimensional geometry involved in the case of oblique cutting, in which a perpendicular to the cutting edge makes some angle γ with respect to the direction of relative motion of tool and work, is shown in Fig. 8. As in the previous case, the chip is formed by a process of shear on a plane which makes an angle ϕ with the surface generated. However, the direction of chip flow up the tool face is no longer perpendicular to the cutting edge, but makes an angle

β with such a perpendicular. For the sake of clarity in visualizing the oblique cutting process, the chip is here represented as having no tendency to curl away from the tool face, contrary, of course, to the behavior observed in practice, but without effect on the present analysis.

If the chip thickness ratio r_t is again defined as t_1/t_2, where t_1 and t_2 are the chip thicknesses measured as indicated in Fig. 8, then it is evident that Equations [1] and [1*a*] also hold for the case of oblique cutting, namely

$$\tan \phi = \frac{t_1/t_2 \cos \alpha}{1 - t_1/t_2 \sin \alpha} \quad [1]$$

$$r_t = \frac{t_1}{t_2} = \frac{\sin \phi}{\cos (\phi - \alpha)} \quad [1a]$$

where α is the rake angle of the tool measured in a plane perpendicular to the cutting edge. Angle α is known as the oblique rake angle as distinguished from the conventional true rake angle, t, (Fig. 9) which is measured in a plane parallel to the direction of relative motion of tool and work and perpendicular to the surface generated.

It is evident from Fig. 8 that the width w_2 of the chip after

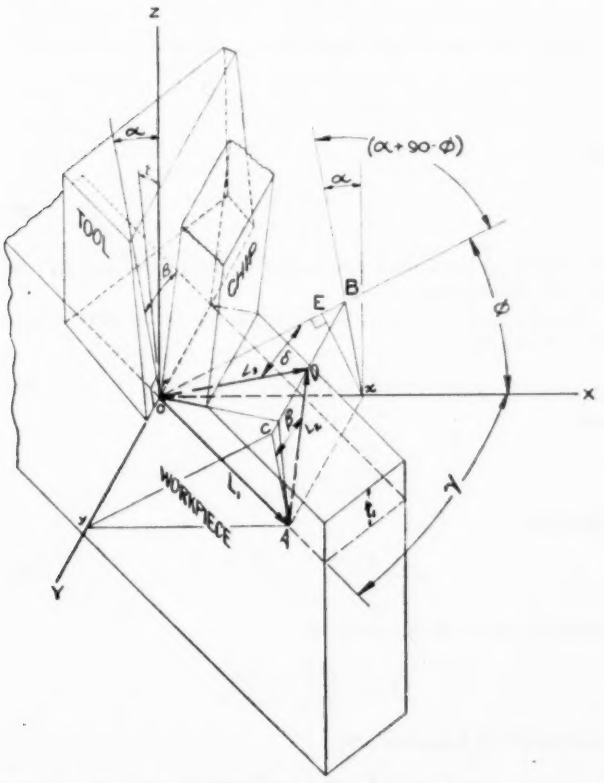


FIG. 9 OBLIQUE REPRESENTATION OF SYSTEM SHOWN IN FIG. 8, ILLUSTRATING FURTHER GEOMETRICAL RELATIONSHIPS OCCURRING IN OBLIQUE CUTTING

removal is greater than the width w_1 of the chip before removal. Knowing these widths and the angle γ, it is then possible to find the angle β from the following equation readily derivable from the geometry of Fig. 8

$$\cos \beta = \frac{\cos \gamma}{w_1/w_2} \quad [18]$$

If we call the ratio w_1/w_2 the "chip width ratio," r_w, then

$$r_w = \frac{w_1}{w_2} = \frac{\cos \gamma}{\cos \beta} \quad [18a]$$

A further appreciation of the geometry involved in oblique cutting may be obtained from Fig. 9, where X, Y, and Z axes have been introduced. The axes are so chosen that the cutting edge of the tool is parallel to the Y axis and thus perpendicular to the XZ plane. The direction of motion of tool relative to work is indicated by the vector L_1, and thus makes an angle γ with the X axis. Plane $OBCy$ is an extension of the shear plane, while plane $ACBx$ is parallel to the tool face and passes through the terminal point A of vector L_1. If the cutting tool advances along the workpiece a distance L_1, then a point which was originally at O on the chip will have advanced up the tool face a distance L_2 in the direction of chip flow, as given by β, and will have advanced relative to the workpiece a distance L_3 in the plane of shear, thus bringing it to point D. Thus L_3 represents the direction of shear of the metal on the shear plane. It is interesting to note that the direction of shear is not perpendicular to the cutting edge in the case of oblique cutting, but makes an angle δ with such a perpendicular. The smaller the angle δ is, the more the direction of chip flow deviates from a perpendicular to the cutting edge, and vice versa. From the geometry of Fig. 9, it is possible to derive the following relationship between δ and β

$$\tan \delta = \frac{\tan \gamma \cos (\phi - \alpha) - \tan \beta \sin \phi}{\cos \alpha} \quad [19]$$

It is evident that the cutting ratio, r_c, or chip length ratio, r_L, is given by the ratio of L_2 to L_1. The following expression for the cutting ratio can be derived from Fig. 9

$$r_c (= r_L) = \frac{L_2}{L_1} = \frac{\cos \gamma}{\cos \beta} \frac{\sin \phi}{\cos (\phi - \alpha)} \quad [20]$$

or, from Equations [1*a*] and [18*a*]

$$r_c = r_w r_t \quad [20a]$$

By analogy with the reasoning used in deriving Equation [3] for orthogonal cutting, it may be seen that in the case of oblique cutting, referring to Fig. 9, the shearing strain in the chip is

$$\text{Strain} = \epsilon = \frac{L_3}{Ex}$$

or, from the geometry of Fig. 9

$$\epsilon = \frac{\cot \phi + \tan (\phi - \alpha)}{\cos \delta} \quad [21]$$

Again it will be seen later that this expression represents the natural strain in the chip.

It is evident from the form of Equation [21] that in regard to ϕ the strain will be minimum for the same value of ϕ as that which made Equation [3] a minimum, or

$$[\phi]_{\epsilon = \min} = \frac{\alpha}{2} + 45 \text{ deg} \quad [4]$$

However, it may also be seen from Equation [21] that, with respect to δ, the strain will be a minimum when δ is zero, i.e.

$$[\delta]_{\epsilon = \min} = 0 \quad [22]$$

Substituting Equation [22] into Equation [19], and applying Equation [4], it is found that

$$\left[\frac{\tan \gamma}{\tan \beta}\right]_{\epsilon = \min} = \left[\frac{\sin \phi}{\cos (\phi - \alpha)}\right]_{\epsilon = \min} = 1 \quad [23]$$

However, the conditions expressed in Equation [23] make the value of Equation [20] unity, or

$$[r_e]_{e=\min} = 1$$

Thus, again, the cutting ratio must be unity for the strain to be a minimum. It may be noted that it is a necessary but not a sufficient condition for minimum strain that either r_t or r_w be unity, while r_L ($= r_c$) = 1 is both a necessary and sufficient condition for minimum strain. It is for this reason that the chip length ratio has been dignified by the special name of "cutting ratio."

It is evident from the foregoing discussion of the vectors L_1, L_2, and L_3, appearing in Fig. 9, that they are proportional, respectively, to the velocities of cutting, of chip flow, and of shear, or

$$\frac{V_c}{L_1} = \frac{V_f}{L_2} = \frac{V_s}{L_3} \quad \ldots\ldots\ldots\ldots\ldots\ldots [24]$$

On this basis, the following relationships can be derived from Fig. 9

$$V_s = V_c \frac{\cos \gamma \cos \alpha}{\cos \delta \cos (\phi - \alpha)} \quad \ldots\ldots\ldots\ldots\ldots\ldots [25]$$

$$V_f = V_c \frac{\cos \gamma \sin \phi}{\cos \beta \cos (\phi - \alpha)} = V_c r_c \quad \ldots\ldots\ldots [26]$$

Force Relationships

The three-dimensional force system acting upon the tool-chip-work system pictured in Fig. 9 is shown in Fig. 10 and refers to

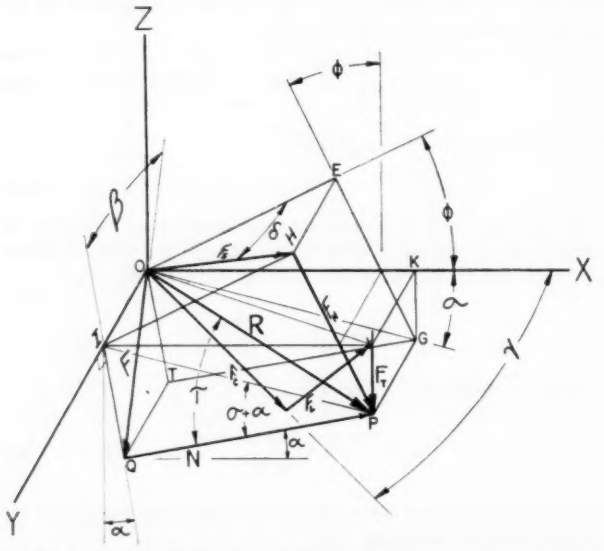

Fig. 10 Oblique Representation of Force System Acting in Case of Oblique Cutting, Indicating Geometrical Relationships Between Force Components

the same set of axes as used for Fig. 9. The outlines of the tool, chip, and workpiece have been omitted to eliminate inessential lines.

Plane *OIQT* represents an extension of the plane of the tool face, and plane *OEHI* an extension of the shear plane. Plane *EGPH* is perpendicular to the shear plane.

As in the case of the simple force system for orthogonal cutting, the force system for oblique cutting has been derived on the principle that the chip is held in equilibrium by two equal, opposite, and parallel resultant forces, which for simplicity have been combined into a single resultant force R in Fig. 10, just as was done in Fig. 7 in the case of orthogonal cutting.

The resultant force R in Fig. 10 may be resolved into a frictional component F in the plane of the tool face and acting necessarily in the direction of chip flow, as given by angle β, and into a normal component N perpendicular to the tool face. It may also be resolved into a shearing component F_s acting in the shear plane in the direction of shear, as given by angle δ and a normal component F_n perpendicular to the shear plane. Finally, R may be resolved into a component F_c which acts in the direction of cutting and is responsible for the total work done in cutting, a lateral component F_l, the lateral force, which is perpendicular to F_c and parallel to the surface generated, and a thrust component F_t which is perpendicular to F_c and to the surface generated.

The readily observable or directly measurable quantities from among those shown in Figs. 8, 9, and 10 are F_c, F_l, F_t, t_1, w_1, α, β (or δ), γ, and ϕ. The remaining quantities shown in Fig. 10, as well as other quantities of basic interest, can be calculated from these observables, with the aid of the relationships now to be developed.

Use will be made of the following equation derivable from Fig. 10

$$\tan \sigma = \frac{F_t}{F_c \cos \gamma + F_l \sin \gamma} \quad \ldots\ldots\ldots\ldots [27]$$

The coefficient of friction may be found as follows

$$\mu = \tan \tau = \frac{F}{N} = \frac{IQ}{N \cos \beta}$$

or

$$\mu = \frac{\tan (\sigma + \alpha)}{\cos \beta} \quad \ldots\ldots\ldots\ldots\ldots\ldots [28]$$

an expression to be used in conjunction with Equation [27] for the sake of simplicity of form.

The expression for the force of friction F may be derived from Fig. 10 as follows

$$IO = KJ = F_c \sin \gamma - F_l \cos \gamma \quad \ldots\ldots\ldots [29]$$

and

$$F = \frac{IO}{\sin \beta}$$

Therefore

$$F = \frac{F_c \sin \gamma - F_l \cos \gamma}{\sin \beta} \quad \ldots\ldots\ldots\ldots [30]$$

Similarly, for F_s, the shearing force

$$F_s = \frac{HE}{\sin \delta} = \frac{KJ}{\sin \delta}$$

and thus from Equation [29]

$$F_s = \frac{F_c \sin \gamma - F_l \cos \gamma}{\sin \delta} \quad \ldots\ldots\ldots\ldots [31]$$

The mean shear stress S_s on the shear plane, which is equal to the mean shear strength of the metal, is then evidently

$$S_s = \frac{\sin \phi \cos \gamma}{A_0 \sin \delta} (F_c \sin \gamma - F_l \cos \gamma)$$

The work done in overcoming friction between chip and tool, per unit volume of metal removed, is evidently

$$W_f = \frac{FL_2}{A_0 L_1}$$

or, from Equation [20]

$$W_f = \frac{F}{A_0} r_c = \frac{F}{A_c} \quad [32]$$

The work done in shearing the metal on the shear plane, per unit volume of metal removed, is evidently

$$W_s = \frac{F_s L_3}{A_0 L_1}$$

which from the geometry of Fig. 10 is found to be

$$W_s = \frac{F_s}{A_0} \frac{\cos \alpha \cos \gamma}{\cos \delta \cos (\phi - \alpha)} = S_s \epsilon \quad [33]$$

Since the work done in cutting has been seen to be the sum of the work done in overcoming friction and the work done in shearing the metal, then

$$W_c = W_s + W_f = S_s \epsilon + F/A_c \quad [34]$$

Conclusion

In the analyses presented in this paper only the fairly simple case has been considered in which all the cutting is done by a single straight cutting edge, and a plane surface is generated on the workpiece. However, the results can actually be applied quite accurately to such practical operations as milling, turning, planing, broaching, shaping, etc., with straight-edged tools, where a secondary cutting edge usually occurs, provided that the active length of the secondary cutting edge is quite small compared to the active length of the main cutting edge, and that the radius of curvature of the surface generated is not extremely small. This will be the case, for example, in face milling, if the depth of cut is quite large compared to the feed per tooth, and an ordinary size of milling cutter is employed; it will likewise be the case in turning, if the depth of cut is large compared to the feed per revolution, and the diameter of the workpiece is not unusually small.

The foregoing analyses also have, in theory at least, been limited to the case where a continuous chip is formed, with no built-up edge adjacent to the cutting edge of the tool. However, it has been found that the presence of a built-up edge actually introduces very little error, provided it is fairly small compared to the thickness of the chip. In fact, the discrepancies have been found not to be excessively large even in the case where a discontinuous chip is formed. As has already been pointed out, in the case of present-day machining operations with sintered-carbide cutting tools, the type of chip formation obtained is virtually identical with that discussed in this paper, thus making the application of the derived relationships to such operations particularly accurate.

In conclusion it may be mentioned that although in this paper the author has limited himself to a discussion of the metal-cutting process, it has undoubtedly been apparent to the reader that the analyses made apply equally well to any type of cutting process where the geometrical conditions are similar.

Acknowledgments

The author wishes to express his appreciation for the helpful comments and suggestions contributed by Mr. Hans Ernst, Research Director, and Dr. Max Kronenberg, member of the Research staff, both of the author's company, and to acknowledge certain experimental observations in regard to oblique cutting made by Prof. W. T. Dempster of the Anatomical Laboratory, University of Michigan, which were described by him in a personal communication, and which proved helpful to the author in arriving at an understanding of the geometry of chip formation in the case of oblique cutting.

Application of the Fourier Method to the Solution of Certain Boundary Problems in the Theory of Elasticity

By GERALD PICKETT,[1] CHICAGO, ILL.

The paper shows how the Fourier method may be used to obtain exact solutions for stresses in rectangular prisms or circular cylinders for any boundary condition.

Introduction

EXACT solutions for stresses in rectangular prisms or circular cylinders under any boundary conditions expressible by Fourier series can be obtained by the Fourier method, i.e., the stresses and displacements at the boundary have a finite number of ordinary discontinuities and a finite number of maxima and minima. The solutions are exact in the sense that stresses are expressed by series and become exact in the limit as more terms are used. To obtain these exact solutions, however, requires the use of more types of particular solutions in the same problem than are commonly used. The chief difference between the method, as explained in this paper, and the usual Fourier method for boundary-value problems is that not one[2] but two or more series of particular solutions are chosen as needed. Each of these series is selected so as to give a Fourier-series expression for one component of stress (or of displacement) at some boundary. The coefficients of the terms in a series are determined by Fourier analysis so as to give not only the desired stress (or displacement) at the boundary for which the series was selected but also to cancel any stress (or displacement) that may have been unavoidably introduced by the other series of particular solutions. Because of the interdependency of these two or more series of particular solutions, the expression for a coefficient of a term in one series will contain the coefficients of one or all the other series. The final solution, therefore, involves the solution of simultaneous equations giving relations between the coefficients.

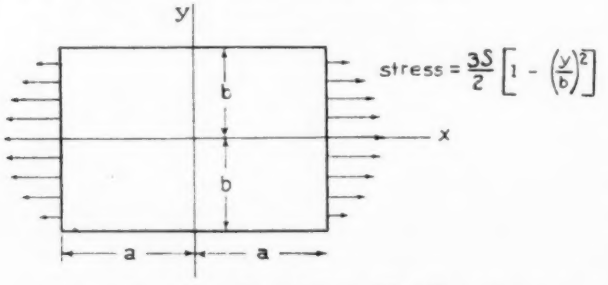

Fig. 1 Rectangular Plate Loaded With Parabolically Distributed Forces

[1] Research Physicist, Portland Cement Association. Mem. A.S.M.E.

[2] A series divided into a series of even functions and a series of odd functions is still considered as a single series in the present discussion.

Presented at the National Meeting of the Applied Mechanics Division, Chicago, Ill., June 16-17, 1944, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

Rectangular Plate

The method will now be demonstrated by solving for the stresses in the rectangular plate shown in Fig. 1. This particular problem was selected because of its relative simplicity and because it has been discussed several times in the literature (1),[3] (2), (3).[4] The fact that it is the simplest of the problems for which the usual methods fail probably accounts for the amount of attention it has received.

Detailed steps by which the correct particular solutions are obtained for each series need not be given here;[5] however, it may be verified by substitution that the following equations for stresses satisfy the appropriate differential equations[6] for all values of the constants A_n, B_m, α_n, and β_m.

$$\sigma_x = S + \sum_{n=1}^{\infty} \frac{A_n \cos \alpha_n y}{\cosh \alpha_n a} [\alpha_n x \sinh \alpha_n x - (1 + \alpha_n a \coth \alpha_n a) \cosh \alpha_n x] - \sum_{m=1}^{\infty} \frac{B_m \cos \beta_m x}{\cosh \beta_m b} [\beta_m y \sinh \beta_m y + (1 - \beta_m b \coth \beta_m b) \cosh \beta_m y] \quad [1]$$

$$\sigma_y = - \sum_{n=1}^{\infty} \frac{A_n \cos \alpha_n y}{\cosh \alpha_n a} [\alpha_n x \sinh \alpha_n x + (1 - \alpha_n a \coth \alpha_n a) \cosh \alpha_n x]$$

[3] The numbers in parentheses refer to the list of references given at the end of the paper.

[4] The paper by Winslow, which was presented at the Fourth International Congress of Applied Mechanics, is of interest because in it he concludes:

"1 For the simple arrangement of loading . . . the fundamental stress and strain relations of the elastic theory, when applied with mathematical precision, are inadequate and fail to give a stress solution.

"2 Therefore, in general, this mathematical theory of elasticity cannot lead to complete stress solutions which satisfy all boundary conditions (except in certain instances in which the conditions happen to be sufficiently reduced in complexity)."

Winslow's proof that a solution was impossible was based upon results he obtained by expanding certain functions of a complex variable about the corners of the plate. This was an error because those functions are in general discontinuous at the corners and, therefore, the expansion is not permissible.

[5] These solutions may be composed from the elementary forms given in the Appendix, or, since the boundary conditions are expressed in terms of stresses alone, these solutions are as readily obtained by means of a stress function (4).

[6] The differential equations are (4)

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} = 0, \qquad \frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau_{xy}}{\partial x} = 0, \qquad \nabla^2(\sigma_x + \sigma_y) = 0$$

The first two are the equilibrium equations and the third is the compatibility equation. The third is necessary when the equilibrium equations are expressed in terms of stresses but not necessary when they are expressed in terms of displacements.

Throughout this paper the nomenclature is that used by Timoshenko in his "Theory of Elasticity" (1).

$$+ \sum_{m=1}^{\infty} \frac{B_m \cos \beta_m x}{\cosh \beta_m b} [\beta_m y \sinh \beta_m y - (1 + \beta_m b \coth \beta_m b) \cosh \beta_m y] \quad [2]$$

$$\tau_{xy} = \sum_{n=1}^{\infty} \frac{A_n \sin \alpha_n y}{\cosh \alpha_n a} [\alpha_n a \coth \alpha_n a \sinh \alpha_n x - \alpha_n x \cosh \alpha_n x]$$

$$+ \sum_{m=1}^{\infty} \frac{B_m \sin \beta_m x}{\cosh \beta_m b} [\beta_m b \coth \beta_m b \sinh \beta_m y - \beta_m y \cosh \beta_m y] \quad [3]$$

The stress τ_{xy} will be zero at the edges $x = \pm a$ if $\beta_m = \frac{m\pi}{a}$, and this stress will also be zero at the edges $y = \pm b$ if $\alpha_n = \frac{n\pi}{b}$.

The substitution of $\sigma_y = 0$ and $y = \pm b$ into Equation [2] gives

$$\sum_{n=1}^{\infty} \frac{(-1)^n A_n}{\cosh \alpha_n a} [\alpha_n x \sinh \alpha_n x + (1 - \alpha_n a \coth \alpha_n a) \cosh \alpha_n x]$$

$$= \sum_{m=1}^{\infty} B_m [\beta_m b (\tanh \beta_m b - \coth \beta_m b) - 1] \cos \beta_m x \quad [4]$$

and the substitution of $\sigma_x = \frac{3}{2} S \left[1 - \left(\frac{y}{b}\right)^2\right]$ and $x = \pm a$ into Equation [1] gives

$$\frac{3}{2} S \left[1 - \left(\frac{y}{b}\right)^2\right] + \sum_{m=1}^{\infty} \frac{(-1)^m B_m}{\cosh \beta_m b} [\beta_m y \sinh \beta_m y + (1 - \beta_m b \coth \beta_m b) \cosh \beta_m y]$$

$$= S + \sum_{n=1}^{\infty} A_n [\alpha_n a (\tanh \alpha_n a - \coth \alpha_n a) - 1] \cos \alpha_n y \quad [5]$$

It is thus apparent that the A series was chosen to give a Fourier-series expression in the equation for σ_x at $x = \pm a$ and the B series was chosen so as to give a Fourier-series expression in the equation for σ_y at $y = \pm b$.

Equations for the coefficients A_n and B_m will now be determined in the usual manner. The multiplication of both sides of Equation [4] by $\cos \beta_n x \, dx$ and integration from $-a$ to $+a$ shows that

$$B_m = \frac{\sum_{n=1}^{\infty} (-1)^{n+m-1} \frac{4}{m\pi} \frac{na}{mb} \frac{\tanh \frac{n\pi a}{b}}{\left\{1 + \left(\frac{na}{mb}\right)^2\right\}^2} A_n}{1 + \frac{m\pi b}{a} \left(\coth \frac{m\pi b}{a} - \tanh \frac{m\pi b}{a}\right)} \quad [6]$$

Treating Equation [5] in a similar manner shows that

$$A_n = \frac{\frac{6S(-1)^n}{n^2\pi^2} + \sum_{m=1}^{\infty} (-1)^{n+m-1} \frac{4}{n\pi} \frac{mb}{na} \frac{\tanh \frac{m\pi b}{a}}{\left\{1 + \left(\frac{mb}{na}\right)^2\right\}^2} B_m}{1 + \frac{n\pi a}{b} \left(\coth \frac{n\pi a}{b} - \tanh \frac{n\pi a}{b}\right)} \quad [7]$$

When the A's and the B's have the values indicated by Equations [6] and [7], the boundary conditions for the normal stresses are exactly satisfied by Equations [1] and [2]. When the α's and the β's have the values just given, the boundary conditions for shear stresses are satisfied by Equation [3]. Thus all the arbitrary constants have now been determined, so that all three equations for stresses satisfy the boundary conditions.

The foregoing mathematical procedure is not entirely new, as it is very similar to that used by Taylor (5) and by Timoshenko (6) in problems of buckling and bending of rectangular plates.

Some indication of the rapidity of the convergence of the series is indicated by Figs. 2 and 3. Curve A in Fig. 2 shows the distribution of σ_x on the section $x = 0$ for a square plate ($a = b$) as computed when only the first term in each series is used. Curves B and C are obtained when two and four terms, respectively, are used in each series.

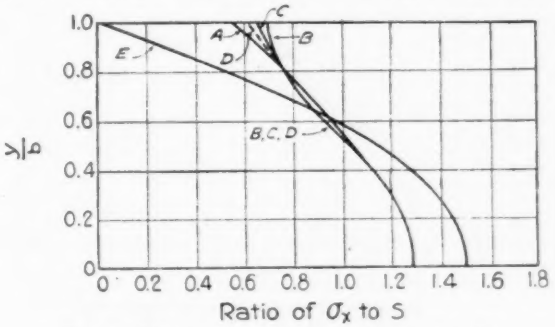

FIG. 2 DISTRIBUTION OF σ_x ON SECTION $x = 0$

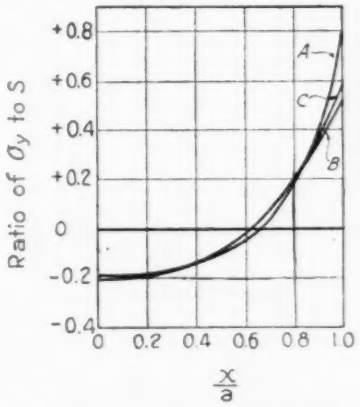

FIG. 3 DISTRIBUTION OF σ_y ON SECTION $y = 0$

For comparison, curve[7] D is shown, giving the distribution as computed by the energy method when three terms are used in the appropriate series (1). All four curves are practically alike except near the boundary $y = b$, indicating that each series requires only one term to give sufficient accuracy, except near the boundary. Similar results are indicated in Fig. 3: Curves A, B, and C show the distribution of σ_y on the section $y = 0$ as computed when one, two, and four terms, respectively, are used in each series.

Rectangular Plate Under Concentrated Loads. For a rectangular plate loaded with two equal and opposite concentrated forces, as shown in Fig. 4, the mathematical development is just like that previously given except that the boundary stress σ_x at $x = \pm a$ is

$$S + 2S \sum_{n=1}^{\infty} \cos \frac{n\pi y}{b}$$

[7] Curve E shows the parabolic distribution at $x = \pm a$.

This change necessitates a corresponding change in Equation [5], and $-2S$ replaces $\frac{6S(-1)^n}{n^2\pi^2}$ in Equation [7].[8]

Curves A, B, and C, Fig. 5, show the distribution of σ_y upon the section $y = 0$ for a square plate as computed when one, two, and four terms, respectively, are used in each series.

If an infinite number of terms were used in each series, the computed distribution would be approximately that given by the

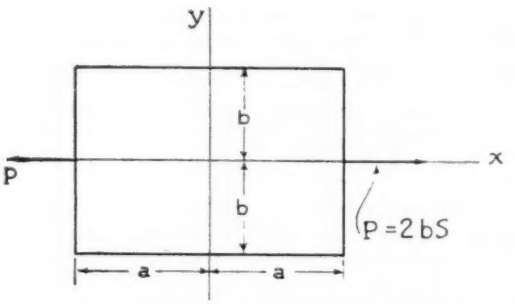

FIG. 4 PLATE LOADED WITH EQUAL AND OPPOSITE CONCENTRATED FORCES

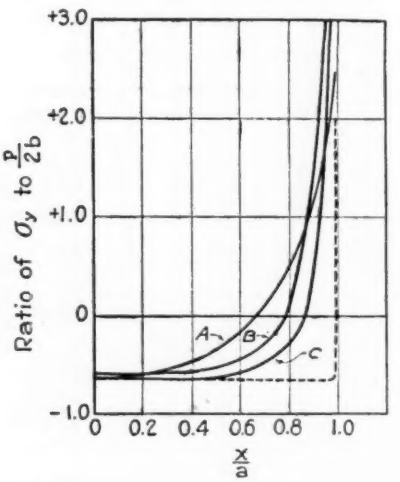

FIG. 5 DISTRIBUTION OF σ_y ON SECTION $y = 0$

dotted curve, i.e., $\sigma_y \approx -\frac{P}{\pi b}$ for all values of x except $x = \pm a$, where it is plus infinity.[9] The slower convergence in this problem is due to the slow convergence of Fourier series when discontinuous functions are represented by them. As is often true with Fourier analysis, the formal derivations are as simple when the boundary conditions are given by discontinuous functions as when given by simple algebraic functions.

For the problem just discussed, the energy method as used by Timoshenko and others is as usable as the method of this paper. However, the Fourier method is also applicable for any specified distribution of loads or displacements, whereas the energy method appears to be unsatisfactory when displacements are specified and may be inconvenient to use when the distribution of loading cannot be represented by a simple algebraic expression.

[8] For the boundary stress, $\sigma_x = f(y)$ at $x = \pm a$, this term in Equation [7] becomes

$$-\frac{1}{b}\int_{-b} f(y) \cos \frac{n\pi y}{b}\, dy$$

where $f(y)$ is an even function of y.

[9] The distribution of stress on this section of a square plate should be approximately the same as that upon the corresponding section of a circular disk (7). Goodier indicates a slightly different distribution of stress near the edges $x = \pm a$ (2).

CIRCULAR CYLINDER UNDER AXIAL COMPRESSION—FILON'S PROBLEM

To show how the method can be used when displacements are specified at part but not all of the boundary, the problem of a cylinder with given displacements at the ends will be considered. The example will be that of a cylinder loaded in compression, the loading being similar to that produced by the ordinary testing machine. In the usual testing of a cylinder, the cylinder is compressed longitudinally, as shown in Fig. 6. As it shortens, it tends to expand radially. Frictional forces at the planes of contact between the cylinder and the testing machine tend to prevent this expansion and also tend to make the ends concave. However, the rigidity of the testing machine keeps the ends approximately plane and in doing so gives rise to nonuniformity in the forces normal to the ends, the intensity of the normal forces being greater near the periphery than in the central part.

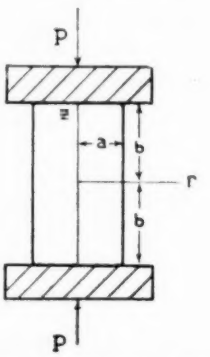

FIG. 6 CYLINDER COMPRESSED LONGITUDINALLY

The conditions just described are approximately represented by the following four boundary conditions:

I The shear stress τ_{rz} is zero at the cylindrical boundary $r = a$.

II The normal stress σ_r is zero at the cylindrical boundary $r = a$.

III The ends remain plane while being subjected to a resultant axial compressive force P.

IV The ends do not expand at any point, i.e., radial slipping at the planes of contact with the testing machine does not occur.

A series of particular solutions (the A-series to follow) can be found which satisfies conditions I and IV and gives a Fourier-Bessel expression for the vertical displacement at $z = \pm b$, and thus condition III can be met by the proper choice of Fourier-Bessel coefficients. This series alone will not satisfy condition II because of radial stresses at $r = a$. A second series (the B-series to follow) can be found which also satisfies conditions I and IV and gives a Fourier-series expression for the stress σ_r at $r = a$.

Without details as to how these particular solutions are chosen, the following equations for the radial displacement u and the vertical displacement w are given:

$$u = \sum_{n=0,1}^{\infty} \frac{A_n J_1(\beta_n r)}{\cosh \beta_n b} [z \sinh \beta_n z - b \tanh \beta_n b \cosh \beta_n z] + \sum_{m=1}^{\infty} \frac{B_m \cos \alpha_m z}{i J_1(i\alpha_m a)} \left[r J_0(i\alpha_m r) + \left(\frac{\lambda + 2G}{(\lambda + G)\alpha_m a} - \frac{J_0(i\alpha_m a)}{i J_1(i\alpha_m a)} \right) a i J_1(i\alpha_m r) \right] \quad [8]$$

$$w = \sum_{n=0,1}^{\infty} \frac{A_n J_0(\beta_n r)}{\cosh \beta_n b}\left[\left(\frac{\lambda + 3G}{\lambda + G} + \tanh \beta_n b\right) b \sinh \beta_n z - z \cosh \beta_n z\right] + \sum_{m=1}^{\infty} \frac{B_m \sin \alpha_m z}{iJ_1(i\alpha_m a)}\left[riJ_1(i\alpha_m r) - \left(\frac{\lambda + 2G}{(\lambda + G)\alpha_m a} + \frac{J_0(i\alpha_m a)}{iJ_1(i\alpha_m a)}\right) aJ_0(i\alpha_m r)\right] \quad \ldots [9]$$

Equations [8] and [9] satisfy the appropriate equations of equilibrium[10] for all values of the constants A_n, B_m, β_n, and α_m. The relations between the stresses and the displacements are

$$\sigma_r = \lambda\left(\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z}\right) + 2G\frac{\partial u}{\partial r} \quad \ldots [10]$$

$$\sigma_\theta = \lambda\left(\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z}\right) + 2G\frac{u}{r} \quad \ldots [11]$$

$$\sigma_z = \lambda\left(\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z}\right) + 2G\frac{\partial w}{\partial z} \quad \ldots [12]$$

$$\tau_{rz} = G\left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial r}\right) \quad \ldots [13]$$

The substitution of Equations [8] and [9] into Equations [10] to [13] gives

$$\frac{\sigma_r}{2G} = \sum_{n=0,1}^{\infty} \frac{A_n}{\cosh \beta_n b}\left[\left\{\left(\frac{\lambda}{\lambda + G} - \beta_n b \tanh \beta_n b\right)\cosh \beta_n z + \beta_n z \sinh \beta_n z\right\} J_0(\beta_n r) + \left\{\beta_n b \tanh \beta_n b \cosh \beta_n z - \beta_n z \sinh \beta_n z\right\}\frac{J_1(\beta_n r)}{\beta_n r}\right] - \sum_{m=1}^{\infty} \frac{B_m \cos \alpha_m z}{iJ_1(i\alpha_m a)}\left[i\alpha_m r J_1(i\alpha_m r) + \left(1 - \frac{\alpha_m a J_0(i\alpha_m a)}{iJ_1(i\alpha_m a)}\right) J_0(i\alpha_m r) + \left(\frac{\lambda + 2G}{\lambda + G} - \frac{\alpha_m a J_0(i\alpha_m a)}{iJ_1(i\alpha_m a)}\right)\frac{iJ_1(i\alpha_m r)}{\alpha_m r}\right] \quad \ldots [14]$$

$$\frac{\sigma_\theta}{2G} = \sum_{n=0,1}^{\infty} \frac{A_n}{\cosh \beta_n b}\left[\frac{\lambda}{\lambda + G}\cosh \beta_n z J_0(\beta_n r) - \left\{\beta_n b \tanh \beta_n b \cosh \beta_n z - \beta_n z \sinh \beta_n z\right\}\frac{J_1(\beta_n r)}{\beta_n r}\right] + \sum_{m=1}^{\infty} \frac{B_m \cos \alpha_m z}{iJ_1(i\alpha_m a)}\left[\frac{G}{\lambda + G} J_0(i\alpha_m r) + \left(\frac{\lambda + 2G}{\lambda + G} - \frac{\alpha_m a J_0(i\alpha_m a)}{iJ_1(i\alpha_m a)}\right)\frac{iJ_1(i\alpha_m r)}{\alpha_m r}\right] \quad \ldots [15]$$

[10] These equations are as follows:

$$G\left(\nabla^2 u - \frac{u}{r^2}\right) + (\lambda + G)\frac{\partial}{\partial r}\left(\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z}\right) = 0$$

$$G\nabla^2 w + (\lambda + G)\frac{\partial}{\partial z}\left(\frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial w}{\partial z}\right) = 0$$

$$\frac{\sigma_z}{2G} = \sum_{n=0,1}^{\infty} \frac{A_n J_0(\beta_n r)}{\cosh \beta_n b}\left[\left(\frac{\lambda + 2G}{\lambda + G} + \beta_n b \tanh \beta_n b\right)\cosh \beta_n z - \beta_n z \sinh \beta_n z\right] + \sum_{m=1}^{\infty} \frac{B_m \cos \alpha_m z}{iJ_1(i\alpha_m a)}\left[i\alpha_m r J_1(i\alpha_m r) - \left(2 + \frac{\alpha_m a J_0(i\alpha_m a)}{iJ_1(i\alpha_m a)}\right) J_0(i\alpha_m r)\right] \quad \ldots [16]$$

$$\frac{\tau_{rz}}{2G} = \sum_{n=0,1}^{\infty} \frac{A_n J_1(\beta_n r)}{\cosh \beta_n b}\left[\beta_n z \cosh \beta_n z - \left(\frac{G}{\lambda + G} + \beta_n b \tanh \beta_n b\right)\sinh \beta_n z\right] + \sum_{m=1}^{\infty} \frac{B_m \sin \alpha_m z}{iJ_1(i\alpha_m a)}\left[\frac{\alpha_m a J_0(i\alpha_m a) iJ_1(i\alpha_m r)}{iJ_1(i\alpha_m a)} - \alpha_m r J_0(i\alpha_m r)\right] \quad \ldots [17]$$

Boundary condition I (the shear stress τ_{rz} is zero at the boundary $r = a$) is satisfied by making

$$J_1(\beta_n a) = 0 \quad \ldots [18]$$

Boundary condition IV (no radial displacement at the ends) is satisfied by making

$$\cos \alpha_m b = 0 \quad \ldots [19]$$

The usual Fourier analysis shows that boundary condition II (the normal stress σ_r is zero at the boundary $r = a$) is satisfied if the B's have the values given by[11]

$$B_m = \frac{\dfrac{2b}{a}\displaystyle\sum_{n=0,1}^{\infty} \frac{A_n J_0(\beta_n a)\left(\dfrac{\lambda}{\lambda + G} - \dfrac{2}{1 + \left(\dfrac{\alpha_m}{\beta_n}\right)^2}\right)}{(\beta_n b)^2\left[1 + \left(\dfrac{\alpha_m}{\beta_n}\right)^2\right]}}{(-1)^{m-1}\left[1 - \left\{\dfrac{J_0(i\alpha_m a)}{iJ_1(i\alpha_m a)}\right\}^2 + \dfrac{\lambda + 2G}{(\lambda + G)(\alpha_m a)^2}\right]} \quad \ldots [20]$$

and that part of boundary condition III which requires that the ends remain plane is satisfied if the A's other than A_0 have the values given by

$$A_n = \frac{\dfrac{2a}{b}\displaystyle\sum_{m=1}^{\infty} \frac{(-1)^m B_m\left(\dfrac{\lambda + 2G}{\lambda + G} - \dfrac{2}{1 + \left(\dfrac{\beta_n}{\alpha_m}\right)^2}\right)}{(\alpha_m a)^2\left[1 + \left(\dfrac{\beta_n}{\alpha_m}\right)^2\right]}}{\left[\left(\dfrac{\lambda + 3G}{\lambda + G}\right)\dfrac{\tanh \beta_n b}{\beta_n b} - \dfrac{1}{\cosh^2 \beta_n b}\right] J_0(\beta_n a)} \quad \ldots [21]$$

The remaining part of condition III, which requires that the

[11] Equation [20], which gives the value of the B's that make $\sigma_r = 0$ at $r = a$, is obtained by setting $r = a$ and $\sigma_r = 0$ in Equation [14], multiplying both sides by $\cos \alpha_n z\, dz$, and integrating between $-b$ and $+b$. Equation [21], which gives the values of the A's that make the ends plane, is obtained by setting $z = b$ and w equal to a constant in Equation [9], multiplying both sides by $rJ_0(\beta_n r)dr$, and integrating between 0 and a.

resultant force be P, is satisfied if the first term of the A series A_0 has the value given by

$$A_0 = -\frac{\lambda + G}{2G(\lambda + 2G)} \frac{P}{\pi a^2} \quad [22]$$

This may be verified by substituting σ_z from Equation [16] into the following equation for P

$$P = -2\pi \int_0^a \sigma_z r\, dr \quad [23]$$

Equations [14] to [23] suffice for the determination of stresses, to any accuracy desired, for all parts of the cylinder except the edges $r = a$, $z = \pm b$ where the stresses are discontinuous. The stresses are discontinuous at the edges because the assumed boundary requirements in regard to the curved surface $r = a$ and the plane ends $z = \pm b$ are different here. According to condition II the stress σ_r must be zero at $r = a$ whereas condition IV that the ends do not slip means that $\sigma_r = \sigma_z = \frac{\mu}{1 - \mu} \sigma_z$ at the plane ends.[12] This discontinuity in σ_r leads to discontinuity in the shear stress τ_{rz} and to higher principal stresses in this region than elsewhere.

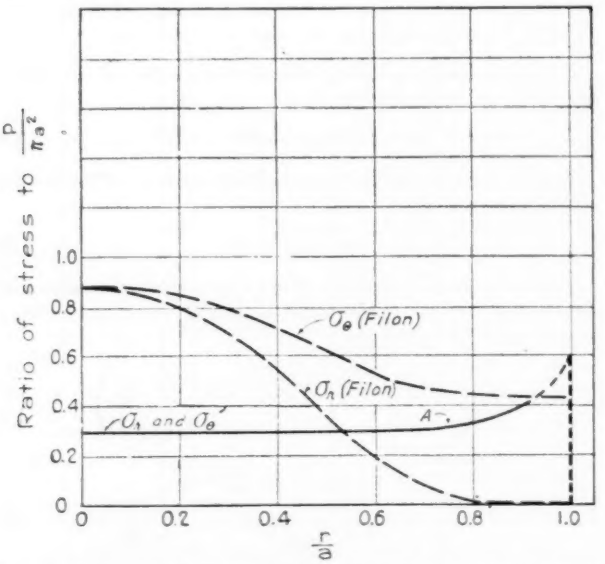

FIG. 7 DISTRIBUTION OF RADIAL STRESS σ_r AND TANGENTIAL STRESS σ_θ AT $z = b$ AS COMPUTED BY FILON AND AS COMPUTED BY THE METHOD OF THIS PAPER
(Filon's values are for $b/a = \pi/3$ whereas other values are for $b = a$, a = radius, $2b$ = length.)

Curve A, Fig. 7, shows the distribution, as given by the foregoing equations, of σ_r and σ_θ at the plane $z = b$ for a length-diameter ratio of 1.0 and a Poisson's ratio of 0.25. The curve is shown dashed for values near the edge of the cylinder because an insufficient number of terms was used in the computations for good

[12] If the radial displacement is zero everywhere at the ends, then the radial strain

$$\frac{1}{E}[\sigma_r - \mu\sigma_\theta - \mu\sigma_z] = 0$$

and the tangential strain

$$\frac{1}{E}[\sigma_\theta - \mu\sigma_r - \mu\sigma_z] = 0$$

Therefore $\sigma_r = \sigma_\theta = \frac{\mu}{1 - \mu} \sigma_z$

where $\mu = \frac{\lambda}{2(\lambda + G)}$

is Poisson's ratio.

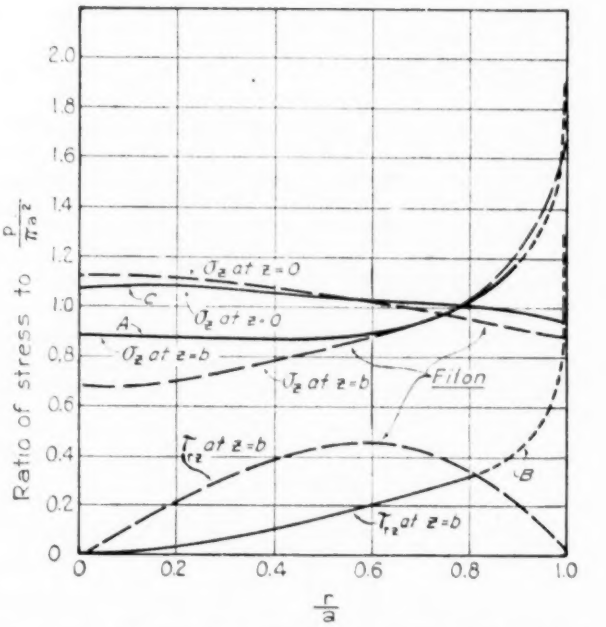

FIG. 8 DISTRIBUTION OF NORMAL STRESS σ_z AND SHEAR STRESS τ_r ON END OF CYLINDER AND OF σ_z AT CENTRAL SECTION $z = 0$ AS COMPUTED BY FILON AND AS FOUND BY THE METHOD OF THIS PAPER
(Filon's values are for $b/a = \pi/3$ whereas other values are for $b = a$, a = radius, $2b$ = length.)

accuracy in this region. In fact, the convergence is very slow for stresses at all points of the end boundary; therefore, methods applicable to slowly converging alternating series were used for computing points on the solid portion of this curve.

The distributions of the boundary forces at the ends (σ_z and τ_{rz} at the plane $z = b$) are shown by curves A and B, Fig. 8. Both boundary forces increase as the edge is reached. The maximum value of σ_z is believed to be less than $\frac{1}{1 - 2\mu}$ times its average value, but no estimate of the maximum value of τ_{rz} has been made.

Curve C, Fig. 8, shows the distribution of σ_z at the central plane $z = 0$. Points on this curve were computed readily because convergence was very good. For example, at $r = 0$, $z = 0$, σ_z is found to be $-1.100 \frac{P}{\pi a^2}$ when the series terminate with A_1 and B_1, and $-1.076 \frac{P}{\pi a^2}$, $-1.079 \frac{P}{\pi a^2}$, and $-1.079 \frac{P}{\pi a^2}$ as one, two, and three additional terms, respectively, are added to each series.

Filon's Solution. Also shown in Figs. 7 and 8 are corresponding distributions of stresses, as determined by Filon (8), who considered this problem at some length.[13] He was unable to obtain a solution meeting all boundary conditions but gave a solution which he considered to be approximately correct. His solution satisfies the differential equations and meets all boundary conditions except condition IV that the ends do not expand at any point. According to his solution, all points on the ends except those on the perimeter are displaced toward the center. This radial movement was due primarily to an incorrect distribution of tangential forces across the ends. His τ_{rz} curve in Fig. 8 differs appreciably from the correct curve.

Although values given by Filon's solution for stresses at the ends differ appreciably from the correct values given by the

[13] Filon used a length-diameter ratio of $\pi/3$ and a Poisson's ratio of 0.25 in his computations. His values would have been only slightly different if he had used a length-diameter ratio of 1.0.

Fourier method, the difference is small near the center of the cylinder. This tendency of Filon's solution to approach the correct solution as points at greater distances away from the ends are considered is in agreement with the principle of Saint Venant.

Number and Form of Series of Particular Solutions. Because of symmetry and because components of either stresses or displacements were zero at certain surfaces in the problems of the rectangular plate and circular cylinder, only two series of particular solutions were needed for each problem. More will be needed when more general boundary conditions are specified. The number and form for each that should be used will depend upon the conditions specified and the choice of co-ordinate axes and will have to be determined for each separate problem. However, in order that the series be convergent for all points in the interior, it is usually necessary to place the origin of the axes at the center of the body.

The particular solutions used in any given series may be composed from certain elementary forms of particular solutions. These elementary forms are given in the Appendix for:

1 Problems of axial symmetry in the cylindrical co-ordinates r and z.

2 Problems of plane strain or plane stress in the rectangular co-ordinates x and y.

3 Three-dimensional problems in the rectangular co-ordinates x, y, and z.

Three-Dimensional Problems

To show how the method may be used for three-dimensional problems, the preliminary steps in solving for stresses in a rectangular prism of dimensions $2a \times 2b \times 2c$ will be indicated. The origin of rectangular co-ordinates will be taken at the center of the prism. The only loading will be $\sigma_z = f(x, y)$, an even function of both x and y, at the planes $z = \pm c$.

Consider the following A-series of particular solutions for displacements.

$$u = \sum_{n=0}^{\infty}\sum_{m=0}^{\infty} \frac{A_{nm} \sin \alpha_n x \cos \beta_m y}{\gamma^2_{nm} c \cosh \gamma_{nm} c} \left[\alpha_n z \sinh \gamma_{nm} z - \left(\alpha_n c \coth \gamma_{nm} c - \frac{G}{\lambda + G} \frac{\alpha_n}{\gamma_{nm}} \right) \cosh \gamma_{nm} z \right]$$

$$v = \sum_{n=0}^{\infty}\sum_{m=0}^{\infty} \frac{A_{nm} \cos \alpha_n x \sin \beta_m y}{\gamma^2_{nm} c \cosh \gamma_{nm} c} \left[\beta_m z \sinh \gamma_{nm} z - \left(\beta_m c \coth \gamma_{nm} c - \frac{G}{\lambda + G} \frac{\beta_m}{\gamma_{nm}} \right) \cosh \gamma_{nm} z \right]$$

$$w = -\sum_{n=0}^{\infty}\sum_{m=0}^{\infty} \frac{A_{nm} \cos \alpha_n x \cos \beta_m y}{\gamma^2_{nm} c \cosh \gamma_{nm} c} \left[\gamma_{nm} z \cosh \gamma_{nm} z - \left(\gamma_{nm} c \coth {}_{nm}\gamma c - \frac{\lambda + 2G}{\lambda + G} \right) \sinh \gamma_{nm} z \right]$$

where γ_{nm} is written for $(\alpha^2_n + \beta^2_m)^{1/2}$.

The foregoing equations for displacements satisfy the appropriate differential equations for all values of the constants A_{nm}, α_n, and β_m.[14]

[14] These differential Equations [9] are as follows:

$$G\Delta^2 u + (\lambda + G) \frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right) = 0$$

$$G\Delta^2 v + (\lambda + G) \frac{\partial}{\partial y}\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right) = 0$$

$$G\Delta^2 w + (\lambda + G) \frac{\partial}{\partial z}\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right) = 0$$

By setting $\alpha_n = \frac{n\pi}{a}$ and $\beta_m = \frac{m\pi}{b}$ all tangential components of boundary forces will be zero ($\tau_{xy} = 0$ at $x = \pm a$ and $y = \pm b$; $\tau_{xz} = 0$ at $x = \pm a$ and $z = \pm c$; and $\tau_{yz} = 0$ at $y = \pm b$ and $z = \pm c$) and the normal boundary force at the planes $z = \pm c$ (σ_z at $z = \pm c$) will be given by the double Fourier series[15]

$$\frac{\sigma_z}{2G} = \sum_{n=0}^{\infty}\sum_{m=0}^{\infty} A_{nm} \left[\frac{2}{\gamma_{nm} c} + \coth \gamma_{nm} c - \tanh \gamma_{nm} c \right] \cos \alpha_n x \cos \beta_m y$$

There will also be normal boundary forces on the planes $x = \pm a$ and $y = \pm b$.

Two more series similar to the foregoing A series may be written such that one, say a B series, gives a double Fourier-series expression for σ_x at $x = \pm a$ and the other, say, a C series, a similar expression for σ_y at $y = \pm b$. The procedure of determining equations for the coefficients of each of these three series so that all boundary conditions are rigorously satisfied is very similar to that for the two-dimensional problem, and resulting equations are very similar to Equations [6] and [7]. To finish the solution all that is necessary is to take the steps indicated.

Appendix

Elementary forms of particular solutions for displacements in elastic bodies are as follows:

1 *In the Cylindrical Co-Ordinates r and z:*

(A) $u = \frac{1}{\alpha} J_1(\alpha r) \begin{Bmatrix} \sinh \alpha z \\ \cosh \alpha z \end{Bmatrix}$ *

$$w = -\frac{1}{\alpha} J_0(\alpha r) \begin{Bmatrix} \cosh \alpha z \\ \sinh \alpha z \end{Bmatrix}$$

(B) $u = z J_1(\alpha r) \begin{Bmatrix} \sinh \alpha z \\ \cosh \alpha z \end{Bmatrix}$

$$w = -\frac{1}{\alpha} J_0(\alpha r) \begin{Bmatrix} [\alpha z \cosh \alpha z - \frac{\lambda + 3G}{\lambda + G} \sinh \alpha z] \\ [\alpha z \sinh \alpha z - \frac{\lambda + 3G}{\lambda + G} \cosh \alpha z] \end{Bmatrix}$$

(C) $u = \frac{1}{\alpha} i J_1(i\alpha r) \begin{Bmatrix} \sin \alpha z \\ \cos \alpha z \end{Bmatrix}$

$$w = \frac{1}{\alpha} J_0(i\alpha r) \begin{Bmatrix} -\cos \alpha z \\ \sin \alpha z \end{Bmatrix}$$

(D) $u = r J_0(i\alpha r) \begin{Bmatrix} \sin \alpha z \\ \cos \alpha z \end{Bmatrix}$

[15] The stresses are obtained from the displacements by the formulas (9)

$$\sigma_x = 2G \frac{\partial u}{\partial x} + \lambda \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right) \qquad \tau_{xz} = G\left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right)$$

$$\sigma_y = 2G \frac{\partial v}{\partial y} + \lambda \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right) \qquad \tau_{xy} = G\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)$$

$$\sigma_z = 2G \frac{\partial w}{\partial z} + \lambda \left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}\right) \qquad \tau_{yz} = G\left(\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}\right)$$

* Either term in the bracket may be used provided that, when the upper term is used in the expression for u, the upper term is used in the expression for w, etc.

$$w = \frac{1}{\alpha}\left[i\alpha r\, J_1(i\alpha r) - 2\,\frac{\lambda + 2G}{\lambda + G}\, J_0(i\alpha r)\right] \begin{Bmatrix} -\cos \alpha z \\ \sin \alpha z \end{Bmatrix}$$

2 *In the Rectangular Co-ordinates x and y:*

$$(A)\quad u = \frac{1}{\alpha} \begin{Bmatrix} \sin \alpha x \\ \cos \alpha x \end{Bmatrix} \begin{Bmatrix} \sinh \alpha y \\ \cosh \alpha y \end{Bmatrix} \dagger$$

$$v = \frac{1}{\alpha} \begin{Bmatrix} -\cos \alpha x \\ \sin \alpha x \end{Bmatrix} \begin{Bmatrix} \cosh \alpha y \\ \sinh \alpha y \end{Bmatrix}$$

$$(B)\quad u = y \begin{Bmatrix} \sin \alpha x \\ \cos \alpha x \end{Bmatrix} \begin{Bmatrix} \sinh \alpha y \\ \cosh \alpha y \end{Bmatrix}$$

$$v = \frac{1}{\alpha} \begin{Bmatrix} -\cos \alpha x \\ \sin \alpha x \end{Bmatrix} \begin{Bmatrix} [\alpha y \cosh \alpha y - K \sinh \alpha y] \\ [\alpha y \sinh \alpha y - K \cosh \alpha y] \end{Bmatrix}$$

where $K = 3 - 4\,\mu$ for plane strain and $K = \dfrac{3 - \mu}{1 + \mu}$ for plane stress.

Two more forms, one similar to (A), and one similar to (B), are readily obtained by transposition of x and y and u and v.

3 *In the Rectangular Co-ordinates x, y, and z:*

$$(A)\quad u = \frac{1}{\alpha} \begin{Bmatrix} \sin \alpha x \\ \cos \alpha x \end{Bmatrix} \begin{Bmatrix} \sin \beta y \\ \cos \beta y \end{Bmatrix} \begin{Bmatrix} \sinh \gamma z \\ \cosh \gamma z \end{Bmatrix}$$

$$v = 0$$

$$w = \frac{1}{\gamma} \begin{Bmatrix} -\cos \alpha x \\ \sin \alpha x \end{Bmatrix} \begin{Bmatrix} \sin \beta y \\ \cos \beta y \end{Bmatrix} \begin{Bmatrix} \cosh \gamma z \\ \sinh \gamma z \end{Bmatrix}$$

† Either term may be taken from each bracket.

$$(B)\quad u = \frac{\alpha z}{\gamma} \begin{Bmatrix} \sin \alpha x \\ -\cos \alpha x \end{Bmatrix} \begin{Bmatrix} \sin \beta y \\ \cos \beta y \end{Bmatrix} \begin{Bmatrix} \sinh \gamma z \\ \cosh \gamma z \end{Bmatrix}$$

$$v = \frac{\beta z}{\gamma} \begin{Bmatrix} \cos \alpha x \\ \sin \alpha x \end{Bmatrix} \begin{Bmatrix} -\cos \beta y \\ \sin \beta y \end{Bmatrix} \begin{Bmatrix} \sinh \gamma z \\ \cosh \gamma z \end{Bmatrix}$$

$$w = \begin{Bmatrix} \cos \alpha x \\ \sin \alpha x \end{Bmatrix} \begin{Bmatrix} \sin \beta y \\ \cos \beta y \end{Bmatrix} \begin{Bmatrix} \left[-z \sinh \gamma z + \dfrac{\lambda + 3G}{\lambda + G} \dfrac{\cosh \gamma z}{\gamma} \right] \\ \left[-z \cosh \gamma z + \dfrac{\lambda + 3G}{\lambda + G} \dfrac{\sinh \gamma z}{\gamma} \right] \end{Bmatrix}$$

where $\gamma = (\alpha^2 + \beta^2)^{1/2}$.

Seven more forms, five similar to (A) and two similar to (B), are readily obtained by permutation of x, y, z, accompanied by a corresponding permutation of u, v, w.

Analysis of the Valverde Thermostat

By A. M. WAHL,[1] EAST PITTSBURGH, PA.

In this paper, a method based on the theory of initially curved bars axially loaded is developed for calculating snapping temperatures and stresses in a new type of thermostat known as the Valverde thermostat. For facilitating practical use of the derived formulas, curves are given by means of which the effect of dimensional changes on the free snapping or buckling temperatures may easily be evaluated. The analysis has been found useful in the practical design of thermostats of this type.

Introduction

A TYPE of thermostat which has been coming into extensive use in recent years is one known as the Valverde thermostat.[2] Essentially the thermostat consists of three strips of bimetal, an inner and two outer strips, as shown in Fig. 1. In manufacturing the thermostat the outer strips are crimped by means of a crimping machine. This tends to shorten their effective lengths thus putting them in tension. At the same time the inner strip is put in compression causing it to deflect still more. Thus when cold the thermostat has the shape shown in Fig. 1, the inner strip having a larger chord height[3] than the outer strip. The strips are so curved that the high-expansion component of the bimetal is on the concave side. An illustration of the strip thermostat itself is shown in Fig. 2, while a view of the unit assembled into a switch is shown in Fig. 3.

In operation, as the thermostat is heated both the inner and outer strips tend to straighten out. However, the inner strip being in compression tends to resist this process. As the heating continues both the compression load on the inner strip and the moment at its ends increase until, at a certain critical temperature, both inner and outer strips snap over as indicated by the dashed lines of Fig. 4. This temperature will be called the "upper critical" temperature. If now the thermostat is cooled, the curvature of the strips tends to decrease in the opposite direction until, at a certain temperature (which may be far below the upper critical temperature), the strips suddenly snap back to the positions indicated by the full lines of Fig. 4. This temperature will be called the "lower critical" temperature. These temperatures apply only to the thermostat when free, as shown in Fig. 1.

In actual practice the thermostat may be incorporated into a switch by means of various methods. In one of these, Fig. 5, the inner strip is fastened to the frame carrying the contacts as shown. One end of the thermostat carries the contacts while the other end may be rotated by means of an arm and an adjusting screw. This rotation makes it possible to vary the opening or closing temperatures through a considerable range while at the

[3] The maximum distance between the center line of the strip and the line or chord connecting its ends is known as the "chord height."

Presented at the National Meeting of the Applied Mechanics Division, Cambridge, Mass., June 19-20, 1942, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until October 10, 1944, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

same time the differential between these temperatures is kept relatively small.

Among the advantages of this type of thermostat, as compared with other types, the following may be mentioned: (1) Lower temperature differentials are possible; (2) lower stresses are present, resulting in longer life; (3) less wastage of bimetal occurs than in the case of a disk type since the Valverde type may be cut directly from strips of bimetal.

In the present paper, the analysis will be limited to the determination of the upper and lower critical temperatures and stresses of the free thermostat as contrasted to the assembled thermostat of Fig. 5. The effects of various design changes, such as length, depth, and number of crimps, initial curvature of the strips, etc., will also be investigated.

Method of Analysis

Essentially the method of analysis used involves the theory of buckling of initially curved bars axially loaded.[4] It also involves the application of methods used by Timoshenko in the calculation of the buckling temperatures of initially curved bimetal strips with hinged ends.[5] In Timoshenko's analysis, the axial force required to prevent buckling of the strip was determined as well as the force actually developed. The point at which buckling occurs was taken as that point at which these two forces became equal, i.e., at the instant of buckling or snap action the force required to prevent buckling is just equal to the force developed. In the present analysis, on the other hand, the point at which snap action occurs was taken as the point at which the derivative of the temperature with respect to deflection of the center strip becomes zero. (It may be shown that this latter criterion will also give results identical with those obtained from the method used by Timoshenko for the case of a single strip with hinged ends.)

Referring to Fig. 1, it will be assumed that the thermostat consists of two strips, an inner strip and an outer strip rigidly fastened together at their ends. (Actually, besides the inner strip there are two outer strips, but for purposes of analysis these may be considered as a single strip.) In addition, the further assumption is made that the two strips when free have initially the same mean curvature. In other words, it is assumed that if the strips were separated (say, by cutting slots in the ends), the initial curvature (or the chord height a_4 of Fig. 6) of the two strips would be the same. This assumption is not exact, but in many cases it is approximately realized in the manufacture of these thermostats. Where this condition does not hold, however, considerable deviation between the results of the theory and actual test results may be expected.

Assume now that the two strips are separated when cold, as indicated in Fig. 6(a) and (d). On the basis of our assumption that the initial free curvature of both strips is the same, both the inner and the outer strip will have the same initial chord height a_4 at room temperature t_0. On heating the two strips to a temperature t, if free, both of these strips will deflect by an amount a_0. Neglecting the effect of the slight difference in initial length produced by crimping, the expression for a_0 is[6]

$$a_0 = \frac{3}{16}\frac{l^2}{h}(\alpha_1 - \alpha_2)(t - t_0) \quad \ldots\ldots\ldots\ldots [1]$$

where

l = length of strip

h = bimetal thickness

α_1, α_2 = expansion coefficients of high and low side components of bimetal[7]

Thus when the two free strips are heated, the chord heights become equal to $a_2 = a_4 - a_0$, Fig. 6(b) and (e). Because of the crimping operation on the outer strip, the effective free length of the latter will be slightly less than that of the inner strip by an amount λ_1. This difference λ_1 depends upon the number and depth of the crimps. If it be assumed that the crimps are of sinusoidal form and that there are n half waves or crimps of depth a (Fig. 7), the value of λ_1 may be expressed approximately as

$$\lambda_1 = \frac{n^2\pi^2 a^2}{4l_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

where l_1 is the length of the crimped portion. This follows since the difference between arc and chord length of a flat sine wave of depth a and length l_2 is $\pi^2a^2/4l_2$.

The inner and outer strips, after being heated when free as shown in Fig. 6(b) and (e), may be thought of as being assembled to form a complete thermostat. To do this the outer strip must be extended by an amount λ_2' while the inner strip is compressed by an amount λ_2. The length of the inner strip then becomes $(l - \lambda_2)$, that of the outer strip $(l - \lambda_1 + \lambda_2')$ as indicated in Fig. 6

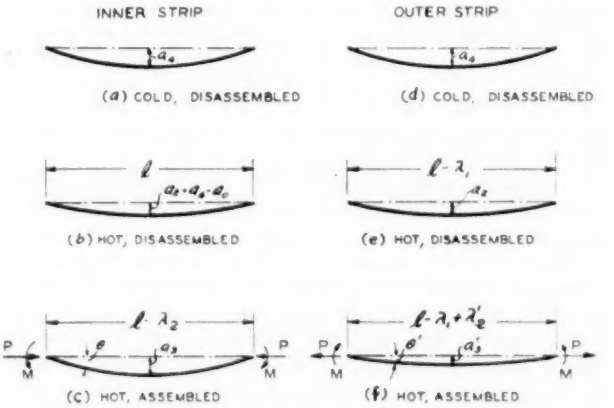

Fig. 6 Valverde-Thermostat Dimensions Under Various Conditions

(c) and (f). On the inner strip a compressive force P and a moment M will act as indicated, while on the outer strip the same moment and a tension force P will act. These forces and moments will change the chord heights of the two strips to a_3 and a_3' as indicated.

The problem now is to determine the deflections produced by an axial force and moment acting at the ends of an initially curved bar. Assuming that the bar has the initial shape of a flat sine wave, by solving the differential equation of the deflection curve of an initially curved bar with proper boundary conditions, the equations for the deflection y and derivative dy/dz at any point at a distance z from the end of the strip may be expressed as[4]

$$y = \frac{M}{P}\left\{1 - \cos kz - \frac{1 - \cos kl}{\sin kl}\sin kz\right\} + \frac{a_2}{1 - \beta}\sin\frac{\pi z}{l} \quad \ldots\ldots [3]$$

[4] For a discussion of problems involving initially curved bars refer to "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Company, Inc., New York, N. Y., 1936.

[5] "Analysis of Bimetal Thermostats," by S. Timoshenko, *Journal of the Optical Society of America*, vol. 11, 1925, pp. 233–255.

[6] This equation was derived by Timoshenko; see ref. (5).

[7] For data on bimetal properties refer to the paper, "Thermostatic Bimetals," by S. G. Eskin and J. R. Fritze, Trans. A.S.M.E., vol. 62, 1940, pp. 433–440. A bibliography on the subject is also given with this paper.

$$\frac{dy}{dz} = \frac{Mk}{P}\left\{\sin kz - \frac{1-\cos kl}{\sin kl}\cos kz\right\} + \frac{\pi a_2}{l(1-\beta)}\cos\frac{\pi z}{l} \quad [4]$$

where

$$k = \sqrt{\frac{P}{EI}}; \qquad \beta = \frac{Pl^2}{EI\pi^2}$$

E = modulus of elasticity of material

I = moment of inertia (this may be taken as $bh^3/12$ where b = width, h = thickness)

The axial deflection λ_2 of the inner strip, due to the force P and moment M, is found as follows: The difference λ_y between the arc and the chord length of the deflected beam is first calculated. From this is subtracted the initial difference λ_i between arc and chord length, while to this is added the direct compression λ_c due to the axial force P. Thus the relative axial movement λ_2 of the ends of the inner strip due to the force P and moment M becomes

$$\lambda_2 = \lambda_y - \lambda_i + \lambda_c \quad [5]$$

But for a flat curve

$$\lambda_y = \frac{1}{2}\int_0^l \left(\frac{dy}{dz}\right)^2 dz \quad [6]$$

where dy/dz is given by Equation [4].

Also, since the initial shape of the bar is a flat sine wave of height a_2

$$\lambda_i = \frac{\pi^2 a_2^2}{4l} \quad [7]$$

The deflection due to direct compression is

$$\lambda_c = c_1\frac{Pl}{Ebh} \quad [8]$$

where c_1 is a factor taking into account the additional flexibility due to crimping. In applying this formula to the inner strip, c_1 is taken as unity since there are no crimps, but in the case of the outer strip the added flexibility due to the crimping must be considered.

Substituting the value of $\frac{dy}{dz}$ given by Equation [4] in Equation [6], integrating and using Equations [6], [7], and [8] in Equation [5], the following expression is obtained

$$\lambda_2 = \frac{\pi^2 a_2^2(2-\beta)\beta}{4l(\beta-1)^2} + \frac{M^2 x}{2P^2 l}\left\{\frac{1-\cos x}{\sin x}\right\}\left\{\frac{x}{\sin x} - 1\right\} - \frac{M}{P}\frac{2\pi a_2\beta}{l(\beta-1)^2} + c_1\frac{Pl}{Ebh} \quad [9]$$

where $x = kl$.

To find λ_2', the axial deflection between the ends of the outer strip due to the tension force P and the moment M, this same formula may be used except that P and M are taken as negative, while β', k', b', and x' (which apply to the outer strip) are used instead of β, k, b, and x. In this case, b' = width of outer strip, $I' = \frac{b'h^3}{12}$, $k' = \sqrt{\frac{P}{EI'}}$, $x' = k'l$, $\beta' = \frac{Pl^2}{EI'\pi^2}$. After simplification and elimination of imaginary quantities this gives

$$\lambda_2' = \frac{\pi^2 a_2^2\beta'(2+\beta')}{4l(\beta'+1)^2} - \frac{M^2 x'}{2P^2 l}\left\{\frac{1-\cosh x'}{\sinh x'}\right\}\left\{\frac{x'}{\sinh x'} - 1\right\} - \frac{M}{P}\frac{2\pi a_2\beta'}{l(\beta'+1)^2} + c_1'\frac{Pl}{Eb'h} \quad [10]$$

where c_1' is a factor to take into account the additional flexibility due to crimping of the outer strip.

From Fig. 6(*c*) and (*f*), since the two strips when assembled must have the same chord length, it follows that

$$l - \lambda_2 = l - \lambda_1 + \lambda_2'$$

or

$$\lambda_1 = \lambda_2 + \lambda_2' \quad [11]$$

Using Equations [9] and [10] in Equation [11] and taking $\epsilon = \lambda_1/l$, $\mu^2 = b/b'$, $\beta' = \mu^2\beta$, the following equation is obtained

$$\epsilon = \frac{\lambda_1}{l} = \frac{\pi^2}{4l^2}a_2^2\beta\left\{\frac{2-\beta}{(\beta-1)^2} + \frac{\mu^2(2+\mu^2\beta)}{(\mu^2\beta+1)^2}\right\} + \frac{M^2 x\psi_0}{2P^2 l^2} - \frac{M(2\pi a_2\beta)}{Pl^2}\left\{\frac{1}{(\beta-1)^2} + \frac{\mu^2}{(\mu^2\beta+1)^2}\right\} + \frac{P}{Ebh}(c_1 + \mu^2 c_1') \quad [12]$$

where

$$\psi_0 = \left(\frac{1-\cos x}{\sin x}\right)\left(\frac{x}{\sin x} - 1\right) - \frac{\mu(1-\cosh \mu x)}{\sinh \mu x}\left(\frac{\mu x}{\sinh \mu x} - 1\right) \quad [13]$$

The ratio $\frac{M}{P}$ which occurs in this equation is found from the condition that the slopes θ and θ' (Fig. 6) at the ends of the inner and outer strips, respectively, must be equal.

From Equation [4], the slope θ at the ends of the inner strip is

$$\theta = \left(\frac{dy}{dz}\right)_{z=0} = -\frac{Mx}{Pl}\left(\frac{1-\cos x}{\sin x}\right) + \frac{\pi}{l}\frac{a_2}{1-\beta} \quad [14]$$

The same expression may be used for θ by reversing the signs of P and M and using β', x' instead of β, x. After simplification this yields

$$\theta' = -\frac{Mx'}{Pl}\left\{\frac{1-\cosh x'}{\sinh x'}\right\} + \frac{\pi}{l}\frac{a_2}{1+\beta'} \quad [15]$$

Equating [14] and [15] we find

$$\frac{M}{Pl} = -\frac{\pi a_2\psi_2}{l} = -\frac{\pi(a_4 - a_0)\psi_2}{l} \quad [16]$$

where

$$\psi_2 = \frac{1}{x\psi_1}\left\{\frac{1}{\beta-1} + \frac{1}{\mu^2\beta+1}\right\} \quad [17]$$

$$\psi_1 = \frac{1-\cos x}{\sin x} - \frac{\mu(1-\cosh \mu x)}{\sinh \mu x} \quad [18]$$

Substituting Equation [16] in Equation [12], we have

$$\epsilon = \frac{a_2^2}{l^2}F(x) + c_3 x^2 \quad [19]$$

where

$$c_3 = (c_1 + \mu^2 c_1')\frac{h^2}{12\,l^2} \quad [20]$$

$$F(x) = \pi^2(A_1 + A_2 + A_3) \quad [21]$$

where

$$A_1 = \beta/4\left\{\frac{2-\beta}{(\beta-1)^2} + \frac{\mu^2(2+\mu^2\beta)}{(\mu^2\beta+1)^2}\right\} \quad [22]$$

$$A_2 = \frac{\psi_0}{2x\psi_1^2}\left\{\frac{1}{\beta-1} + \frac{1}{\mu^2\beta+1}\right\}^2 \quad [23]$$

$$A_3 = \frac{2\beta}{\pi\psi_1}\left\{\frac{1}{(\beta-1)^2}+\frac{\mu^2}{(\mu^2\beta+1)^2}\right\}\left\{\frac{1}{\beta-1}+\frac{1}{\mu^2\beta+1}\right\}$$

and

$$\beta = \pi^2/\pi^2.$$

The chord height $a_2 = (a_4 - a_0) = a_1\left(\frac{a_0}{a_1} - r\right)$ where a_1 = initial chord height of inner strip when assembled, at room temperature t_0 and $r = \frac{a_0}{a_1}$, a_0 being given by Equation [1]. Solving Equation [19] for a_2 and dividing by a_1, we find

$$\frac{a_4}{a_1} - r = \pm\frac{l}{a_1}\sqrt{c_2}\sqrt{\frac{\epsilon/c_2 - x^2}{F(x)}} = \pm f_2(x) \quad [25]$$

or solving for r

$$r = \frac{a_4}{a_1} \pm f_2(x) \quad [26]$$

where

$$f_2(x) = \frac{l}{a_1}\sqrt{c_2}\sqrt{\frac{\epsilon/c_2 - x^2}{F(x)}} \quad [27]$$

From Equation [3], putting $z = l/2$ the chord height a_3 of the inner strip Fig. 6(*c*) is obtained

$$a_3 = -\frac{M}{P}\psi_3 + \frac{a_2}{1-\beta} \quad [28]$$

where

$$\psi_3 = \left(\frac{1-\cos x}{\sin x}\right)\sin\frac{x}{2} - \left(1-\cos\frac{x}{2}\right) \quad [29]$$

Substituting the value of $\frac{M}{P}$ given by Equation [16] in Equation [28], we find

$$\delta = \frac{a_3}{a_1} = \left(\frac{a_4}{a_1} - r\right) f_1(x) = \pm f_2(x)\cdot f_1(x) \quad [30]$$

where $f_2(x)$ is given by Equation [27] and

$$f_1(x) = \pi\psi_2\psi_3 - \frac{1}{\beta-1} \quad [31]$$

Solving Equation [30] for r, the following expression results

$$r = \frac{a_4}{a_1} - \frac{\delta}{f_1(x)} \quad [32]$$

Equation [30] gives δ as a function of x while Equation [26] gives r as a function of x. This makes it possible to plot δ as a function of r. Since δ is directly proportional to the chord height a_3 of the center strip while r is proportional to the temperature rise $(t - t_0)$ above room temperature, a curve of the chord height a_3 versus temperature t may be plotted as shown in Fig. 8. This curve has the rather peculiar shape *ABCED*, the dashed portion between *C* and *E* being unstable.

The operation of the thermostat may perhaps be better understood by reference to Fig. 8. At room temperature t_0 the chord height a_3 of the inner strip corresponds to point *A*. As the thermostat is heated, the chord height a_3 decreases until at a temperature t_{cr1} (point *C*) the thermostat snaps over and the chord height of the inner strip becomes negative (point *D*). At point *C* the derivative $dt/da_3 = 0$ and instability occurs, because the elastic resistance of the strip is not great enough to prevent the tendency toward curvature change induced in the bimetal by the temperature increase.

As the thermostat is now cooled, the chord height decreases along the curve from *D* to *E*. At a temperature t_{cr2} (point *E*), snap action occurs in the opposite direction, and the chord height again changes to a positive value (point *B*). At point *E* the derivative dt/da_3 is also zero.

Since r and δ are linear functions of t and a_3, respectively, the condition $dt/da_3 = 0$ is equivalent to $dr/d\delta = 0$. Therefore, to find the value of x at which buckling occurs, the latter condition may be used.

From Equation [32] since a_4/a_1 is constant

$$\frac{dr}{d\delta} = -\frac{f_1(x) - \delta\frac{df_1}{dx}\frac{dx}{d\delta}}{[f_1(x)]^2} \quad [33]$$

Since $f_1(x) \neq 0$ this becomes zero when

$$f_1(x) = \frac{\delta\frac{df_1}{dx}}{\frac{d\delta}{dx}} \quad [34]$$

Substituting $\delta = f_1(x)f_2(x)$ in this we find

$$f_1(x) = \frac{f_1(x)f_2(x)\frac{df_1}{dx}}{f_2(x)\frac{df_1}{dx} + f_1(x)\frac{df_2}{dx}} \quad [35]$$

To satisfy this equation, the following equation must hold

$$f_1(x)\frac{df_2}{dx} = 0 \quad [36]$$

Since $f_1(x) \neq 0$ this means that $\frac{df_2}{dx} = 0$, and using Equation [25], the condition to be satisfied when buckling occurs becomes

$$\frac{dF(x)}{dx} = \frac{-2xF(x)}{\epsilon/c_2 - x^2} \quad [37]$$

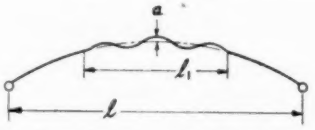

FIG. 7 CRIMPING OF BIMETAL STRIP

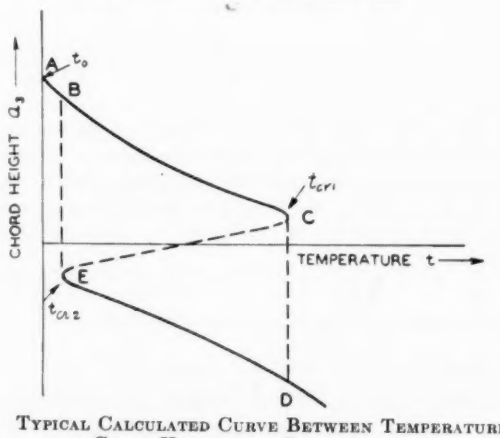

FIG. 8 TYPICAL CALCULATED CURVE BETWEEN TEMPERATURE AND CHORD HEIGHT a_3 OF INNER STRIP
(Snap-action occurs at points *C* and *E*.)

Because of the complicated nature of the function $F(x)$, the following procedure was used in solving this equation: The values of $F(x)$ and dF/dx were computed as functions of x both for $\mu^2 = 1$ and $\mu^2 = 0.8$, the latter value corresponding to a center strip of width equal to 0.8 the combined width of the outer strips. Knowing these values, by substitution in Equation [37], the critical value x_{cr} at which buckling will occur may be found. The results show values of x_{cr} as functions of ϵ/c_2 and are given in Fig. 9 for the range $x_{cr} = 6.8$ to 8.9. It may be noted that there is not much difference between the cases where $\mu^2 = 1$ and $\mu^2 = 0.8$.

Calculation of Critical or Snapping Temperatures

Having found the critical value x_{cr}, the critical values of r may be obtained from Equation [26]. The ratio $r = a_0/a_1$ may be considered as a temperature ratio, i.e., the ratio of the temperature change required to deflect the free strip by an amount a_0 to that required to deflect it by an amount a_1. Since r is a linear function of temperature, a determination of the critical values of r will also enable the determination of the critical temperatures. From Equation [26] it is seen that two values of r are possible, an upper value corresponding to the positive sign (the upper critical temperature), and a lower value corresponding to the negative sign. Thus to find the upper critical value r_{cr1}, the value of x_{cr} determined from Equation [37], or the curve of Fig. 9 is substituted in Equation [26]. This gives

$$r_{cr1} = \frac{a_4}{a_1} + \frac{l}{a_1}\sqrt{c_2}\sqrt{\frac{\epsilon/c_2 - x_{cr}^2}{F(x_{cr})}} \quad \ldots\ldots [38]$$

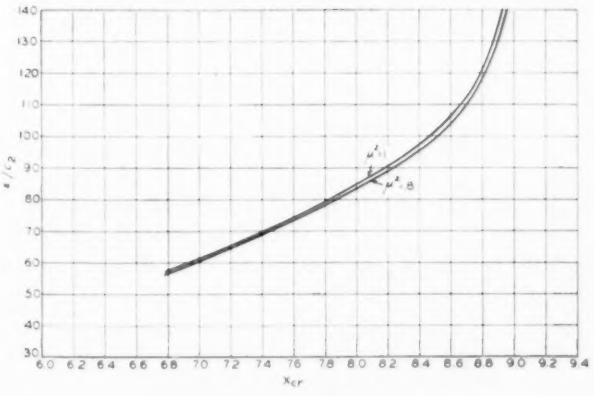

Fig. 9 Curve for Finding x_{cr}

Since x_{cr} is a function of ϵ/c_2 (Fig. 9), the term under the radical may be written

$$f(\epsilon/c_2) = \sqrt{\frac{\epsilon/c_2 - x_{cr}^2}{F(x_{cr})}} \quad \ldots\ldots [39]$$

Values of this function for a range of values of ϵ/c_2 have been plotted in Fig. 10 for $\mu^2 = 1$ and for $\mu^2 = 0.8$. Substituting Equation [39] in Equation [38], the upper-critical-temperature ratio becomes

$$r_{cr1} = \frac{a_4}{a_1} + \frac{l}{a_1}\sqrt{c_2}\, f(\epsilon/c_2) \quad \ldots\ldots [40]$$

The lower-critical-temperature ratio r_{cr2} (for buckling in a reverse direction) is obtained by using the negative sign in Equation [26]. This gives

$$r_{cr2} = \frac{a_4}{a_1} - \frac{l}{a_1}\sqrt{c_2}\, f(\epsilon/c_2) \quad \ldots\ldots [41]$$

Dividing both sides of Equation [1] by a_1 the temperature ratio r becomes

$$r = \frac{a_0}{a_1} = \frac{3}{16}\frac{l^2}{ha_1}(\alpha_1 - \alpha_2)(t - t_0) \quad \ldots\ldots [42]$$

The upper and lower-critical-temperature ratios r_{cr1} and r_{cr2} are obtained from this equation by substituting for t the upper and lower critical temperatures t_{cr1} and t_{cr2}, respectively. This gives

$$r_{cr1} = \frac{3}{16}\frac{l^2}{ha_1}(\alpha_1 - \alpha_2)(t_{cr1} - t_0) \quad \ldots\ldots [43]$$

$$r_{cr2} = \frac{3}{16}\frac{l^2}{ha_1}(\alpha_1 - \alpha_2)(t_{cr2} - t_0) \quad \ldots\ldots [44]$$

Solving these for t_{cr1} and t_{cr2}

$$t_{cr1} = t_0 + \frac{16\,ha_1 r_{cr1}}{3l^2(\alpha_1 - \alpha_2)} \quad \ldots\ldots [45]$$

$$t_{cr2} = t_0 + \frac{16\,ha_1 r_{cr2}}{3l^2(\alpha_1 - \alpha_2)} \quad \ldots\ldots [46]$$

The range between upper and lower critical temperatures is obtained by subtracting Equation [46] from Equation [45]. This gives

$$t_{cr1} - t_{cr2} = \frac{16\,ha_1}{3l^2}\left(\frac{r_{cr1} - r_{cr2}}{\alpha_1 - \alpha_2}\right) \quad \ldots\ldots [47]$$

Substituting in this the values of r_{cr1}, r_{cr2} and c_2 given by Equations [40], [41], and [20], we obtain

$$t_{cr1} - t_{cr2} = \frac{h^2 c}{l^2(\alpha_1 - \alpha_2)} \quad \ldots\ldots [48]$$

where

$$c = 3.09\sqrt{c_1 + \mu^2 c_1'}\, f(\epsilon/c_2) \quad \ldots\ldots [49]$$

Since the temperature range is directly proportional to c, this factor will be called the "temperature-range factor."

By adding Equations [45] and [46], and substituting values of r_{cr1} and r_{cr2} given by Equations [40] and [41], the average critical temperature becomes

$$t_{avg} = \frac{t_{cr1} + t_{cr2}}{2} = t_0 + \frac{16\,ha_4}{3l^2(\alpha_1 - \alpha_2)} \quad \ldots\ldots [50]$$

This indicates that the difference between the average critical temperature t_{avg} and room temperature t_0 is proportional to the free chord height a_4, to the thickness h, and inversely proportional to the square of the length and to the difference in expansion coefficients.

By solving Equations [48] and [50] for t_{cr1} and t_{cr2} we find

$$t_{cr1} = \frac{h^2}{2l^2(\alpha_1 - \alpha_2)}\left(c + \frac{32}{3}\frac{a_4}{h}\right) + t_0 \quad \ldots\ldots [51]$$

$$t_{cr2} = \frac{h^2}{2l^2(\alpha_1 - \alpha_2)}\left(\frac{32}{3}\frac{a_4}{h} - c\right) + t_0 \quad \ldots\ldots [52]$$

Since the inner strip is not crimped c_1 is unity. The flexibility factor c_1' to take into account the additional flexibility of the crimping may be calculated approximately by using as before the theory of initially curved bars axially loaded.[4] Assuming that the half wave length of the crimps l_1/n is small compared to l (Fig. 7) and that the amplitude a is small compared to l_1/n, by using this theory the expression for c_1' becomes approximately

$$c_1' = 1 + \frac{6a^2}{h^2}\frac{l_1}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots [53]$$

Using this expression, and the expression for $f(\epsilon/c_2)$ and λ_1 given by Equations [39] and [2], in Equation [49], the value of c can be determined. It is found that c is a function of the ratio a/h between wave amplitude a of the crimps and the bimetal thickness, of the ratio l_1/l between length of crimped portion and total length, of the ratio $\mu^2 = b/b'$, and of the number of crimps n. In Fig. 11 values of c have been plotted against ratios a/h for three crimps ($n = 3$) and various values of l_1/l, the widths of the two strips being assumed equal. (It should be noted that the amplitude a is only one half the total depth of the crimps.) Likewise in Fig. 12 similar curves are shown for five crimps ($n = 5$). By substituting values of c thus found in Equations [51] and [52], values of the upper and lower critical temperatures may be found.

An examination of Figs. 11 and 12 indicates that for a given number of crimps and a given bimetal thickness the value of c (and hence the range $t_{cr1} - t_{cr2}$) increases with increase in depth of crimping and with decrease in the ratio l_1/l between length of crimped portion to total length. Also the factor c increases with increase in number of crimps. From Equations [51] and [52], it may be seen that the upper critical temperature t_{cr1} increases with increase in h/l, c, and a_4/h while it decreases with increase in $(\alpha_1 - \alpha_2)$. On the other hand, the lower critical temperature t_{cr2} is decreased with increase in c, while it increases with the ratios h/l and a_4/h. If l, h, and $(\alpha_1 - \alpha_2)$ are given, the upper critical temperature may be increased by increasing c or a_4, while the lower critical temperature may be increased by increasing a_4 or by decreasing c.

Calculation of Stress

To calculate the stress during free operation of the thermostat the following procedure may be used: By solving Equation [16] for the moment M at the ends of the strip

$$M = -P\pi(a_4 - a_0)\psi_2 \quad \ldots\ldots\ldots\ldots\ldots [54]$$

It will be found the maximum value of the moment will occur when the load P reaches the critical value corresponding to x_{cr}. Taking $P = P_{cr}$ and $r = r_{cr1}$ corresponding to the positive direction of buckling and to t_{cr1}, the moment at the ends of the strip becomes

$$M_{cr} = -P_{cr}\pi a_1\left(\frac{a_4}{a_1} - r_{cr1}\right)\psi_{2cr} \quad \ldots\ldots\ldots\ldots [55]$$

In this ψ_{2cr} is obtained from Equation [17] using $x = x_{cr}$.

Substituting in this the value of r_{cr1} given by Equation [40] we find

$$M_{cr} = -P_{cr}l\pi\sqrt{c_2}\,\psi_{2cr}f(\epsilon/c_2) \quad \ldots\ldots\ldots\ldots [56]$$

The bending stress at the end is

$$\sigma_{sb} = \frac{6M_{cr}}{bh^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots [57]$$

Using Equation [56] in this, the stress becomes

$$\sigma_{sb} = \frac{\pi}{4\sqrt{3}}\frac{Eh^2}{l^2}x_{cr}^2\psi_{2cr}\sqrt{c_1 + \mu^2c_1'}\,f(\epsilon/c_2) \quad \ldots\ldots [58]$$

Substituting the value of c given by Equation [49] in Equation [48] and solving

$$\sqrt{c_1 + \mu^2c_1'}\,f(\epsilon/c_2) = (t_{cr1} - t_{cr2})(\alpha_1 - \alpha_2)\frac{l^2}{3.09h^2} \quad \ldots [59]$$

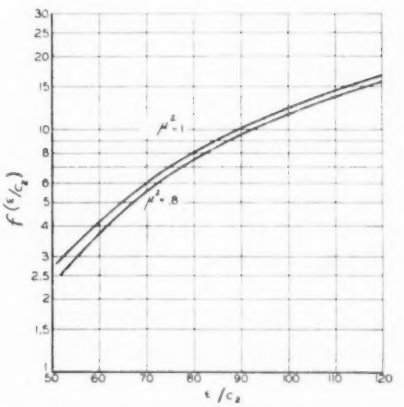

Fig. 10 Curve for Finding Function $f(\epsilon/c_2)$

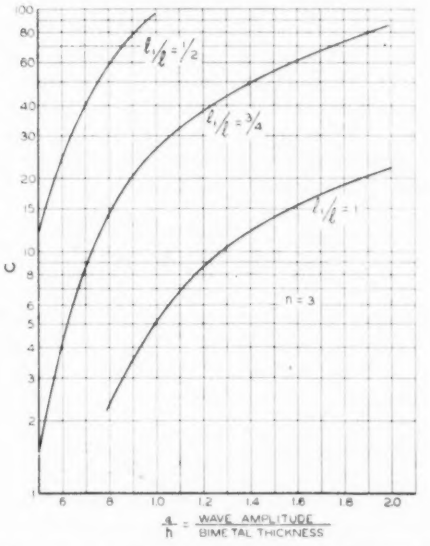

Fig. 11 Curves for Finding Temperature-Range Factor c ($n = 3$ and $b/b' = 1$.)

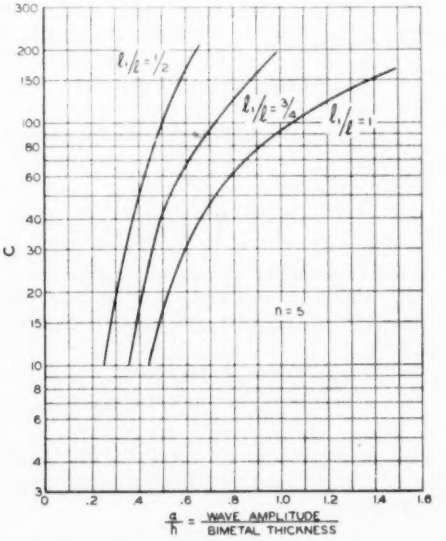

Fig. 12 Curves for Finding Temperature-Range Factor c ($n = 5$ and $b/b' = 1$.)

Using this expression in Equation [58], the stress may be expressed as[5]

$$\sigma_{sb} = c_3(t_{cr1} - t_{cr2})(\alpha_1 - \alpha_2)E \quad [60]$$

where

$$c_3 = 0.147 x_{cr}^2 \psi_{2cr} \quad [61]$$

Since ψ_{2cr} depends upon x_{cr}, which in turn depends upon ϵ/c_3 the factor c_3 may be plotted as a function of this quantity. This has been done in Fig. 13 for $\mu^2 = 1$ and $\mu^2 = 0.8$.

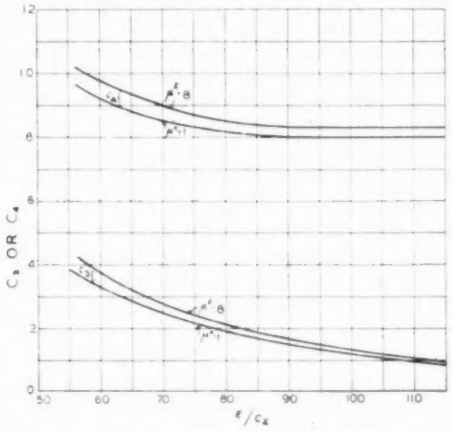

FIG. 13 CURVES FOR FINDING c_3 OR c

The direct compressive stress at the instant of buckling is

$$\sigma_c = \frac{P_{cr}}{bh} = \frac{Eh^2 x_{cr}^2}{12l^2} \quad [62]$$

This follows since $x_{cr}^2 = \dfrac{12\,Pl^2}{Ebh^3}$. In the usual case this stress will be considerably below the bending stress at the middle or end.

The bending stress at the middle of the inner strip at the instant when buckling occurs is

$$\sigma_{mb} = \frac{6(P_{cr}a_{3cr} - M_{cr})}{bh^2} \quad [63]$$

where a_{3cr} is the deflection of the inner strip at the instant of buckling obtained from Equation [28] by using $x = x_{cr}$. Substituting this value of a_{cr} in Equation [63] and simplifying as before, we obtain

$$\sigma_{mb} = c_4(t_{cr1} - t_{cr2})(\alpha_1 - \alpha_2)E \quad [64]$$

where

$$c_4 = \frac{0.462}{\pi^2} x_{cr}^2 \psi_{4cr} \quad [65]$$

and

$$\psi_{4cr} = \frac{1}{(x_{cr}^2/\pi^2) - 1} - \pi\psi_{2cr}(\psi_{2cr} + 1) \quad [66]$$

Values of c_4 have been plotted against ϵ/c_4 in Fig. 13, for $\mu^2 = 1$ and 0.8. Since c_4 is considerably greater than c_3, this indicates that the maximum stress under this condition of free buckling will occur in the middle of the strip.

It should be noted that in actual practice, where the thermostat is assembled in a manner similar to that shown in Fig. 5, a considerably lower stress range may actually exist in operation, as compared with that calculated from Equation [64].

CONCLUSION

By means of the formulas and curves given, the effect of such variables as depth and number of crimps, length and thickness of the bimetal strip, and initial chord height on the free snapping temperatures of the Valverde thermostat may be evaluated. When the thermostat is manufactured in such a way that the assumption made regarding equal free chord heights for the two strips is approximately realized, it may be expected that the theory will yield satisfactory results. Where this is not the case, however, considerable deviation between test and theory may result. In spite of these limitations, the theoretical results obtained in this manner have provided a useful guide in practical design.

ACKNOWLEDGMENT

The author is particularly indebted to Mr. P. R. Lee of the Westinghouse Electric & Manufacturing Company for much valuable practical information concerning the characteristics of the Valverde type of thermostat. He also wishes to acknowledge the helpful discussions on this subject which have been held with Prof. S. Timoshenko of Stanford University and Mr. R. E. Peterson of the Westinghouse Company.

[5] Stress concentration effects are neglected in the calculations.

Discussion

Increase of Stress With Permanent Strain and Stress-Strain Relations in Plastic State for Copper Under Combined Stresses[1]

R. G. Sturm.[2] It is rather significant that large strains such as those measured by the author appear to follow the same general trend as the very small plastic strains. As greater and greater permanent strains are considered, one would expect to find greater asymmetry resulting from the mechanical fibering of the metal in tubes. Recent work by E. Siebel and A. Maier[3] indicates that different metals have different degrees of anisotropy.

The use of Bailey's equation for strain rates as a basis for interpreting large strains is most interesting. If the relationship between strain rates and stresses is similar to the relationship between strains and stresses such that the author's Equation [19] is a true representation, one would expect to find an exponential relationship between the shear strains and the shear stresses. The shear-strain curves do not bear out this relationship but, on the other hand, the author's resulting curve between μ and ν follows very closely the same trend as the relationship between strains obtained by Taylor and Quinney using strains directly rather than strain rates.

Inasmuch as the stresses used by the author were always tensile, the effects of the normal stresses on the shearing stresses would be expected to be all in the same direction as noted by the author. If, however, the tubular specimens had been subjected to an axial compressive load at the same time internal pressure was applied, it is altogether possible that the deviation between μ and ν would be on the other side of the straight line $\mu = \nu$. In other words, the value of K instead of being greater than 3 might well be less than 3.

It seems to the writer that there must be a simpler expression for the relationships between normal stresses, shears, and strains. In this respect, the work of Siebel and Maier[3] has certain advantages. The author's work, on the other hand, tends to open the field to a greater latitude in possible explanations for strains under combined stress.

Author's Closure

The author wishes to thank Dr. Sturm for his discussion. His remarks are self-explaining and require no further comment. The author, however, would like to take this opportunity to rectify an oversight in the original paper. The dependence of the relationship between μ and ξ upon the exponent $n - 2m$ as shown in Fig. 6 was first described by Prof. G. Cook in his discussion of Bailey's paper (reference 10) and proper acknowledgment of this should have been included in the original text.

Closed Surge Tanks[1]

R. W. Angus.[2] The title of this paper does not convey a particularly clear idea of the matter treated, since a surge tank has an open top, while the corresponding vessel with closed top is more generally known as an air chamber. It is somewhat interesting to find this latter device under consideration again for the protection of pipe lines, for it has long been known that it is not efficient as an absorber of kinetic energy but has possibilities as far as potential energy is concerned. The number of power plants using the air chamber must be very small indeed, and for the protection of long pumping lines it has been superseded by much better equipment.

The writer does not understand what the author means in his third paragraph where he says, "The process of starting up is under control, and therefore can be arranged to cause less violent disturbances." Since the author refers to water power stations, the foregoing statement is scarcely correct, because the governor is so adjusted that it will take on load at practically the same rate as it will reject it, and the load changes from full to quarter load, for example, in practically the same time as it will change from quarter to full load.

It is this fact which is so important in the tank. During load rejection, the pipe line must of course be protected, which is not a very difficult thing to do; but when load is suddenly thrown on, a large volume of water must be available near the turbine so as to keep up the supply until the penstock and conduit velocities are accelerated to their proper values.

In a specific plant with differential surge tank, the latter is 60 ft in diam and holds water 35 ft deep at no load, and it is difficult to see how an air chamber could be made which could possibly perform the same duty in supplying water as this tank can. The air chamber therefore requires slow absorption of load, which is not generally possible in modern plants, although the Glenville turbine described by Mr. Pfau at the Annual Meeting, 1943, of the Society, has no tank of any kind but uses the very long closure time of 120 sec.

The author's statement at the end of the second paragraph is incorrect, in view of the fact that engineers have calculated the tanks many times and found their values to agree very closely with those actually observed. There appears to be no great difficulty in obtaining any degree of accuracy required by the "exceedingly laborious step-by-step method of integration," mentioned by the author, but which is, actually, not exceedingly laborious. Like any engineering problem, it requires concentration but enables all factors to be taken into account with great accuracy and does not take an unusually long time.

Mathematical formulas are of value in determining the approximate dimensions of surge tanks, and a good one has been given by R. D. Johnson.[3] This formula assumes the loss of head to vary as the square of the velocity, and after using it to get the first approximation to the size of the tank, the arithmetical method must be used in order to determine the corre-

sponding surges and to modify the size of the tank if necessary.

In 1937, several papers were presented dealing with the air chamber, one by L. Allievi,[4] and one by the writer;[5] other papers dealt with various phases of the same question. The solutions offered are not very tedious but do not include friction. The latter may be incorporated in the manner explained in various papers, including some by the writer.[6] Little would be gained by repeating this material. Mr. Allievi and others have suggested that the entrance of the air chamber may be so designed that the resistance to water entering it will be different from that leaving it, which has some merit.

Discharge lines from pumps may be much better protected by a suitable valve than by an air chamber, but in this case one has only to protect the pipe and machinery against fracture. There is no problem of sudden demand for water at the lower end of the pipe.

The very brief description of the author's apparatus leads one to question its accuracy. The writer has found that the history of the valve closure is very important in this type of problem. With the author's pipe the time of travel of the pressure wave is around $^1/_8$ sec, and it is very important to know whether this is exceeded or not. Curves of pressure rise plotted on a time base would also be helpful.

Author's Closure

The author thanks Professor Angus for his contribution but regrets the implication that the work was not worth doing. He thinks that the interest previously taken in the problem is a sufficient answer to that view. Step-by-step methods of calculation are usually regarded as undesirable, because, besides being lengthy, they suffer inherently from the possibility of cumulative error. His own experience has amply confirmed this opinion, therefore he ventured to suggest a direct method of computation. He agrees that the experiments are not as exhaustive as could be wished. War conditions, however, frustrated his intention of obtaining cinema pictures of the surges with the pressure gage and a clock in the field of view. A notable feature has been the smooth manner in which the air vessel brought the water to rest even when the damping disk was in position. No vestige of shock has been noticed.

Second Law of Thermodynamics for Changes of State and Quantity of Working Substance With Particular Reference to Steam Engines[1]

J. H. Keenan.[2] This paper is a useful contribution to the thermodynamics of the pure substance. Equation [1] was given by Gillespie and Coe[3] who restricted it to conditions in the absence of a discontinuity of pressure at the boundary which fluid crosses and in the absence of gravity, electricity, distortion of solid masses, and capillary tensions. The author should have stated equivalent restrictions.

The results of the first two applications of Equation [1] can be readily obtained by substituting a piston and a cylinder for the steady-flow compressor assumed in the paper and permitting fluid at pressure p_1 to follow the piston in its motion. The triangular area 1-2-3 becomes the net work that must be supplied from outside the fluid to the piston.

The most important item in the paper appears to be Equation [8*a*], which is the logical companion to Equation [1]. Despite the simplicity of its derivation, it seems that it has not been explicitly stated before. It shows that in an adiabatic process the entropy per unit mass within an enclosure does not change if the material introduced has the same enthalpy per unit mass as that already there.

The subject of "open systems" is an extremely important one which authors of engineering texts have been inclined to slight. The author will have performed a great service if he has succeeded in focusing the attention of a few engineers on the thermodynamic problem of flow under nonsteady conditions.

Closure by M. Jakob

The writer has been requested to prepare a closure to the foregoing discussion of the late Professor Zerkowitz's paper. He agrees with Professor Keenan's statement that the author's studies on "open systems" mean a valuable service to engineering. He would further like to mention that the author also dealt thoroughly with an important problemof two-phase open systems, namely, the storage of steam, in a publication of 1927, quoted in footnote 2 of Dr. Zerkowitz's paper.

The writer requests this opportunity to correct some typographical errors in the paper: P should be replaced by p in Equations [5] and [17]; the last term Gdv in footnote 3 should be replaced by Gdu; on page A-111, column 1, line 8, the symbol v is to be replaced by V.

Book Reviews

Modern Turbines

Modern Turbines. By Louis E. Newman, Allen Keller, John M. Lyons, Lawrence B. Wales, all of the General Electric Company. Edited by Louis E. Newman. John Wiley & Sons, Inc., New York, N. Y., 1944. Cloth, $5^1/_2 \times 8^3/_8$ in., 175 pages, 93 figs., $2.50.

Reviewed by C. Richard Soderberg[1]

THE latest addition to the "General Electric Series," which now comprises ten treatises on different aspects of power engineering, is a discussion of the steam turbine expressed in simple language without mathematical frills or scientific verbiage. It consists of nine well-coordinated chapters on all the basic aspects of the steam turbine and the electric generator.

The first three chapters, by Newman, give a summary of the fundamental aspects of turbine application, the range of operating conditions, and the use of the steam chart and tables of theoretical steam rates. Chapters four to six by Newman and Keller cover the main aspects of evaluating the performance of this multitude of turbine applications. Chapter seven by Newman is a

[1] Professor of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. Mem. A.S.M.E.

very useful discussion of the premises to be followed when a purchaser desires to estimate the effect upon a proposal of changes in capacity or operating conditions. Chapter eight by Wales and Newman is a clear and concise description of the basic features of turbine control. Chapter ten by Lyons gives a brief exposition of the fundamentals of electric generators. There is an Appendix abstracted from the "NEMA Turbine Generator Recommended Practices."

While the information presented is properly classified as General Electric catalog material it is strictly informative and free from sales propaganda. An impressive case is made for the great flexibility of the steam turbine as a prime mover, although it should perhaps be pointed out that this very flexibility is itself an indication of the complexity of the steam plant. For the 14 standard ratings of industrial turbines below 7500 kw, 112 different designs are necessary. These designs are still further diversified by the many combinations of inlet and exhaust conditions. The only practical solution is to assemble machines from a well-considered range of standard parts.

The book is highly recommended for those engineers who wish to become acquainted with the possibilities of the turbine as a tool in industrial power-plant planning without entering into the more complicated features of turbine design.

Introduction to Theory of Elasticity

AN INTRODUCTION TO THE THEORY OF ELASTICITY FOR ENGINEERS AND PHYSICISTS. By R. V. Southwell, Professor of Engineering Science in the University of Oxford. Second edition. Oxford University Press, New York, N. Y., 1941. Cloth, 6 × 9 in., v and 509 pp., 120 figs., $10.

REVIEWED BY C. RICHARD SODERBERG[1]

THE second edition of Southwell's "Theory of Elasticity" has now been in print for some time and has been available to American readers for more than a year. The departures from the first edition are only minor in character, consisting chiefly of additions relating to the author's own contributions to relaxation methods. These, however, are covered more fully in his book entitled "Relaxation Methods in Engineering Science." The new edition retains all of the careful, deliberate style of presentation which has become familiar to the many readers of the original "Theory of Elasticity." The background of style, nomenclature, and mode of presentation goes back to Love and Lord Rayleigh. To the American reader this style is a reminder of earlier usage and its relative strangeness to many of the younger men is a reminder of the strong influences of Russian and German writers in this field, which have been at work in America during the last twenty years. No criticism of the "Theory of Elasticity" is implied in this observation, rather, an apologetic feeling of regret that some efforts should be necessary to follow its nomenclature.

The "Theory of Elasticity" has particular value, because it includes not only the usual problems of elasticity but also the major problems of vibrations which often form the ulterior motive for the analysis of the elastic properties of systems. The central theme of the book is the energy method, and whenever practicable the solutions are derived through this medium. This consistency of approach is one of the many reasons for the appeal of the "Theory of Elasticity." As a result of this method of treatment the theorems of Castigliano, as well as the reciprocal theorem, play a very fundamental role. It is regretted by the reviewer that the treatment of these could not have been carried beyond the conventional form.

It is properly emphasized that Castigliano's theorems make no appeal to Hooke's law, but the situation is rather that Hooke's law has always obscured the true meaning of these theorems. For any relation between load P and deflection y, in which the previous history of loading is without influence, the first theorem of Castigliano refers to energy changes $y \cdot \delta P$, while the second deals with changes of the type $P \cdot \delta y$. The latter relate to the usual strain energy, while the former relate to what may be called "complementary strain energy." When Hooke's law is introduced into the picture these two energies become equal and are customarily identified with one another. In actual practice, the first theorem of Castigliano requires the strain energy to be expressed as a function of the forces while the second requires the strain energy as a function of the displacements.

In connection with problems of dynamics, such as in the case of vibrations of complicated systems with discrete mass particles, this dual point of view is no less important. Lagrange's equations of motion demand the strain energy in terms of the displacements, while most mechanical systems are more readily reduced by the first theorem of Castigliano, which requires the strain energy in terms of the forces. When the static properties of a mechanical system have been derived by means of the first theorem of Castigliano, therefore, the alternative formulation of the equations of motion, in which the inertia forces are directly incorporated in the force system, is much to be preferred. This is particularly so, because in this form approximate solutions may be reached by means of the simple and convenient iteration method, which is not so easily applicable to the conventional formulation. The relaxation method is presumably applicable to both methods of formulation, but at least in the reviewer's limited experience, the iteration method appears the simpler.

These remarks do not detract from the great value of the second edition of the "Theory of Elasticity" which like its predecessor will have a place as a valued reference for all who are interested in this important field.

Metals and Alloys Data Book

METALS AND ALLOYS DATA BOOK. By Samuel Hoyt, Technical Advisor of Battelle Memorial Institute. Published by Reinhold Publishing Corporation, New York, N. Y. Cloth, 7 × 10 in., 350 pages, 340 tables, $4.75.

REVIEWED BY PETER E. KYLE[2]

THE author points out in the preface that this book fills his need for a ready reference to the properties of metals and alloys. To the metallurgist, student, or engineer who has tried to find reference to properties of a specific alloy in the previously published literature, this compilation of data will at once appear most helpful. The data contained in this work are as reliable as could be obtained and rather complete information on the composition, structure, heat-treatment, and fabrication methods used is given for each metal and alloy tabulated.

The scope of the book is sufficiently broad to be of use to all users of metals and it includes properties of wrought steels, cast steels, stainless steels, cast irons, heat- and corrosion-resistant casting alloys, nonferrous alloys, and other alloys. The properties reported include tensile properties, hardness, hardenability, creep strength, work hardening, impact strengths, corrosion resistance, etc. Other information includes hardness conversion tables, hot hardness properties, S-curve data, heat contents, thermal-expansion coefficients, grain-size charts, test-specimen sizes, atomic data for the elements, and the usual tables of weights and measures, and conversion tables.

The author has provided an excellent table of contents and index which is so necessary if such a tremendous amount of information is to be made readily available to the reader.

Theory of Wire Drawing

By E. A. DAVIS[1] and S. J. DOKOS,[1] EAST PITTSBURGH, PA.

A theory of wire drawing is presented in which the force required to produce plastic deformation of a wire passing through a die may be determined. The calculations are based upon information obtained from an ordinary tension test of the material to be drawn. Unlike previous mathematical treatments where the metals were assumed to be ideally plastic, the strain-hardening of the wire being drawn is considered.

Nomenclature

The following nomenclature is used in the paper:

r_0 = initial radius of wire
r = outer radius of wire, variable along die
A_0, A_f = initial and final area of wire
A = cross-sectional area of wire, variable along die
ϵ_x, ϵ_t, ϵ_r = principal natural strains
σ_x, σ_t, σ_r = principal true stresses
γ_{tr}, γ_{rx}, γ_{xt} = principal natural shearing strains
τ_{tr}, τ_{rx}, τ_{xt} = principal shearing stresses
p = pressure exerted on wire by die
σ_0, τ_y = idealized yield stress
$\Omega = \frac{\partial \tau}{\partial \gamma}$ = coefficient of strain hardening in shear
F = force required to draw wire
μ = coefficient of friction between die and wire
α = one-half angle of die
$k = \frac{\mu}{\alpha}$

Introduction

An investigation by one of the authors is in progress to determine experimentally the values of the coefficient of friction at very high pressures and at various temperatures ranging from normal room temperatures to very high temperatures.[2] This project should furnish values of the friction in forging and metal-forming operations about which very little information exists. It was thought that the conditions encountered in wire-drawing would be of particular interest in this respect, since the forces could be experimentally measured without any difficulty. In the preliminary review of the literature it was found, however, that the theoretical information available was insufficient for computing the values of the coefficients of friction involved in wire-drawing. To facilitate the evaluation of these friction forces, the theory outlined in this paper is offered.

The force required to draw a wire through a die depends upon several factors, the two most important of which are the friction of the wire on the walls of the die and the resistance of the wire to plastic deformation. The latter factor will depend upon the stress-strain relations of the wire. In most previous mathematical treatments, the material to be drawn was assumed to be ideally plastic. An ideally plastic material has a definite yield point at which the material flows continuously without any increase in the applied stress. In the present paper the strain-hardening of the wire is considered, and the mathematical expressions used have been adjusted to take care of the large strains encountered in the process of wire drawing.

Previous Investigations

A large amount of experimental research in the drawing of wire has been done in the past, and, although it is not the purpose of this paper to make a critical review of the available literature, it may be well to refer to a few investigations which seem to have a direct bearing on the present work.

Thompson and Francis (1, 2)[3] have shown that the force necessary to draw wire is proportional to the reduction of area. This same relation has been found also by Giraud[4] and Brown.[4] In various graphs of drawing force versus reduction of area, they show that the experimental points fall on a straight line which will cut the force axis at some finite value. This seems to indicate that a certain force is required for no reduction of area. This feature will be discussed later. Thompson and Francis (2, 3) also show that a reduction in the drawing force is obtained if a back-tension of a considerable magnitude is applied.

Several investigators have attempted to analyze the wire-drawing problem from a mathematical standpoint. Probably the first work of this kind was done by Sachs (4). He obtained expressions for the force necessary to draw a wire through a given die and for the pressure and stress distribution along the die as the wire is being drawn. Horsburgh (5) has developed similar expressions which are comparable with those of Sachs. The theory as presented by Sachs will appear as a special case of the present development.

Siebel and Hühne (6) have shown, by means of engraved models, the strain distribution and the distortion of the individual cross sections of the material as it passes through the die. Thompson and Barton (7) have carried out photoelastic tests of various shaped dies. Although their tests were two-dimensional in character, they indicate clearly the directions of the principal stresses. How completely this method and the one used by Siebel and Hühne (6) agree with the conditions actually occurring in the wire-drawing process is somewhat questionable. However, it can be stated that, for the smaller angles of reduction, the distortion of the cross-sectional planes will be less and that, for a mathematical treatment, it will be convenient to assume that the original cross sections remain planes.

Theoretical Considerations

In the mathematical development which follows, it has been assumed:

(*a*) That the axial, radial, and tangential directions are principal directions.

[1] Research Engineer, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa.

[2] Funds for this purpose have been made available by the A.S.M.E. Special Research Committee on Plastic Flow of Metals under a grant received from the Engineering Foundation in New York through the A.S.M.E.

Presented at the National Meeting of the Applied Mechanics Division, Chicago, Ill., June 16–17, 1944, of The American Society of Mechanical Engineers.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1945, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

[4] Both references may be found in (1).

(*b*) That the axial tension stress is distributed evenly over the cross-sectional area.

(*c*) That the flow takes place according to some stress-strain relation which can be determined from a pure-tension test on the wire.

(*d*) That the range of speed used in wire-drawing is limited to such an extent that the speed effect can be neglected. This assumption has been checked experimentally by various investigators (2, 8).

Assumptions (*a*) and (*b*) are used purely for reasons of simplicity. To take into consideration the actual stress and strain distribution inside the deformed part of the wire would needlessly

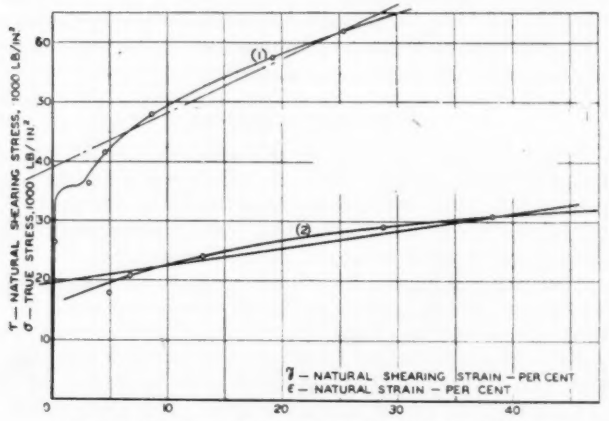

FIG. 1 TENSION DIAGRAMS FOR MILD-STEEL WIRE
(Curve 1, True stress versus natural strain. Curve 2, Natural shearing stress versus natural shearing strain for mild-steel wire.)

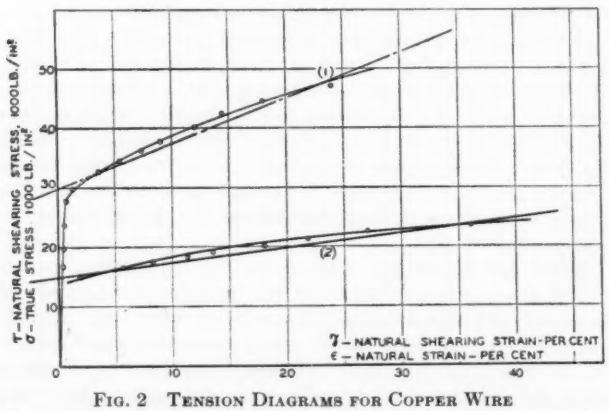

FIG. 2 TENSION DIAGRAMS FOR COPPER WIRE
(Curve 1, True stress versus natural strain. Curve 2, Natural shearing stress versus natural shearing strain for copper wire.)

complicate the problem and would probably render a solution impossible. Assumption (*c*) is based upon some recent work by one of the authors (9). In that paper it was shown that, for cases where there was no rotation of the principal axes of stress and where the ratio of the principal shear stresses did not change during the test, the maximum shear stress was given by the same function of the maximum shear strain regardless of the state of combined stress. It was also shown that a similar relation between the octahedral shearing stress τ_n and the octahedral shearing strain γ_n could be used. The agreement in both cases was not perfect, but was probably close enough for use in the present problem. From this it was assumed that either of the expressions, $\tau_{max} = f(\gamma_{max})$, or $\tau_n = f(\gamma_n)$, determined from a pure tension test, could be used in the analysis of wire drawing. Both cases will be developed.

The strains in the wire passing through the die will be determined by the shape of the die. The increments of the natural strains in the tangential and radial directions are

$$d\epsilon_t = \frac{dr}{r} \quad [1]$$

and

$$d\epsilon_r = \frac{dr}{r} \quad [2]$$

Since the sum of the natural principal strains is zero, the following equations are obtained for the strains

$$\epsilon_z = 2 \ln \frac{r_0}{r} \quad [3]$$

$$\epsilon_r = \epsilon_t = -\frac{\epsilon_z}{2} = \ln \frac{r_0}{r} \quad [4]$$

where r_0 is the original radius of the wire. One of the principal shearing strains $(\epsilon_t - \epsilon_r)$ is zero; the other two are equal in magnitude but opposite in sign. It follows from this symmetrical condition, then, that two of the principal shear stresses are equal but opposite in sign and that the radial and tangential stresses are equal.

Case 1: $\tau_{max} = f(\gamma_{max})$. The tension diagrams of two materials as examples are represented by Figs. 1 and 2. In some cases, due to the nature of the tension diagrams, the maximum shearing stress τ_{max} can be expressed by a power function of the maximum shearing strain γ_{max}

$$\tau_{max} = C (\gamma_{max})^{1/n} \quad [5]$$

where the exponent $\frac{1}{n}$ and C are material constants. In Equation [5] and in all subsequent equations, the elastic strains will be neglected. For a state of stress consisting of a tensile stress σ_z in the axial direction and equal stresses σ_r and σ_t in the perpendicular directions Equation [5] can be expressed in terms of the principal stresses and strains since

$$\tau_{max} = \frac{\sigma_r - \sigma_z}{2} \quad [6]$$

and

$$\gamma_{max} = \epsilon_r - \epsilon_z \quad [7]$$

Equation [5] can now be rewritten as

$$\frac{\sigma_r - \sigma_z}{2} = C \left(\epsilon_r - \epsilon_z\right)^{1/n}$$

or after making use of Equations [3] and [4], as

$$\sigma_z - \sigma_r + a \left(\ln \frac{r}{r_0}\right)^{1/n} = 0 \quad [8]$$

where the constant $a = 2\,C\,3^{1/n}$.

By neglecting the radial component of the friction force, the radial stress σ_r will be assumed equal in magnitude to the pressure p exerted by the die

$$\sigma_r = -p \quad [9]$$

With reference to Fig. 3, representing the forces acting on an element of length dx of the wire, the condition of equilibrium can be expressed by the differential equation

$$2\sigma_z + r\frac{d\sigma_z}{dr} + 2(1 + k)\,p = 0 \quad [10]$$

where $$k = \frac{\mu}{\alpha}$$

The stress distribution along the length of the wire can now be evaluated from Equations [8], [9], and [10]. The solution of the differential equation (Equation [10]) is given by

$$\sigma_x = r^{2k}\left[2a\,(1+k)\int \frac{\left(\ln\frac{r}{r_0}\right)^{1/n} dr}{r^{2k+1}} + C_1\right] \ldots [11]$$

To solve Equation [11] numerical integration is necessary. Instead of computing this integral, a further simplification can be

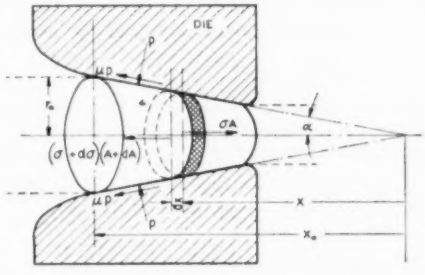

FIG. 3 EQUILIBRIUM OF AN ELEMENT OF WIRE PASSING THROUGH A DIE

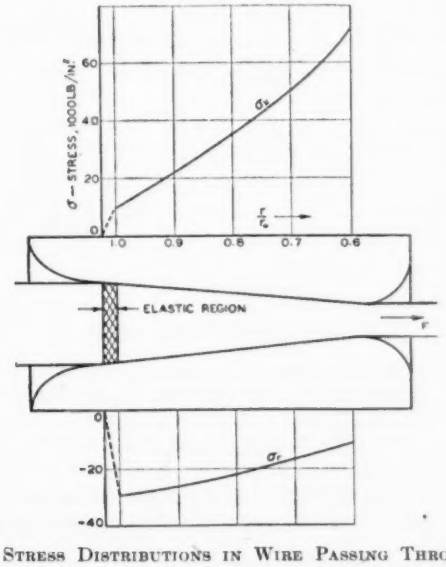

FIG. 4 STRESS DISTRIBUTIONS IN WIRE PASSING THROUGH DIE

introduced. It will be assumed that the tension diagram can be represented by a straight line, as shown in Figs. 1 and 2. For certain materials, such a simplification will be a fairly good approximation to the actual diagram. Thus the maximum shearing stress can be evaluated as the summation of the ordinate intercept τ_y, and the product of the slope Ω and the maximum shearing strain, that is

$$\tau_{max} = \tau_y + \Omega\,\gamma_{max} \ldots [12]$$

Expressed as a linear function of γ_{max}, the equation can be rewritten as

$$\gamma_{max} = \frac{1}{\Omega}(\tau_{max} - \tau_y) \ldots [13]$$

The maximum shearing strain can now be written in terms of the natural strains and the true stresses

$$\gamma_{max} = \epsilon_r - \epsilon_x = \frac{1}{\Omega}\left(\frac{\sigma_r - \sigma_x}{2} + \frac{\sigma_0}{2}\right) \ldots [14]$$

where $\sigma_0 = -2\tau_y$. Equations [3] and [4] may now be substituted into Equation [14], and the following relation between stress and the variable die radius is obtained

$$\sigma_x - \sigma_r - \sigma_0 + 6\,\Omega \ln\frac{r}{r_0} = 0 \ldots [15]$$

The stress distribution along the wire can be evaluated by substituting Equations [9] and [15] into Equation [10]. The differential equation can now be expressed as

$$r\frac{d\sigma_x}{dr} - 2k\sigma_x + 2\,(1+k)\left(\sigma_0 - 6\,\Omega \ln\frac{r}{r_0}\right) = 0 \ldots [16]$$

The solution of Equation [16] is

$$\sigma_x = \frac{1+k}{k}\sigma_0 - \frac{6\,(1+k)\,\Omega}{k}\ln\frac{r}{r_0} - \frac{6\,(1+k)\,\Omega}{2k^2} + C_2 r^{2k} \ldots [17]$$

To determine the constant C_2 from a theoretical standpoint, it would be necessary to consider the stresses in the elastic region where the wire enters the die. The force developed in the elastic region will be the same for any given size of wire regardless of the amount of reduction which follows. If we consider σ_1 to be the stress at the boundary between the elastic and plastic ranges, as shown in Fig. 4, then C_2 can be determined by letting $\sigma_x = \sigma_1$ when $r = r_0$. Then

$$\sigma_x = \frac{1+k}{k}\left\{6\Omega\ln\frac{r_0}{r} - \left(\frac{3\Omega}{k} - \sigma_0\right)\left[1 - \left(\frac{r}{r_0}\right)^{2k}\right]\right\} + \sigma_1\left(\frac{r}{r_0}\right)^{2k} \ldots [18]$$

The stress distribution in terms of the area of reduction is

$$\sigma_x = \frac{1+k}{k}\left\{3\,\Omega\ln\frac{A_0}{A} - \left(\frac{3\Omega}{k} - \sigma_0\right)\left[1 - \left(\frac{A}{A_0}\right)^{k}\right]\right\} + \sigma_1\left(\frac{A}{A_0}\right)^{k} \ldots [19]$$

In order to compare Equation [18] with the one previously developed by Sachs (4), let Ω equal zero. This neglects the effect of strain-hardening and the equation is reduced to

$$\sigma_x = \sigma_0\frac{1+k}{k}\left[1 - \left(\frac{r}{r_0}\right)^{2k}\right] + \sigma_1\left(\frac{r}{r_0}\right)^{2k} \ldots [20]$$

Since the strains in the elastic region were also neglected in Sachs's development, the equation for the axial stress is

$$\sigma_x = \sigma_0\frac{1+k}{k}\left[1 - \left(\frac{r}{r_0}\right)^{2k}\right] \ldots [21]$$

which is identical with his solution (4).

Another interesting case is to let the coefficient of friction μ equal zero. When this substitution is made in Equation [18], the stress becomes indeterminate, and it is therefore necessary to consider the original differential equation (Equation [10]) when $\mu = 0$. This equation reduces to

$$r\frac{d\sigma_x}{dr} + 2\sigma_x + 2\,p = 0 \ldots [22]$$

When Equation [22] is integrated, the axial-stress distribution is found to be

$$\sigma_x = 6\,\Omega\left(\ln\frac{r}{r_0}\right)^2 - 2\,\sigma_0\ln\frac{r}{r_0} + \sigma_1 \ldots [23]$$

The force necessary to draw a wire through a die can now be determined. When Equation [19] is considered, the stress for $A = A_f$ is found to be equal to

$$\sigma_f = \frac{1+k}{k}\left\{3\Omega \ln \frac{A_0}{A_f} - \left(\frac{3\Omega}{k} - \sigma_0\right)\left[1 - \left(\frac{A_f}{A_0}\right)^k\right]\right\} + \sigma_1\left(\frac{A_f}{A_0}\right)^k \quad \ldots\ldots [24]$$

Therefore, the force required to draw a wire is equal to

$$F = A_f\,\sigma_f \quad \ldots\ldots [25]$$

By means of Equations [15] and [16], it is possible to plot the axial and radial stresses as a function of the reduction in radius of a metal passing through a die. A hypothetical material was assumed in plotting the curves of Fig. 5. The strain-hardening coefficient Ω and the idealized yield stress were considered to be 30,000 psi, and 40,000 psi, respectively. At $r = r_0$, the axial

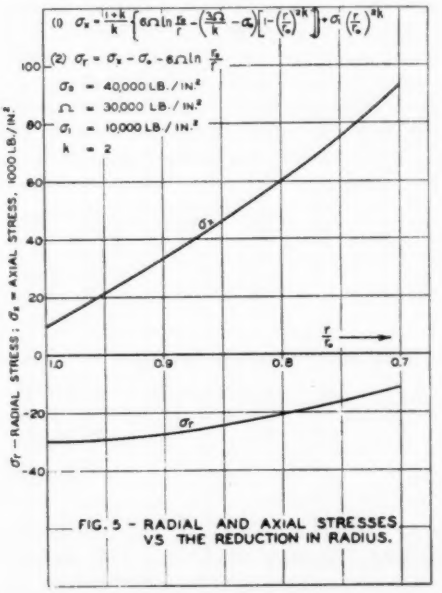

FIG. 5 RADIAL AND AXIAL STRESSES VERSUS REDUCTION IN RADIUS

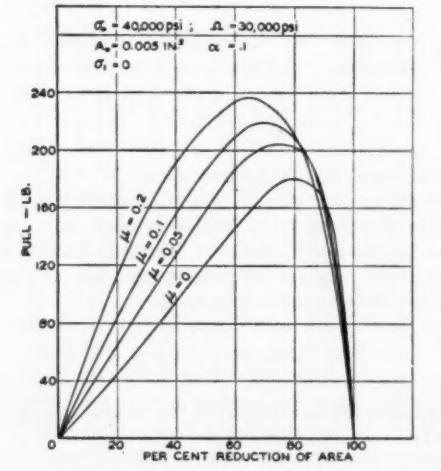

FIG. 6 FORCE REQUIRED TO DRAW WIRE VERSUS REDUCTION OF AREA

stress σ_x is equal to σ_1, and the radial stress is equal to $(\sigma_1 - \sigma_0)$, as indicated in the figure. The axial and radial stresses do not immediately obtain a finite value, but have a definite elastic region in which the stresses build up to the values given at $r = r_0$. This region is, however, so small that it is not indicated by the curves of Fig. 5.

In Fig. 6, the force required to draw a wire is plotted as a function of the reduction of area for various values of μ. The same values of the previous hypothetical material were assumed for Ω and σ_0; σ_1 was assumed to be zero. An examination of the figure reveals that for the various values of the coefficient of friction plotted, the pull is relatively proportional to the reduction of area up to a reduction of 50 per cent. Above 50 per cent reduction the slopes of the curves decrease and begin to descend after a reduction of 75 per cent.

Case 2: $\tau_n = f(\gamma_n)$. The foregoing mathematical development was based on a relationship between the maximum shearing stress τ_{max} and the maximum shearing strain γ_{max}. In some instances it may be preferable to replace this expression by one containing the octahedral shearing stress τ_n and the octahedral shearing strain γ_n. In this case the relation

$$\tau_n = f(\gamma_n) \quad \ldots\ldots [26]$$

would have to be substituted in place of the previous relationship. This theory of flow, which has been described by Dr. A. Nadai (10), states that for any type of loading the curve of the octahedral shearing stress as a function of the octahedral shearing strain is the same. If this theory is applied to the present problem, the results will not be changed materially. Equation [18] will then become

$$\sigma_x = \frac{1+k}{k}\left\{6\Omega \ln \frac{r_0}{r} - \left(\frac{3\Omega}{k} - \sigma_0'\right)\left[1 - \left(\frac{r}{r_0}\right)^{2k}\right]\right\} + \sigma_1\left(\frac{r}{r_0}\right)^{2k} \quad \ldots\ldots [27]$$

where

$$\sigma_0' = \frac{3}{2\sqrt{2}}\,\sigma_0$$

EXPERIMENTS ON WIRE DRAWING

Previously published papers on wire drawing failed to provide complete information for any one test so that the forces predicted for wire drawing in this paper could not be checked with the published results. For this reason a few tests were made at the Westinghouse Research Laboratories.

A wire-drawing bench was used and the special force-measuring arm, shown in Fig. 7, was designed to measure the drawing

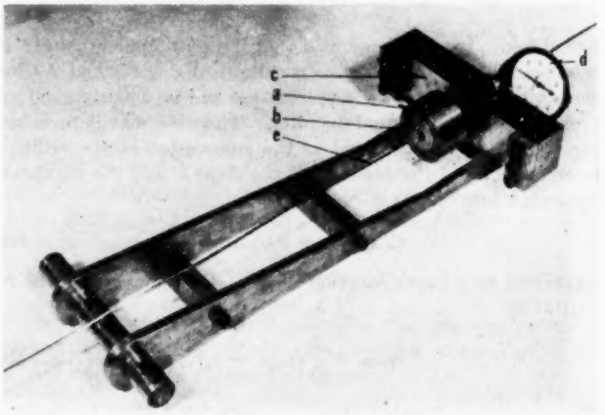

FIG. 7 FORCE-MEASURING ARM

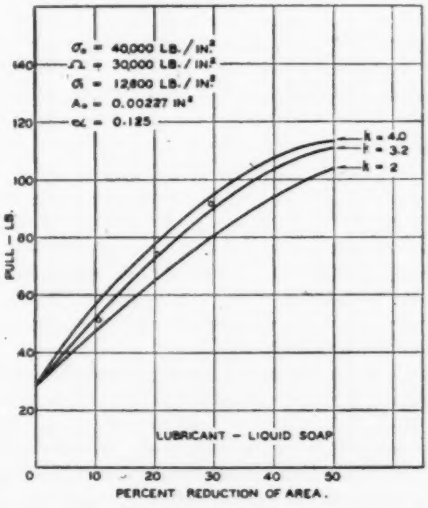

FIG. 11 FORCE REQUIRED TO DRAW MILD-STEEL WIRE

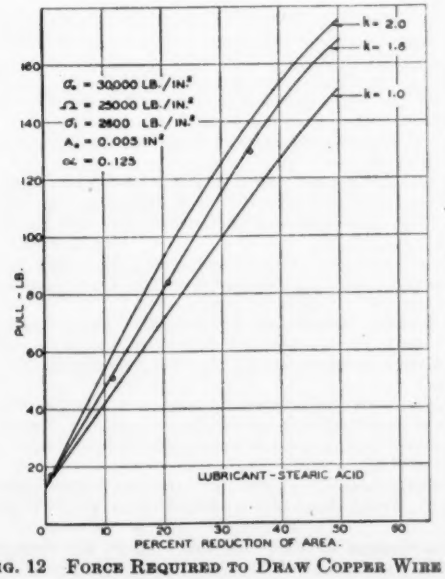

FIG. 12 FORCE REQUIRED TO DRAW COPPER WIRE

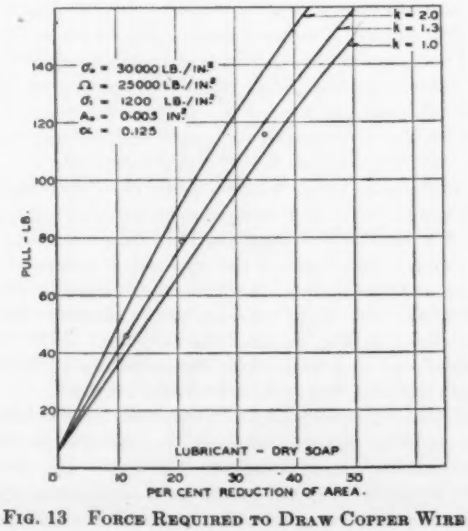

FIG. 13 FORCE REQUIRED TO DRAW COPPER WIRE

forces. The die holder (*a*) and the die (*b*) are fastened to a flat deflecting spring (*c*), whose deflection depends upon the load applied. Carboloy dies with an entrance angle 2α of 14 deg were used. The spring was calibrated before and after the tests were made. A dial indicator (*d*) is fastened to the rigid cross-member and the dial pointer is placed in contact with the deflecting spring. The wire (*e*) was fastened to a rotating drum which had a peripheral velocity of 80 fpm.

Copper and steel wires were drawn through various dies. Prior to use, the wires were drawn down about 0.001 in., to remove surface imperfections and to insure an accurate original diameter. The stress-strain diagrams of both the copper and steel wires were then obtained, as shown in Figs. 1 and 2. Following this, various lubricants, indicated in Figs. 8 and 9, were applied to the surface of the wires before and during the drawing operation so that the effect they have upon reducing the forces required could be measured. The stearic acid was dissolved in carbon tetrachloride and the 12-ft lengths of wire were passed through the solution and then allowed to dry. Similarly, dry soap was dissolved in warm water and, following the cooling of the solution, the wires were treated as described. The liquid soap was applied with a cloth during the drawing operation.

Results of Experiments

The results of the tests performed are shown in Figs. 8 and 9. The forces required to draw a wire under standard conditions appear to be proportional to the reduction of area, as shown by the experimental curves. Thompson (11) has shown that for ferrous metals this proportionality extends to a reduction of about 30 per cent, after which the necessary pull increases less rapidly. For nonferrous metals, the linearity of the curves remains up to a reduction of 50 to 60 per cent. The tests made for this paper do not exceed a reduction of 35 per cent. An examination of Figs. 8 and 9 indicates that when the condition of lubrication is altered the new curve obtained is parallel to the former, but its intercept on the ordinate axis is displaced depending upon whether the lubricant is better or worse.

In Figs. 10 to 13, inclusive, the experimental values for the forces necessary to draw wire using various lubricants are indicated for both the mild-steel and copper wires. Theoretical curves were plotted for various values of k, in order to obtain the curve which conforms as accurately as possible to the experimental points. In all cases the curves fall very close to the experimental points. The values of the coefficient of friction for mild steel using stearic acid and liquid soap as lubricants are 0.3 and 0.4, as shown in Figs. 10 and 11, respectively. In Figs. 12 and 13 stearic acid and dry soap were used as lubricants for the copper tests. The values of the coefficient of friction were evaluated as 0.2 and 0.16, respectively. It may be of interest to emphasize here that although the two curves, both in Fig. 8 and in Fig. 9, are parallel, the coefficient of friction in the mathematical treatment in each case is higher for the poorer lubricant.

The constant σ_1 was evaluated from the experimental data of Figs. 8 and 9, which is dependent upon the lubricant used. No attempt has been made to evaluate the stress distribution in the elastic region. The value of the constant σ_1 is dependent upon numerous considerations; the two most important of which are as follows: (*a*) The stress due to the elastic strains in the wire, as shown in Fig. 4; and (*b*) the effect of the lubricant. This latter factor may be partially due to the film of the lubricant built up at the point where the wire enters the die.

If back-tension were applied to the wire as it is drawn through a die, this would be treated in the theory as causing an increase in σ_1. Such an increase causes a definite decrease in the pressure as shown by Equation [15], but would cause an increase in the force necessary for drawing. Actually, however, the resisting force built up in a die is decreased when back-tension is applied (3). This can be readily illustrated upon examination of the curves for $k = 2$, in Figs. 10 and 11. The values of the initial force, $\sigma_1 A_0$, are 20 lb and 30 lb. If it is assumed that this difference is due to back-tension rather than to the lubricant, the mathematical treatment would not be changed. The results indicate that on both curves the forces at 50 per cent reduction are approximately equal. However, the resisting force built up in the die when back-tension is applied is approximately 10 lb less than when no back-tension is present. This was checked experimentally in the tests made. When back-tension was applied, the force recorded by the dial was reduced.

Conclusions

1 The mathematical theory of wire drawing can be improved by taking into consideration the strain-hardening of the wire.

2 Except for a finite load, corresponding to no reduction of area, the force necessary to draw wire is nearly proportional to the reduction in area. A straight line drawn through the points for various reductions intercepts the force axis at a finite value, $\sigma_1 A_0$.

3 Since this intercept force, $\sigma_1 A_0$, is the same, regardless of the amount of the reduction, it must be due to conditions prevailing at the point where the wire enters the die.

4 From a mathematical point of view, the constant σ_1 presents one of the greatest problems in wire drawing. Since many factors affect the value of σ_1, it can only be determined by experimentation.

5 The initial stress σ_1 varies with the lubricant used. It is also affected by back-tension.

6 Back-tension reduces the pressure on the walls of the dies. This can be shown mathematically as well as experimentally.

7 The mathematical theory of wire drawing may be used as a means of determining the coefficient of friction between the die and the metals undergoing plastic deformation.

8 The theory may be used to determine the relative values of the coefficient of friction due to boundary lubrication, when various lubricants are used to reduce the friction forces.

Drawing Thin-Walled Tubing With a Moving Mandrel Through a Single Stationary Die

By G. SACHS,[1] J. D. LUBAHN,[2] AND D. P. TRACY[3]

The fundamental equations for the drawing of tubing with a moving mandrel have been solved for the simplified cases of both cold-drawing and hot-drawing of thin-walled tubing through a stationary die. For the solution of the fundamental equation, a method of successive improvement can be used for any contour of the tools and any shape of the stress-strain curve. Algebraic solutions were developed for tapered tools and for a metal exhibiting a constant flow stress in cold-working, and for a metal with the flow stress depending exponentially upon the strain rate in hot-working. The effects of the die and punch contours and the friction coefficients between the metal and the die and punch, respectively, on the stresses in the metal, the draw forces, and the limits of drawing were determined. The calculations reveal that, with a small die angle and high friction on the mandrel, the process resembles extrusion rather than drawing, the limit being determined by the strength of the die rather than by the tensile strength of the metal.

Introduction

THE drawing of a tubular part through a die with an inserted moving punch (mandrel or rod) has an extensive practical significance. While it is only infrequently used for the fabrication of tubing, it comprises a major portion of the drawing of cartridge cases, of high-explosive-shell bottles, and of other redrawing or "ironing" operations on cup-shaped parts.

The fundamental differential equation for this process can be derived readily and can be integrated for some special cases.[4] However, such a simple approach to the problem has not been found suitable for a complete evaluation of the effects of the numerous variables occurring in practice.

For example, it has been observed during some experimentation on cartridge cases that the reduction in cross-sectional area performable in a single draw may scatter or vary from 30 to over 90 per cent under certain conditions, while it may be consistent within ±3 per cent for other combinations of variables and may be as high as 75 per cent. A working theory of drawing tubing over a mandrel must eventually account for such disturbing observations.

The following discussion presents a new approach to this problem, and it should be applicable also to other problems of metal working. A method of gradual approach to the final solution has been developed, which permits evaluation of the effects of any variable.

So far, the theory has been developed only for tubing having a very thin wall. Extension of the theory to heavy-walled tubing is contemplated; and another future problem is the drawing of tubing through several dies in tandem.

The simple fundamental theory of tube-drawing[4] established a differential equation relating the longitudinal drawing force and the radial pressure. This equation has been solved for the case of a variable die angle by replacing the variable pressure on the surfaces by a mean pressure. A more accurate solution was developed for a die and mandrel having constant angles. In this case, however, it was necessary to make the additional assumption that the radial pressure is equal to the flow stress. In all the calculations of the previous paper,[4] the flow stress was assumed to be constant.

In this paper, the same fundamental differential equation will be solved by a different method which does not require the previous simplifying assumptions. The method involves a succession of approximations by means of graphical integration; and the solution may be made very nearly exact in five to seven repetitions of the process. Any combination of metal properties and tool contours may be treated with the aid of families of curves calculated for this purpose.

An algebraic solution will be developed for tools having straight tapers and a metal having a constant flow stress. This method offers the advantage of a direct numerical solution without recourse to successive approximations or graphical methods.

Other forming processes can be investigated in fundamentally the same manner, but they differ regarding the directions of the frictional forces. The friction may also change in sign over the length of the contact area, such as in drawing tubing through a roller die, in rolling strip (by means of tension or with driven rolls), and in forging.[5]

The Fundamental Equation of Equilibrium

Fig. 1 shows a longitudinal section through one wall of a thin-walled tube which is being drawn with a mandrel. The die and mandrel are shown with straight tapers, but the analysis based on this figure will be seen to apply equally well to tools with any contour. Consider an element of the tube cut out perpendicular to the axis at a distance x along the mandrel from the point where the tube first makes contact with the die. Let the tapers of the die and mandrel (half angles) at this point be α and β, respectively, let the friction coefficients of die and mandrel be μ_1

and μ_2, respectively, and let the thickness of the tube wall be h. For the case of a thin-walled tube, the element can be considered to have unit width in a direction perpendicular to the plane of the figure.

The element, Fig. 2, has acting upon it a longitudinal force H, a normal pressure p, and shearing stresses

$$\tau_1 = p\mu_1, \qquad \tau_2 = p\mu_2 \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

at the surfaces of the tools due to the effects of friction.

Any shearing forces on the vertical sides of the elements will not appear in the summation of longitudinal forces. For a thin-walled tube, the circumferential forces on the tube element can be neglected, and the normal pressures p can be assumed to be equal on both the die and the mandrel, as shown in Fig. 2. Also, the horizontal stress s and the normal pressure p are assumed to be principal stresses, for the purpose of integration, as shown later. This implies that the angles α and β are small. Therefore, the developed relations will become less exact the larger the tool angles are, and particularly if the difference between the two angles is large.

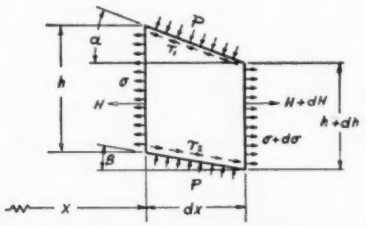

FIG. 2 ELEMENT OF THE TUBE AT POSITION x; SEE FIG. 1

The fundamental differential equation is obtained by the summation of forces in the longitudinal direction, Fig. 2

$$H + dH - H - p\frac{dx}{\cos\alpha}\sin\alpha + p\frac{dx}{\cos\beta}\sin\beta - \tau_1\frac{dx}{\cos\alpha}\cos\alpha + \tau_2\frac{dx}{\cos\beta}\cos\beta = 0 \ldots\ldots [2]$$

Inserting Equation [1] in Equation [2] and making minor simplifications, the desired differential equation is obtained

$$dH = pdx(\tan\alpha - \tan\beta + \mu_1 - \mu_2) = Cpdx \ldots\ldots [3]$$

where

$$C = \tan\alpha - \tan\beta + \mu_1 - \mu_2 \ldots\ldots\ldots\ldots [4]$$

In regular drawing (through a single die) no force is applied to the tube entering the die, i.e., for $x = 0$, $H = 0$. Then Equation [3] may be integrated between the limits $x = 0$ and $x = x$ as follows

$$\int_0^H dH = H = \int_0^x pCdx \ldots\ldots\ldots\ldots [5]$$

PART 1 COLD-DRAWING

SOLUTION OF DIFFERENTIAL EQUATION BY METHOD OF SUCCESSIVE IMPROVEMENT

In the general equation for cold-working, the two principal stresses may be correlated by the maximum-shear-stress theory[6]

$$\sigma + p = \sigma_0 \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

[6] If the strain-energy theory is used, which is a more accurate approximation than the shear-stress theory, all stresses and forces would still be determined by the same equations. Differences would occur only when numerical values of the flow stress are used which were determined by means of tension or compression. In order to agree with the strain-energy theory, these values must be increased by 15 per cent if used in the equations developed in this section.

in which σ is the longitudinal stress and σ_0 is the flow stress or yield strength. For thin-walled tubing the longitudinal stress will be nearly uniformly distributed throughout the wall of the tube; therefore

$$\sigma = \frac{H}{h} \ldots\ldots\ldots\ldots\ldots\ldots [7]$$

Inserting Equation [7] in Equation [6], the force H is

$$H = \sigma_0 h - ph \ldots\ldots\ldots\ldots\ldots\ldots [8]$$

Eliminating H between Equation [8] and Equation [5] and solving for p

$$p = \sigma_0 - \frac{1}{h}\int_0^x pCdx$$

$$= \sigma_0 - \frac{1}{h}\int_0^x p\,(\tan\alpha - \tan\beta + \mu_1 - \mu_2)dx \ldots [9]$$

In this equation p, σ_0, h, C, α, and β may all be functions of x. The coefficients of friction, μ_1 and μ_2, can be considered generally as constant.

In order to solve Equation [9], a method of successive improvement has been developed. In this method, an arbitrary but reasonable pressure distribution p_1 is assumed, as a first approximation. The second and following approximations of the pressure, p_2, p_3, p_{n-1}, p_n are then obtained by graphical integration of the right side of Equation [9] as follows

$$\left.\begin{aligned} p_2 &= \sigma_0 - \frac{1}{h}\int_0^x p_1 Cdx \\ p_3 &= \sigma_0 - \frac{1}{h}\int_0^x p_2 Cdx \\ p_n &= \sigma_0 - \frac{1}{h}\int_0^x p_{n-1} Cdx \end{aligned}\right\} \ldots\ldots\ldots\ldots [10]$$

The pressure distribution can be obtained to any desired accuracy, which is determined by the difference $p_n - p_{n-1}$.

This method of successive improvement can be applied also to other forming problems, provided that the difference between two successive solutions becomes gradually smaller.

The application of this method to the drawing of tubing will be described first for the simplified condition of constant tool angles and a constant flow stress, and subsequently for the general condition.

Example 1. Metal exhibiting no strain-hardening, drawn through tapered die with straight mandrel:

The following values are then constant: α, β, and σ_0. For constant tool angles, the wall thickness h at each point becomes, Fig. 1

$$h = h_0 - x\,(\tan\alpha - \tan\beta) = h_0 - xD \ldots\ldots [11]$$

where

$$D = \tan\alpha - \tan\beta \ldots\ldots\ldots\ldots [12]$$

The fundamental Equation [9] then reduces to

$$p = \sigma_0 - \frac{C}{h_0 - xD}\int_0^x pdx \ldots\ldots [13]$$

For a constant flow stress σ_0 and no back tension on the tubing the pressure p_x will vary from σ_0 at $x = 0$ to zero at some value of $x = C_1 h_0$, as can be seen from Equation [13]. As a first approximation, p_1, a linear distribution of p, can be used that satisfies Equation [13] for $x = 0$ and $x = C_1 h_0$. The general equation for such a straight line is

$$\frac{p_1}{\sigma_0} = 1 - \frac{x}{C_1 h_0} \ldots\ldots\ldots\ldots [14]$$

* Z_n throughout this table is a representation for the formula $Z_n = \int_0^{x/h_0} p_n \frac{dx}{h_0}$.

in which the unknown constant C_1 must be determined in accordance with Equation [13]. This is accomplished by substituting Equation [14] in Equation [13] and solving for C_1, yielding

$$C_1 = \frac{2}{C + 2D} \quad \text{[15]}$$

thus, the desired linear relation for use as a first approximation becomes

$$\frac{p_1}{\sigma_0} = 1 - \frac{x(C + 2D)}{2h_0} \quad \text{[16]}$$

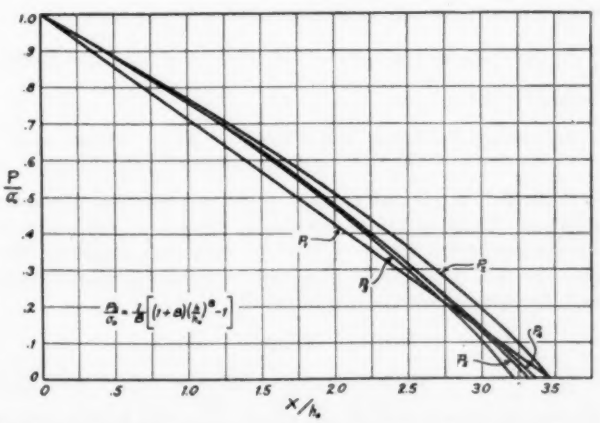

FIG. 3 GRAPHICAL SOLUTION FOR CONSTANT FLOW STRESS AND TOOL ANGLES

This function is plotted in Fig. 3, for an example possessing the following characteristic values

$$\left.\begin{aligned} &\alpha = 10 \text{ deg } (\tan \alpha = 0.176) \quad \beta = 0 \\ &\mu_1 = 0.15 \quad \mu_2 = 0.10 \\ &C = \tan \alpha - \tan \beta + \mu_1 - \mu_2 = 0.226 \\ &D = \tan \alpha - \tan \beta = 0.176 \end{aligned}\right\} \quad \text{[17]}$$

The first approximation, Equation [16], becomes

$$\frac{p_1}{\sigma_0} = 1 - \frac{x}{3.44\,h_0} \quad \text{[18]}$$

The second approximation p_2 is now obtained from the left member of the general Equation [13] by substituting p_1 for p in the right member

$$\frac{p_2}{\sigma_0} = 1 - \frac{0.226}{h_0 - 0.176x} \int_0^x \frac{p_1}{\sigma_0}\,dx \quad \text{[19]}$$

This equation can be solved graphically, as shown in Table 1 and Fig. 3. The procedure is then repeated by substituting p_2 in Equation [19] and obtaining p_3, and so forth, until a pressure distribution is obtained which satisfies the equation to the desired accuracy. For this particular example, five such steps were made, see Table 1 and Fig. 3.

Example 2. Copper drawn through radius die with straight mandrel:

Under these conditions the only values which are constant are β, μ_1, and μ_2. They can be grouped together

$$C_2 = -\tan \beta + \mu_1 - \mu_2 \quad \text{[20]}$$

resulting in the following form of the general Equation [9]

$$p = \sigma_0 - \frac{1}{h} \int_0^x p\,(\tan \alpha + C_2)\,dx \quad \text{[21]}$$

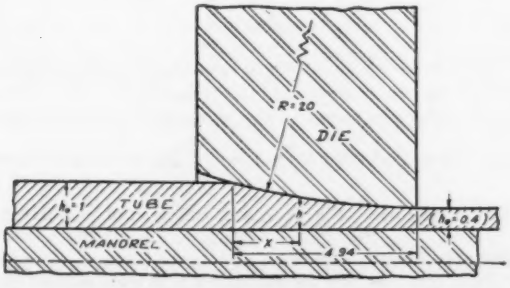

FIG. 4 CONDITIONS OF DRAWING FOR SAMPLE SOLUTION SHOWN IN FIG. 7, IN WHICH A TUBE IS REDUCED BY 60 PER CENT IN A RADIUS DIE

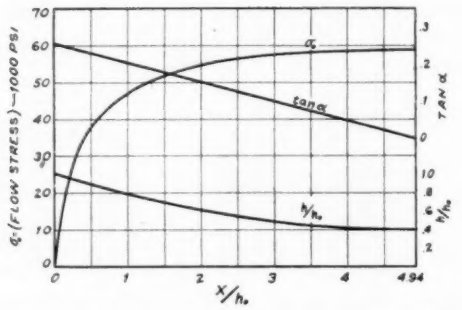

FIG. 5 VARIATION OF FLOW STRESS, DIE ANGLE, AND REDUCTION WITH x/h_0 IN EXAMPLE OF FIG. 4

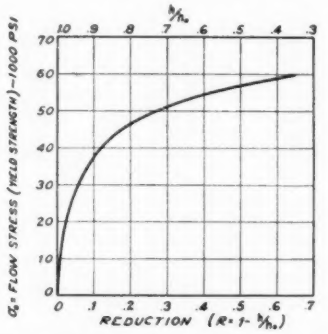

FIG. 6 STRESS-STRAIN CURVE FOR COPPER TUBING

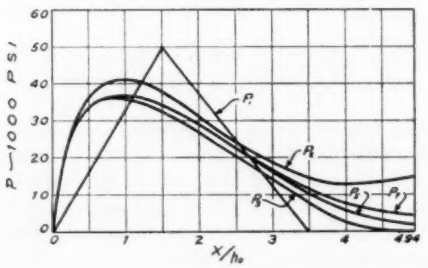

FIG. 7 GRAPHICAL SOLUTION OF PRESSURE DISTRIBUTION FOR COPPER TUBE REDUCED BY 60 PER CENT IN DIE HAVING RADIUS OF 20 TIMES ORIGINAL WALL THICKNESS OF TUBE

in which σ_0, h, and tan α are functions of x or, more conveniently for these calculations, functions of $\frac{x}{h_0}$. The wall thickness h and slope of the die contour tan α can be readily obtained from the geometry of the tools and tubing. For the example illustrated in Fig. 4, having a die radius of 20 in. and an initial wall thickness $h_0 = 1$ in., the values tan α and h have been calculated and plotted in Fig. 5, as functions of $\frac{x}{h_0}$.

The flow stress or yield strength σ_0 of copper can be determined by a tensile test as a function of the reduction in area, which can be considered as equivalent to the reduction in wall thickness on drawing thin-walled tube $R = 1 - \frac{h}{h_0}$, Fig. 6. From the values of σ_0, Fig. 6, and of $\frac{h}{h_0}$, Fig. 5, σ_0 as a function of $\frac{x}{h_0}$ can be readiy obtained and plotted, Fig. 5.

Equation [21] can now be solved by a process similar to that used for the first example. Again a linear function may be used as a first approximation to the pressure p_1; but in order to reduce the calculations, it should consist of two branches, i.e., first increase from a value at $x = 0$ equal to the yield strength, which is close to zero for annealed copper, to a maximum corresponding to an average value of flow stress at an arbitrary position, and then again drop to zero at a value of $\frac{x}{h_0}$ which is arbitrary but not too distant from the exit, Fig. 4. More definite rules cannot be given for the selection of the first approximation. The further approximations p_2, p_3, etc., are then obtained by exactly the same procedure as described for Example 1, see Table 2 and Fig. 7. For the selected example, seven steps were carried out in this manner.

In Fig. 8, the pressures within the die for the two examples.

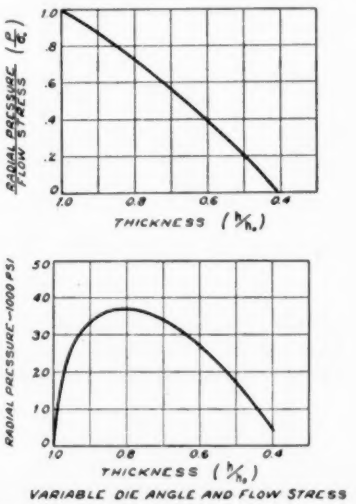

FIG. 8 RADIAL PRESSURE AS A FUNCTION OF WALL THICKNESS FOR TWO ASSUMPTIONS REGARDING VARIATION OF FLOW STRESS AND TOOL ANGLES

Figs. 3 and 7, are represented as functions of the thickness ratio $\frac{h}{h_0}$, rather than as functions of the distance x from the entering side of the die.

ALGEBRAIC SOLUTION FOR CONSTANT FLOW STRESS AND CONSTANT TOOL ANGLES

If the flow stress and the tool angles are assumed to remain constant (Example 1) it is possible to develop a formula for p, the die pressure at any point, without recourse to graphical integration. The following relations then correlate the co-ordinate x and the metal thickness h, see Equation [11]

$$h = h_0 - x\,(\tan\alpha - \tan\beta)$$

$$dh = -(\tan\alpha - \tan\beta)dx \qquad [22]$$

Also the horizontal force H, the flow stress σ_0, the thickness, and the pressure are related by, see Equation [8]

$$H = \sigma_0 h - ph$$

$$dH = \sigma_0 dh - pdh - hdp \qquad [23]$$

Substituting the value of dx from Equation [22] and of dH from Equation [23] into the fundamental differential Equation [3], the following equation is obtained

$$\sigma_0 dh - pdh - hdp = -pdh\,\frac{(\tan\alpha - \tan\beta + \mu_1 - \mu_2)}{\tan\alpha - \tan\beta}$$

$$= -pdh(1 + B) \qquad [24]$$

* Y_n throughout this table is a representation for the formula $Y_n = \int^{x/h_0} p_n(\tan\alpha + c_2)\frac{dx}{h_0}$.

where

$$B = \frac{\mu_1 - \mu_2}{\tan\alpha - \tan\beta} \quad [25]$$

The resulting differential equation

$$\frac{dh}{h} = \frac{dp}{\sigma_0 + pB} \quad [26]$$

yields the final solution for the boundary condition

$$h = h_0, \quad H = 0, \quad p = \sigma_0$$

$$\int_{h_0}^{h} \frac{dh}{h} = \int_{\sigma_0}^{p} \frac{dp}{\sigma_0 + pB} \quad [27]$$

$$\ln\frac{h}{h_0} = \frac{1}{B}\ln\frac{\sigma_0 + Bp}{\sigma_0 + B\sigma_0} \quad [28]$$

$$\frac{p}{\sigma_0} = \frac{1}{B}\left[(1+B)\left(\frac{h}{h_0}\right)^B - 1\right] \quad [29]$$

Equation [29] may be used to check the graphical method developed in the previous section. Fig. 3 gives the distribution of the pressure p for the case of a constant flow stress σ_0 and the numerical values of other constants given by Equation [18]. In this case $B = 0.2839$ and inserting this value of B and the value of h from Equation [22] into Equation [29], the following numerical relation is obtained

$$\frac{p}{\sigma_0} = \frac{1}{0.2839}\left(1.2839\left[1 - \frac{x}{h_0}(\tan\alpha - \tan\beta)\right]^{0.2839} - 1\right) \quad [30]$$

Using the values of [18] again

$$\frac{p}{\sigma_0} = \frac{1}{0.2839}\left[1.2839\left(1 - 0.17633\frac{x}{h_0}\right)^{0.2839} - 1\right] \quad [31]$$

This has been solved by tabular substitution in Table 3. By comparing these values of p with those in the last column of Table 1, it can be seen that the fifth approximation of the graphical solution is very nearly exact.

By introducing Equation [6] into Equation [29], the horizontal stress is found to be

$$\frac{\sigma}{\sigma_0} = 1 - \frac{p}{\sigma_0} = \frac{1+B}{B}\left[1 - \left(\frac{h}{h_0}\right)^B\right] \quad [32]$$

Total Draw Force

The total draw force F is the sum of the horizontal forces on the tubing F_1, and on the mandrel F_2. For convenience, these forces will be considered per unit circumference of the tubing.

The force on the tubing, having the thickness h_1 at the exit, is, according to Equation [32]

TABLE 3 SOLUTION OF EQUATION [31]

s/h_0	$0.17633\,s/h_0$	$1-0.17633\,s/h_0$	$\frac{1.2839}{\left(1-0.17633\,s/h_0\right)^{0.2839}}$	$\frac{1.2839}{\left(1-0.17633\,s/h_0\right)^{0.2839}}-1$	p/σ_0

2.0	0.35266	0.64734	1.1347	0.1347	0.475
2.5	0.44082	0.55918	1.0886	0.0886	0.312
3.0	0.52899	0.47101	1.0368	0.0368	0.130
3.5	0.61715	0.38285	0.9777	−0.0223	−0.079

$$F_1 = \sigma_e h_e = \frac{\sigma_0 h_e}{B}(B+1)\left[1-\left(\frac{h_e}{h_0}\right)^B\right] \quad [33]$$

The force on the mandrel according to Fig. 2 is

$$F_2 = (\tan\beta + \mu_2)\int_0^{x_e} p\,dx \quad [34]$$

To integrate Equation [34], the variable x can be replaced by h, see Equations [11] and [22]

$$F_2 = \frac{\tan\beta+\mu_2}{D}\int_0^{h_e} p\,dh \quad [35]$$

and with Equation [29], the final differential equation is obtained

$$F_2 = \frac{\tan\beta+\mu_2}{D}\int_{h_0}^{h_e} dh\,\frac{1}{B}\left[(1+B)\left(\frac{h}{h_0}\right)^B - 1\right] \quad [36]$$

The solution of this equation is

$$F_2 = \frac{\sigma_0 h_e \tan\beta+\mu_2}{BD}\left[1-\left(\frac{h_e}{h_0}\right)^B\right] \quad [37]$$

The total draw force then becomes

$$\left.\begin{aligned}\frac{F}{\sigma_0 h_e} &= \frac{F_1+F_2}{\sigma_0 h_e} = \frac{\tan\alpha+\mu_1}{\mu_1-\mu_2}\left[1-\left(\frac{h_e}{h_0}\right)^B\right]\\ \frac{F}{\sigma_0 h_0} &= \frac{\tan\alpha+\mu_1}{\mu_1-\mu_2}\left[\frac{h_e}{h_0}-\left(\frac{h_e}{h_0}\right)^{B+1}\right]\end{aligned}\right\} \quad [38]$$

The last expression, yielding the "draw stress," related to the cross-sectional area of the tubing on entering the die, is preferred frequently; and values of this draw stress, for certain combinations of the variables, are illustrated in Figs. 11 to 14, inclusive. Equations [38] are indeterminate when $\mu_1 = \mu_2$.

The analysis must be revised for this case from the point where the quantity $\mu_1 - \mu_2$ first appears, see Equation [26]. For the case of $\mu_1 = \mu_2$, $B = 0$, see Equation [25]; and Equation [26] becomes

$$\frac{dh}{h} = \frac{dp}{\sigma_0} \quad [39]$$

Noting that when $h = h_0$, $p = \sigma_0$

$$\int_{h_0}^{h}\frac{dh}{h} = \int_{\sigma_0}^{p}\frac{dp}{\sigma_0} \quad [40]$$

$$\ln\frac{h}{h_0} = \frac{p}{\sigma_0} - 1 \quad [41]$$

$$\frac{p}{\sigma_0} = 1 + \ln\frac{h}{h_0} \quad [42]$$

Using Equation [42] rather than Equation [29] as a starting point, and proceeding with the same analysis as that used in developing Equations [29] through [37], the value of F is found to be, for the special case of $\mu_1 = \mu_2$

$$\left.\begin{aligned}\frac{F}{\sigma_0 h_e} &= \left[\frac{\tan\alpha+\mu_1}{\tan\alpha-\tan\beta}\right]\ln\left(\frac{h_0}{h_e}\right)\\ \frac{F}{\sigma_0 h_0} &= \left[\frac{\tan\alpha+\mu_1}{\tan\alpha-\tan\beta}\right]\frac{h_e}{h_0}\ln\left(\frac{h_0}{h_e}\right)\end{aligned}\right\} \quad [43]$$

Effects of Processing Variables on Stresses

For the simplified case of straight tapered tools and a metal possessing a constant flow stress, the foregoing equations may be used to produce a graphical representation of the dependence of the stress distribution during drawing thin-walled tubing upon variations of the processing conditions.

The stress state is described at each section of the tubing by the die pressure p, assumed to be the same on both the outer and inner surface of the tubing, and the longitudinal or horizontal stress σ, assumed to be uniformly distributed over the thickness.

The most important independent variables which determine the stresses are the half die angle α, the half angle of mandrel angle β, and the friction coefficients between die and tubing μ_1 and mandrel and tubing μ_2. For a given combination of these variables and for a given flow stress σ_0, the stresses in the metal depend upon the reduction in wall thickness or in cross-sectional area R

$$R = \frac{h_0 - h_e}{h_0} \quad [44]$$

The die pressure has been calculated according to Equation [29] for numerous combinations of these variables, Figs. 9 and 10. The friction coefficients enter into these equations only as their difference, $u = \mu_1 - \mu_2$. The tool tapers also occur only in the combination $\tan\alpha - \tan\beta$. The examples are represented for a cylindrical mandrel, $\beta = 0$, but also apply to any other condition in which the value $\tan\alpha - \tan\beta$ is the same as the value of $\tan\alpha$ in the illustrations.

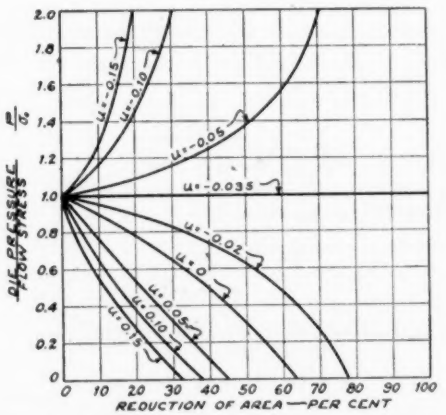

FIG. 9 EFFECT OF FRICTION AND REDUCTION ON DIE PRESSURE FOR α = 2 DEG, β = 0 DEG

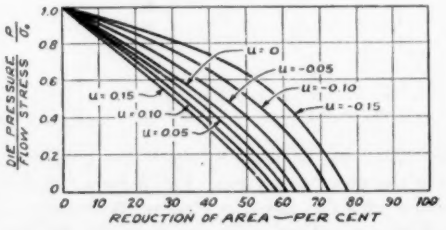

FIG. 10 EFFECT OF FRICTION AND REDUCTION ON DIE PRESSURE FOR α = 15 DEG, β = 0 DEG

The effect of the variables α, u, and R on the die pressure is shown in Fig. 9 as a function of the reduction R for $\alpha = 2$ deg, and in Fig. 10 for $\alpha = 15$ deg, each figure employing a family of curves to represent the effect of different values of u. These graphs illustrate that the die pressure gradually decreases with increasing reduction as the metal passes through the die, for the usual commercial conditions, in which the die and mandrel friction coefficients are approximately equal (i.e., their difference small), and the die angle is not too small, Fig. 10.

If, however, the mandrel friction is high in comparison to the die friction, i.e., their difference u is negative, and if its absolute value is larger than tan α (or tan α — tan β), the die pressure increases with increasing reduction, Fig. 9. Such a process is similar to "extrusion" rather than drawing. It results from the opposing actions of die and mandrel. As the metal proceeds through the die, a component of longitudinal tension is built up resisting the friction against the die and the longitudinal component of the normal pressure at the working face of the die. On the other hand, a component of a longitudinal compression in the tubing is created because of friction against the mandrel. If the latter effect exceeds the former, the metal is pushed or "extruded" rather than drawn through the die, Fig. 9. It is interesting to note from Fig. 9 that a rather small variation in friction, from $u = 0$ to $u = -0.05$, will cause a radical change in the pressure distribution if the die angle is very small. This effect will be discussed in greater detail later.

The longitudinal stress σ is readily obtained from the pressure p by means of the condition of plasticity Equation [6], $\sigma = \sigma_0 - p$. Thus the curves in Figs. 9 and 10 also represent the longitudinal stress in the die (right-hand scale) as a function of the reduction in wall thickness. Fig. 9 illustrates the difference between drawing under conditions where longitudinal tension is present, varying gradually from zero at the entering side of the die to a value equal to the flow stress σ_0 at a certain reduction, and where longitudinal compression (extrusion) is present, beginning at zero at the entering side of the die and increasing at a steadily accelerating rate.

Effect of Processing Variables on Draw Force

The total draw force, according to Equations [38] and [43], generally increases with increasing (total) reduction in wall thickness, increasing friction between tube and tools, and decreasing die angle, Figs. 11 to 14, inclusive.

Fig. 11 shows that the total draw force may increase with increasing reduction in various manners. It will be noted from Equations [38] that when $B = -1$, the relation between total draw force and reduction becomes linear. For the conditions of Fig. 11, $B = -1$ when $\mu_2 = 0.10$, and the corresponding curve is then a straight line.

If μ_2 is larger than 0.10, or B smaller than —1, the draw force increases continuously with increasing reduction, at a gradually increasing rate. Such conditions represent the previously discussed case of "extrusion" where the longitudinal stress in the tubing is compression.

However, if μ_2 is smaller than 0.10, or B larger than —1, the draw force will reach a maximum at a certain reduction, according to Equations [38] or [43]. For such conditions, where the longitudinal stress is tension, the draw force for reductions beyond the maximum point has no physical significance, as can be seen from the subsequent analysis. The reduction of area corresponding to the maximum in the total drawing-force curves can be found by differentiating Equations [38] with respect to h_e and setting the left side equal to zero

$$\frac{dF}{dh_e} = 0 = \frac{d}{dh_e}\left[\sigma_0 h_e \frac{\tan\alpha + \mu_1}{\mu_1 - \mu_2}\right]\left[1 - \left(\frac{h_e}{h_0}\right)^B\right] \quad \ldots [45]$$

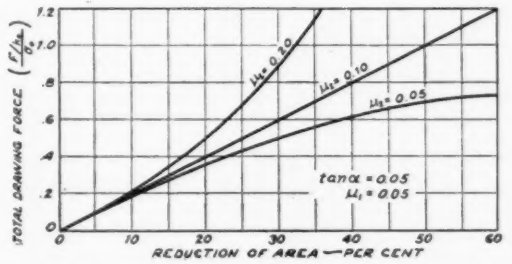

Fig. 11 Effect of Reduction of Area and Mandrel Friction on Total Drawing Force

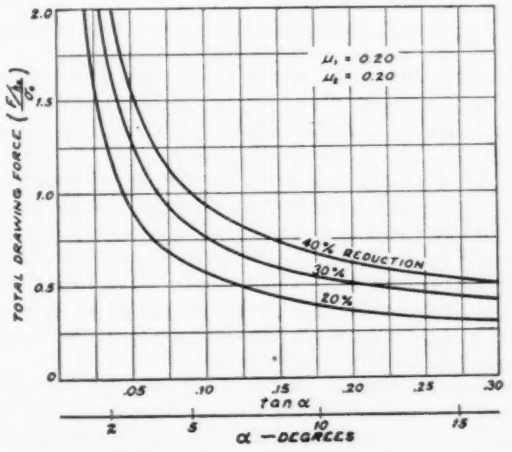

Fig. 12 Effect of Die Angle and Reduction of Area on Total Drawing Force

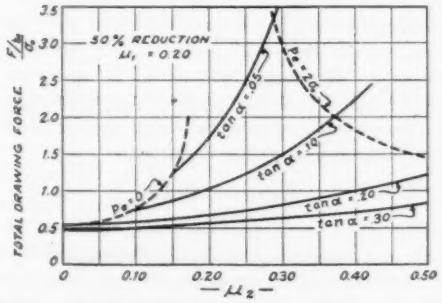

Fig. 13 Effect of Mandrel Friction and Die Angle on Total Drawing Force

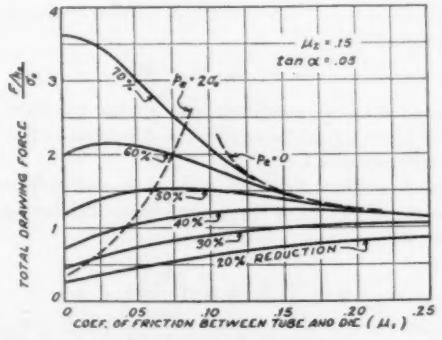

Fig. 14 Effect of Die Friction and Reduction of Area on Total Drawing Force

This yields the value of the reduction at the point of maximum force

$$\frac{h_0 - h_e}{h_0} = 1 - \left(\frac{1}{1+B}\right)^{1/B} \text{ or } \frac{h_e}{h_0} = \left(\frac{1}{1+B}\right)^{1/B} \quad [46]$$

This, however, is the same value of h_e at which the die pressure becomes zero, or changes from compression to tension, according to Equation [29] (see later). For a greater reduction than that corresponding to Equation [46], there is no longer any contact between the die and the tubing and any equation involving frictional relationships is not applicable.

The effect of the die angle on the total draw force is shown in Fig. 12, for various reductions, the friction coefficients being identical, i.e., 0.20 for both die and mandrel. The die angle has little effect except for very small angles, in which case the draw force increases rapidly as the die angle approaches zero. This is to be expected from the fact that, for a given reduction, a longer contact area is required for a smaller die angle; and the frictional force opposing the draw force increases in proportion to the contact length.

This effect may be minimized by the influence of the other variables. If the total draw force is large, because of a small die angle, the force can be reduced by decreasing the reduction, Fig. 11, or by decreasing the coefficient of friction between the tubing and mandrel, Fig. 13. Decreasing the mandrel friction is of particular advantage in the case of a small die angle, but there is a limit to the amount that the drawing force can be reduced by this means, as will be shown later.

Reducing the friction coefficient between the tube and die may or may not decrease the total drawing force, Fig. 14, depending upon the reduction. For small reductions, increasing the die friction causes the expected increase of draw force. However, for reductions exceeding a certain value, the total draw force may decrease with increasing die friction. This is explained by the fact that when the die friction becomes small in comparison to the mandrel friction, the die pressure and the resulting frictional force become very high, even though the friction coefficient decreases. The rapid increase of die pressure with decreasing die friction is caused by the previously discussed phenomenon that the process becomes extrusion rather than drawing, for certain combinations of the variables.

Drawing Limits

In drawing processes of various types, the limit of reduction performable in a single draw is usually determined by the condition that the longitudinal stress at the exit cannot exceed the strength of the metal. For a metal which does not exhibit strain-hardening, as was assumed here, the highest possible value of longitudinal stress σ_e, at the exit, cannot exceed the flow stress σ_0, or the pressure at the exit p_e cannot be smaller than zero, as previously discussed. This limiting condition is expressed by the following equations

$$\sigma_e = \sigma_0, \quad p_e = 0 \quad [47]$$

This tension-failure condition also applies to drawing tubing with a moving mandrel for certain combinations of the variables, as previously discussed.

The limiting value of reduction R_{max}, or wall thickness at the exit $h = h_e$, is obtained from Equation [29] by substituting Equations [47], as mentioned previously

$$p_e = 0 = \frac{\sigma_0}{B}\left[(1+B)\left(\frac{h_e}{h_0}\right)^B - 1\right] \quad [48]$$

$$\frac{h_e}{h_0} = \left(\frac{1}{1+B}\right)^{1/B} \quad [49]$$

$$R_{max} = \frac{h_0 - h_e}{h_0} = 1 - \left(\frac{1}{1+B}\right)^{1/B} \quad [50]$$

The effect of several variables on this drawing limit, or "drawability," i.e., the maximum reduction performable in a single draw, is illustrated in Figs. 15 and 16 (curves $p_e = 0$). These

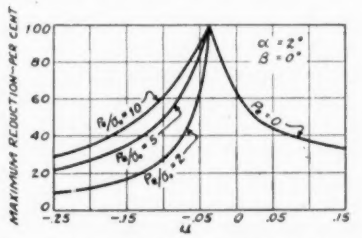

Fig. 15 Effect of Varying Flow Stress on Maximum Possible Reduction for Constant Limiting Die Pressure

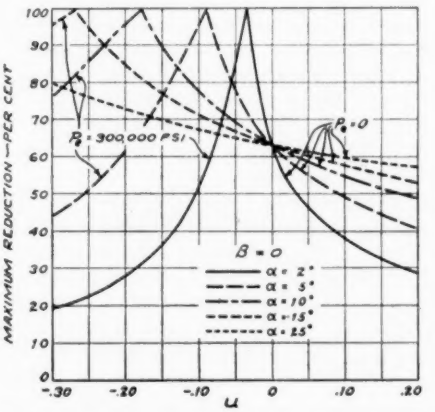

Fig. 16 Limiting Reductions in Cold-Drawing of Mild-Steel Tubing Without Failure in Tension ($P_e/\sigma_0 = 0$) or Failure of Die by Internal Pressure ($P_e/\sigma_0 = 300{,}000/55{,}000 = 5.46$)

figures indicate that a large increase in drawability may be obtained by increasing the friction on the mandrel over that on the die (negative values of u), particularly if the die angle is small. Also, small variations in friction may cause very large scattering of the reductions for an acute die angle.

While in other drawing processes the draw force cannot exceed the strength of the metal, the total draw force for drawing tubing with a stationary mandrel may become considerably higher if the die angle is small (or the difference between die and mandrel tapers is small), and the mandrel friction exceeds the die friction. This is illustrated in Figs. 13 and 14 for certain ranges of the processing variables.

These graphs, however, also illustrate the previously discussed fact that, within other ranges of the processing variables, no longitudinal tension exists and, consequently, that a tension failure cannot determine the drawability. It has also been discussed previously that the die pressure may then become very high; this would cause the die to rupture (by internal pressure) rather than cause the tubing to fail in tension. Assuming that the die will permit a maximum die pressure at the exit p_e that is a multiple n of the flow stress

$$p_e = n\sigma_0 \quad [51]$$

the following limiting condition is obtained from Equation [29]

$$p_e = n\sigma_0 = \frac{\sigma_0}{B}\left[(1+B)\left(\frac{h_e}{h_0}\right)^B - 1\right] \quad [52]$$

$$\frac{h_e}{h_0} = \left(\frac{1 + nB}{1 + B}\right)^{1/B} \quad \ldots\ldots\ldots\ldots\ldots [53]$$

The general effect of such a limiting condition of the total draw force is illustrated in Figs. 13 and 14 for $n = 2$, while Fig. 15 shows the influence of some processing variables on the drawing limit, or maximum reduction, performable in a single draw for dies of various strength, $n = \frac{p_e}{\sigma_0} = 2$, 5, and 10. A further example is represented in Fig. 16, for the drawing of mild steel, $\sigma_0 = 55{,}000$ psi, and a maximum die pressure taken arbitrarily as $p_e = 300{,}000$ psi. For these values, Equation [53] becomes

$$1 - \frac{h_e}{h_0} = 1 - \left(\frac{1 + 5.46B}{1 + B}\right)^{1/B} \quad \ldots\ldots\ldots\ldots [54]$$

The two possible limiting conditions, tension failure in the metal and bursting of the die, determine the drawability of tubing on drawing with a stationary mandrel in a rather peculiar manner, according to Figs. 15 and 16. Within a narrow range of tool shapes and frictional conditions, a reduction of almost 100 per cent appears possible, and this has been actually observed during experimentation, both on the drawing of cartridge cases and on drawing copper tubing with a moving mandrel.

PART 2 HOT-DRAWING

General Solution

The characteristic feature of hot-forming is that the flow stress depends primarily upon the rate of strain, while the influence of the amount of strain (strain-hardening) can be considered as negligible.

In order to develop an algebraic solution for the fundamental equation of equilibrium, Equation [3], for the hot-drawing of thin-walled tubing, therefore, the influence of the strain rate upon the flow stress must be known in the form of a simple relation, and the strain rate within the die must be expressed as a function of the velocity of the metal at the exit and the contours of the tools.

According to experimentation on the extrusion of brass,[7] Fig. 17, and according to high-temperature tensile tests on steel,[8] Fig. 18, the effect of velocity on the flow stress during hot-forming can be expressed as an exponential function. The tests on steel yield the flow stress σ_0 directly as a function of the strain rate $\frac{d\epsilon}{dt}$, taking the flow stress as equal to the tensile strength

$$\sigma_0 = a\left(\frac{d\epsilon}{dt}\right)^b \quad \ldots\ldots\ldots\ldots\ldots [55]$$

where a and b are constants, depending upon the metal and the temperature. Apparently the exponent b decreases and the coefficient a increases with decreasing temperature, Fig. 18.

The strain rate within the die is a function of the velocity V_e at which the metal comes out of the die, and the position x of the section considered, depending upon the geometry of the die, Fig. 2. Let the velocity at this point be V, and the velocity of a point dx farther be $(V + dV)$. Within a small interval of time dt, the point originally at x moves a distance Vdt and the point originally at $(x + dx)$ moves a distance $(V + dV)dt$. The change in length (d^2x) of the element dx, within the time interval dt, is then

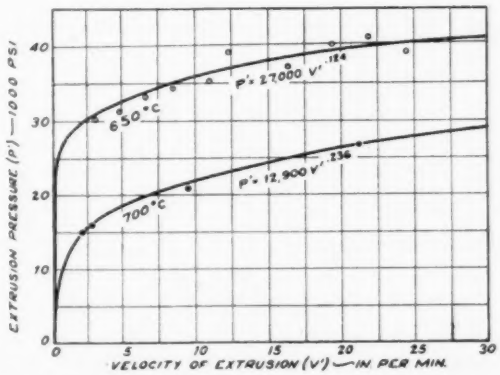

FIG. 17 EFFECT OF EXTRUSION RATE ON PRESSURE FOR 58 PER CENT CU, 42 PER CENT ZN BRASS BILLETS
(7-in-diam billets extruded to 2-in-diam rods.)

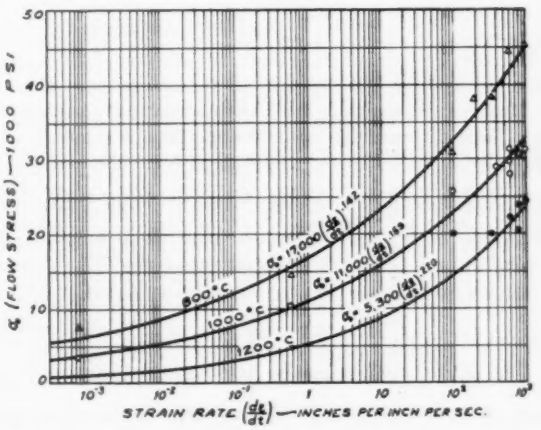

FIG. 18 EFFECT OF STRAIN RATE ON TENSILE STRENGTH, I.E., FLOW STRESS OF MILD STEEL[7]

$$d^2x = (V + dV)dt - Vdt + dVdt \quad \ldots\ldots\ldots [56]$$

The strain $d\epsilon$ is correspondingly

$$d\epsilon = \frac{d^2x}{dx} = \frac{dVdt}{dx} \quad \ldots\ldots\ldots\ldots [57]$$

and the strain rate $\frac{d\epsilon}{dt}$ becomes

$$\frac{d\epsilon}{dt} = \frac{dV}{dx} \quad \ldots\ldots\ldots\ldots [58]$$

Thus the strain rate at any point is the derivative of the velocity at that point.

Considering that the volume of the metal does not change during plastic flow, the following relation applies

$$Vh = V_e h_e \quad \ldots\ldots\ldots\ldots [59]$$

$$V = \frac{V_e h_e}{h} \quad \ldots\ldots\ldots\ldots [60]$$

Differentiating with respect to h yields the equation

$$\frac{dV}{dh} = -\frac{V_e h_e}{h^2} \quad \ldots\ldots\ldots\ldots [61]$$

According to Fig. 2, for any tool contour

$$dh = -dx\,(\tan\alpha - \tan\beta) \quad \ldots\ldots\ldots\ldots [62]$$

[7] "Practical Metallurgy," by G. Sachs and K. R. Van Horn, American Society for Metals, 1940, p. 373.

[8] "Plastic States of Stress in Curved Shells; Forging of Steel Shells," by A. Nadai, special pamphlet, "Forging of Steel Shells," Trans. A.S.M.E., 1944. See index to that volume.

The strain rate then becomes, combining Equations [58], [61], and [62]

$$\frac{d\epsilon}{dt} = \frac{V_s h_s}{h^2}(\tan\alpha - \tan\beta) \quad [63]$$

$$= \frac{V_s h_s D}{h^2}$$

and the flow stress Equation [55] is

$$\sigma_0 = a\left(\frac{v_s h_s D}{h^2}\right)^b \quad [64]$$

With this value of σ_0, the fundamental differential Equation [9] for the die pressure p becomes

$$\left.\begin{aligned} p &= \sigma_0 - \frac{1}{h}\int_0^x pC\,dx \\ p &= a\left(\frac{V_s h_s D}{h^2}\right)^b - \frac{1}{h}\int_0^x x_0 pC\,dx \end{aligned}\right\} \quad [65]$$

In order to solve this equation for the general case of curved tool contours, the variables must be first determined as functions of x. Then the resulting equation in p and x may be solved graphically in the same way as described for cold-working.

Algebraic Solution for Constant Tool Angles

If the tool angles α and β are constant, an algebraic solution can be obtained using the following relations: The horizontal force H is subject to the shear-stress relation Equation [8]

$$H = \sigma_0 h - ph$$

$$dH = \sigma_0 dh + h d\sigma - p dh - h dp \quad [66]$$

Replacing dx in Equation [3] by the value derived from Equations [11] and [22] yields the desired fundamental equation

$$dH = C p dx = -\frac{C}{D} p dh \quad [67]$$

$$\sigma_0 dh - h d\sigma_0 - p dh - h dp = \frac{C}{D} p dh \quad [68]$$

$$\frac{dp}{dh} - \frac{Bp}{h} = \frac{\sigma_0}{h} + \frac{d\sigma_0}{dh} \quad [69]$$

using the relation

$$\frac{C}{D} - 1 = \frac{(\tan\alpha - \tan\beta + \mu_1 - \mu_2) - (\tan\alpha - \tan\beta)}{\tan\alpha - \tan\beta} = B \quad [70]$$

The derivate $\frac{d\sigma_0}{dh}$ is obtained by differentiating Equation [64]

$$\frac{d\sigma_0}{dh} = -\frac{2ab(V_s h_s)^b}{h^{2b+1}} \quad [71]$$

Introducing σ_0 from Equation [64] and $\frac{d\sigma_0}{dh}$ from Equation [71] into Equation [69] yields the desired differential equation

$$\frac{dp}{dh} - \frac{Bp}{h} = a\frac{(1-2b)}{h^{2b+1}}(V_s h_s D)^b \quad [72]$$

This is a linear differential equation, the solution of which is

$$p = h^B\left[-\frac{a(1-2b)(V_s h_s D)^b}{(B+2b)h^{B+2b}} + c_3\right] \quad [73]$$

The constant of integration c_3 can be determined from the fact that at the entering side of the die $x = 0$, $h = h_0$, and the die pressure is equal to the flow stress σ'_0 at this point. The flow stress, of course, is a function of h, and its value at the entering side of the die can be determined by substituting $h = h_0$ in Equation [64]

$$\sigma_0' = a\left(\frac{V_s h_s D}{h_0^2}\right)^b \quad [74]$$

Substituting $h = h_0$ and $p = \sigma'_0$ in Equation [73] and solving for c_3 gives

$$c_3 = \frac{a(1+B)(V_s h_s D)^b}{(B+2b)h_0^{B+2b}} \quad [75]$$

Substituting Equation [75] in Equation [73], simplifying by the use of Equation [74], and solving for p yield the final equation

$$\frac{p}{\sigma_0'} = \frac{1}{B+2b}\left[(1+B)\left(\frac{h}{h_0}\right)^B - (1-2b)\left(\frac{h_0}{h}\right)^{2b}\right] \quad [76]$$

Equation [76] also includes the case of cold-drawing of a metal, with a constant flow stress σ_0 as a special case. For $\sigma_0' = \sigma_0$, $b = 0$ and Equation [76] reduces to Equation [29].

The physical significance of the quantity σ_0' is that it represents the flow stress of the metal under the strain-rate conditions prevailing on entering the die. As previously discussed, the flow stress is a function of the strain rate $\frac{d\epsilon}{dt}$, and the strain rate at the entering side of the die, where $h = h_0$, is, according to Equation [55]

$$\left(\frac{d\epsilon}{dt}\right)_b = h_0 = \frac{V_s h_s D}{h_0^2}$$

$$= \frac{V_s}{h_0}\left(\frac{h_s}{h_0}\right)(\tan\alpha - \tan\beta) \quad [77]$$

According to this relation, the strain rate at the entering side of the die is proportional to each of three quantities: To the ratio of velocity at the exit to initial thickness, i.e., the ratio of the two independent variables, $\left(\frac{V_s}{h_0}\right)$; to the thickness ratio $\left(\frac{h_s}{h_0}\right)$, or ratio of thickness before and after drawing; and to a trigonometric function of the tool tapers $(\tan\alpha - \tan\beta)$, which increases with decreasing die angle and increasing mandrel taper.

For the purpose of calculating the die pressure, it is more convenient to replace the velocity at the exit V_s, by the velocity on entering the die V_0, by means of the condition that the volume of the metal remains constant (see Equation [59])

$$V_s h_s = V_0 h_0 \quad [78]$$

The flow stress on entering the die, Equation [74], then becomes

$$\sigma_0' = a\left(\frac{V_0 D}{h_0}\right)^b \quad [79]$$

and the strain rate on entering the die, Equation [77], is correspondingly

$$\left(\frac{d\epsilon}{dt}\right)_{h=h_0} = \frac{V_0}{h_0}(\tan\alpha - \tan\beta) \quad [80]$$

According to this relation, the strain rate on entering the die is proportional to each of two quantities, to the ratio of velocity at

the entering side of the die to initial thickness $\left(\frac{V_0}{h_0}\right)$, and to the trigonometric function $\tan \alpha - \tan \beta$.

Equation [76] becomes indeterminate, when $B = -2b$. This results from the fact that, in the solution of Equation [72], an expression must be integrated which involves the quantity $\frac{1}{h^{2b+B+1}}$. When $B = -2b$, this quantity reduces to $\frac{1}{h}$, and $\int \frac{dh}{h} = \ln h$. Proceeding as before, the formula for p is then found to be

$$\frac{p}{\sigma_0'} = \left(\frac{h_0}{h}\right)^{2b}\left[(1-2b)\ln\frac{h}{h_0}+1\right] \quad \ldots\ldots [81]$$

Effects of Processing Variables on Die Pressure

The flow stress in hot-drawing is not constant but varies with the position of the metal within the die. Consequently, it is more lucid to determine the absolute die pressure rather than the ratio of die pressure to flow stress, see Figs. 9 and 10, for cold-drawing.

The die-pressure distribution as given by Equations [76] and [78], has been plotted in Figs. 19 and 20 for mild steel, using the reduction of metal thickness, $R = 1 - \frac{h}{h_0}$ as abscissas. Curves for various frictional conditions, $u = \mu_1 - \mu_2$ are represented while the other factors are kept constant. The die angle has been selected very small, $\alpha = 2$ deg and the mandrel has been assumed to be straight, $\beta = 0$ or $D = \tan \alpha - \tan \beta = +0.035$, in order to illustrate the large effect of the friction difference under such circumstances; i.e., for a small value of $D = \tan \alpha - \tan \beta$. Curves for cold-drawing, where $\sigma_0 = 55{,}000$ psi, are shown on the right side of Figs. 19 and 20, to be compared with the curves for hot-drawing at a selected temperature of 2200 F, at a velocity V_0 on entering the die of 6 fpm, and for an initial wall thickness h_0 of 1.20 in., or a "specific" velocity on entering the die (V_0/h_0) of 1 per sec. The value of σ_0' for such conditions is approximately 2500 psi, according to Fig. 20, and is plotted for a range of reductions extending up to 97 per cent ($h_s = 0.03\ h_0$), but the curves have a physical meaning only if the die pressure exceeds zero. In those cases where a reduction of 97 per cent is theoretically feasible, the velocity at the exit would be 200 fpm, see Equation [78]. Fig. 20 enlarges the portion of Fig. 19 representing die pressures less than 5000 psi.

Figs. 19 and 20 illustrate that three types of pressure distributions may occur in hot-drawing as opposed to the two types encountered in cold-drawing. The pressure-distribution characteristic for "drawing," where the die pressure continuously decreases as the exit side of the die is approached, is observed in hot-drawing for large values of $B = u/D > (2b - 1)$, while this condition extends to smaller values of $B > -1$ in cold-drawing. The pressure-distribution characteristic for "extrusion," where the die pressure continuously increases toward the exit, prevails in both hot-drawing and cold-drawing for small values of $B < -1$.

In addition to these two types of pressure distribution, a third one exists in hot-drawing when $-1 < B < (2b - 1)$. Then the pressure distribution shows a maximum at a certain position in the die, decreasing rapidly to zero with further approach to the exit. This condition is illustrated by the curve for $u = -0.0304$ in Figs. 19 and 20.

As previously discussed, each curve in Figs. 19 and 20, for hot-drawing, represents the pressure distribution for any total reduction, for a given set of conditions. This is the case if the strain-rate function of the velocity and thickness is kept constant on entering the die. In practice, however, the velocity at the exit and the initial thickness usually will be the independent variables. For a set of conditions in which these two factors are constant, Fig. 21 illustrates the pressure distribution present in drawing to final reductions ($R_s = 1 - h_s/h_0$), varying between 20 and 99.99 per cent. The decrease of the pressure at the entering side of the die with increasing total reduction is explained by the decrease of the strain rate at the entering side with increasing total reduction, which determines the flow stress σ_0', or the die pressure at this point.

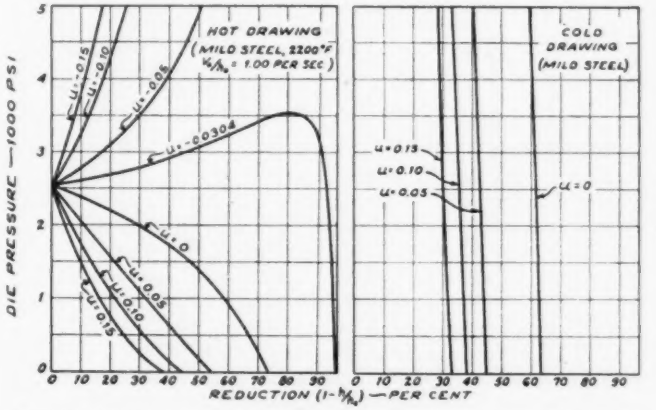

Fig. 20 Effect of Friction on Distribution of Die Pressure for Hot- and Cold-Drawing of Mild Steel; $\alpha = 2$ Deg, $\beta = 0$ Deg; Enlargement of Fig. 19

Drawing Limits

The drawing limits for hot-drawing are determined in much the same manner as in cold-drawing. These limits are also similarly affected by the processing variables, as illustrated in Figs. 15 and 22.

For the "drawing" type of pressure distribution, the drawing limit or "drawability," i.e., the maximum reduction $\left(R_s = 1 - \frac{h_s}{h_0}\right)$, performable in a single draw, is given as the reduction

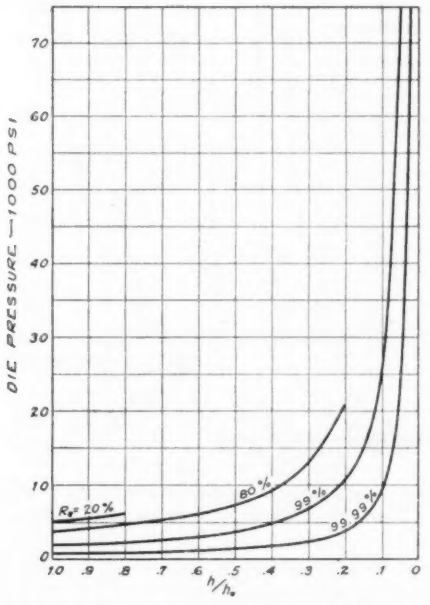

FIG. 21 PRESSURE DISTRIBUTION FOR VARIOUS TOTAL REDUCTIONS (R = 20 TO 99.99 PER CENT) FOR HOT-DRAWING OF MILD STEEL AT 2200 F

(α = 2 deg, β = 0 deg, u = —0.05, V_0/h_0 = 33.1 per sec or (200 fpm) for h_0 = 1.21 in.)

at which the die pressure becomes zero. This reduction differs only slightly for hot-drawing and cold-drawing, if the tools and frictional conditions are identical, Figs. 19 and 20. Theoretically, slightly larger reductions can be obtained on hot-drawing than on cold-drawing. Actually, however, the conditions during hot-drawing are difficult to control, and variations in temperature and frictional conditions should reduce the drawability. Also, the metal at the exit, which is subjected to the maximum tension, may exhibit a tendency to creep, and a corresponding decrease in strength may occur, as has been occasionally observed.

For the "extrusion" type of pressure distribution, the limit of drawing will be determined again by the strength of the die. The die pressures in hot-drawing are of course considerably smaller than those in cold-drawing, under identical conditions, as expected from the smaller flow stress at elevated temperatures. However, the die pressure in hot-drawing also becomes very large under certain conditions, see Figs. 19 to 21; but it does not increase as rapidly nor does it reach a large value at such a small reduction as the pressure in cold-drawing. Consequently, a larger reduction is possible in hot-drawing without failure of the die than in cold-drawing, due to the smaller flow stress. The effect of varying conditions on the drawing limit can be determined if an arbitrary value of die pressure is considered as the maximum internal pressure which the die will stand without failure, say, 300,000 psi.

Regarding these limiting reductions in drawing, there is one important difference between hot- and cold-drawing. For any particular die angle, the curve representing the drawing limit as a function of u consists of two branches, corresponding to failure of the tubing by tension and failure of the die by internal pressure, respectively. The two branches form a sharp peak in the case of cold-drawing, Fig. 15, particularly for small die angles whereas in the case of hot-drawing the peak is broad and rounded, Fig. 22. This means that the friction conditions are not as critical and the variations of the drawing limits resulting from small variations in the friction conditions should not be as pronounced in hot-drawing as in cold-drawing.

It may be pointed out that for equal friction coefficients at the die and mandrel, the drawability for both cold-drawing, Fig. 15, and hot-drawing, Fig. 22, is slightly higher than 60 per cent.

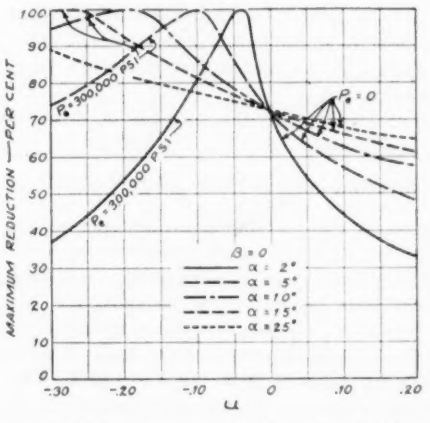

FIG. 22 LIMITING REDUCTIONS IN HOT-DRAWING (2200 F) OF MILD STEEL TUBING WITHOUT FAILURE IN TENSION (Pe/σ_0 = 0), OR FAILURE OF DIE BY INTERNAL PRESSURE (P_e = 300,000 PSI)

This is a basic value ($1 - 1/e$) of drawability, derived for other types of drawing, such as wire-drawing and deep-drawing if friction is absent. Thus, regarding the drawability for drawing tubing with a moving mandrel, equal friction coefficients on the die and mandrel yield the same conditions as zero friction in other drawing processes.

Influence of Rate of Strain and Temperature on Yield Stresses of Mild Steel

By M. J. MANJOINE,[1] EAST PITTSBURGH, PA.

This paper describes the influence of rate of strain and temperature on the yield stresses of mild steel. Tensile tests are reported for room temperature, 200, 400, and 600 C, at rates of strain which vary from 10^{-6} to 10^{3} per sec. The results of these tensile tests are plotted to show more clearly the effects of strain-aging on the yield stresses and ultimate stress. The comparison of the yield stress at various strain rates permits an analysis of the influence of strain. The conditions necessary for discontinuous yielding are described and compared with test experiences.

Introduction

CONSIDERABLE research has been devoted to the influence of temperature and of speed of testing on the yield-point stress and the ultimate strength of mild steel. This paper is presented as a step further in the understanding of the yielding of mild steel and describes the influence of temperature and rate of strain on the yield stresses at various strains as well as on the stresses at the lower yield point and at the ultimate load of a tension test. In a previous paper (1)[2] by A. Nadai and the author, tensile tests were described at various rates of strain and temperatures, but only results concerning the ultimate stress were reported. In this paper the tensile tests for mild steel are further analyzed.

Because of the numerous articles on the testing of mild steel, reference will be made only to a few which contain a more complete bibliography. In 1938, Davis (2) reviewed the literature on the effect of speed of testing on the yield point of mild steel and added the influence of loading rate. Other work has been published since that time. Edwards, Phillips, and Jones (3) described the influence of some special elements on the strain-aging and yield-point characteristics of low-carbon steel. High-speed tension tests were reported by Brown and Vincent (4). Smith and Wood (5) gave the stress-strain curve for the atomic lattice of mild steel and related the change of the lattice spacing to the external yield point.

As early as 1909, Le Chatelier (6) pointed out that the peak of the ultimate stress-temperature curve for low-carbon steel could be shifted to a higher temperature by increasing the speed of testing. Later Carpenter and Robertson (7) described the part aging contributes in shifting the peak of the "stress versus strain-rate" curve toward a higher rate for increasing temperature. The term "strain-aging" will be used frequently in this paper and will refer to the change in the physical properties of steel caused by permanent deformation in the "blue-heat" range, or by storing permanently deformed steel at normal or moderate temperatures. A complete review of the literature on the aging of steel and its effect on the physical properties can be found in a paper by Kenyon and Burns (8).

Test Results

Testing Apparatus. Two machines were employed in making the tensile tests described here, a high-speed tension machine for the fast strain rates and a constant strain-rate machine for the intermediate and slow rates of testing. These machines and the shape of the test specimen were described in two previous papers (1, 9). The mild steel used in this investigation was a commercial low-carbon open-hearth steel. The finished test specimens were bright-annealed for 1 hr at 920 C in dissociated ammonia.

Original Curves. Six of the original oscillograms of high-speed tests are shown in Fig. 1. The axes are drawn to outline these load-elongation curves. No scales are given as several different magnifications were used in recording the load and elongation and in photographic enlarging. The large spot at the origin is caused by the electron beam of the oscilloscope which is stationary for about 1 sec before the test starts. The heavy vertical trace in (*a*) and (*b*) was caused by an imperfection in the beam switch which was later changed. The grating which appears in (*d*), (*e*), and (*f*) is a 0.1-in. grid which is placed in front of the cathode-ray screen for quick determination of the deflection of the beam. It is also used as a reference when measurements are taken from enlarged oscillograms. At the beginning and end of the oscillograms, vibrations occur having the natural frequency of the force-measuring system which is excited by the sudden yielding of the specimen or by the drop of the load at fracture. The frequency of this vibration is about 11,000 cycles per sec.

At the strain rate of 100 per sec, oscillogram (*c*), the amplitude of this vibration is small and the upper and lower yield points can readily be seen. The specimen in this test was not broken. The amplitude of the vibrations increases with the speed of testing, as can be seen in (*a*) and (*b*). At higher speeds the amplitude on first yielding becomes nearly as large as the deflection caused by the load. Because of the high writing speed in these latter oscillograms they cannot be satisfactorily reproduced for publication. The vibrations are fortunately damped down as the specimen yields. This can be seen in (*e*) and (*f*). At 400 C, oscillogram (*e*), a yield point can still be distinguished with the vibrations increasing in amplitude at the yield point and dying down as the specimen yields.

Typical recorded curves obtained on the constant strain-rate machine have been photographed and are shown in Fig. 2. The curves shown are those obtained on mild steel at 200 C for four different rates of strains. The elastic constant of the constant strain-rate machine is rather high. The recorder is capable of following vibrations of 20 cycles per sec, and therefore can follow the changes of load which occur during discontinuous yielding. A close inspection of the curves, made at the rates of 8.5×10^{-4} and 2×10^{-2} per sec, illustrates the oscillations of the load which occur during discontinuous yielding.

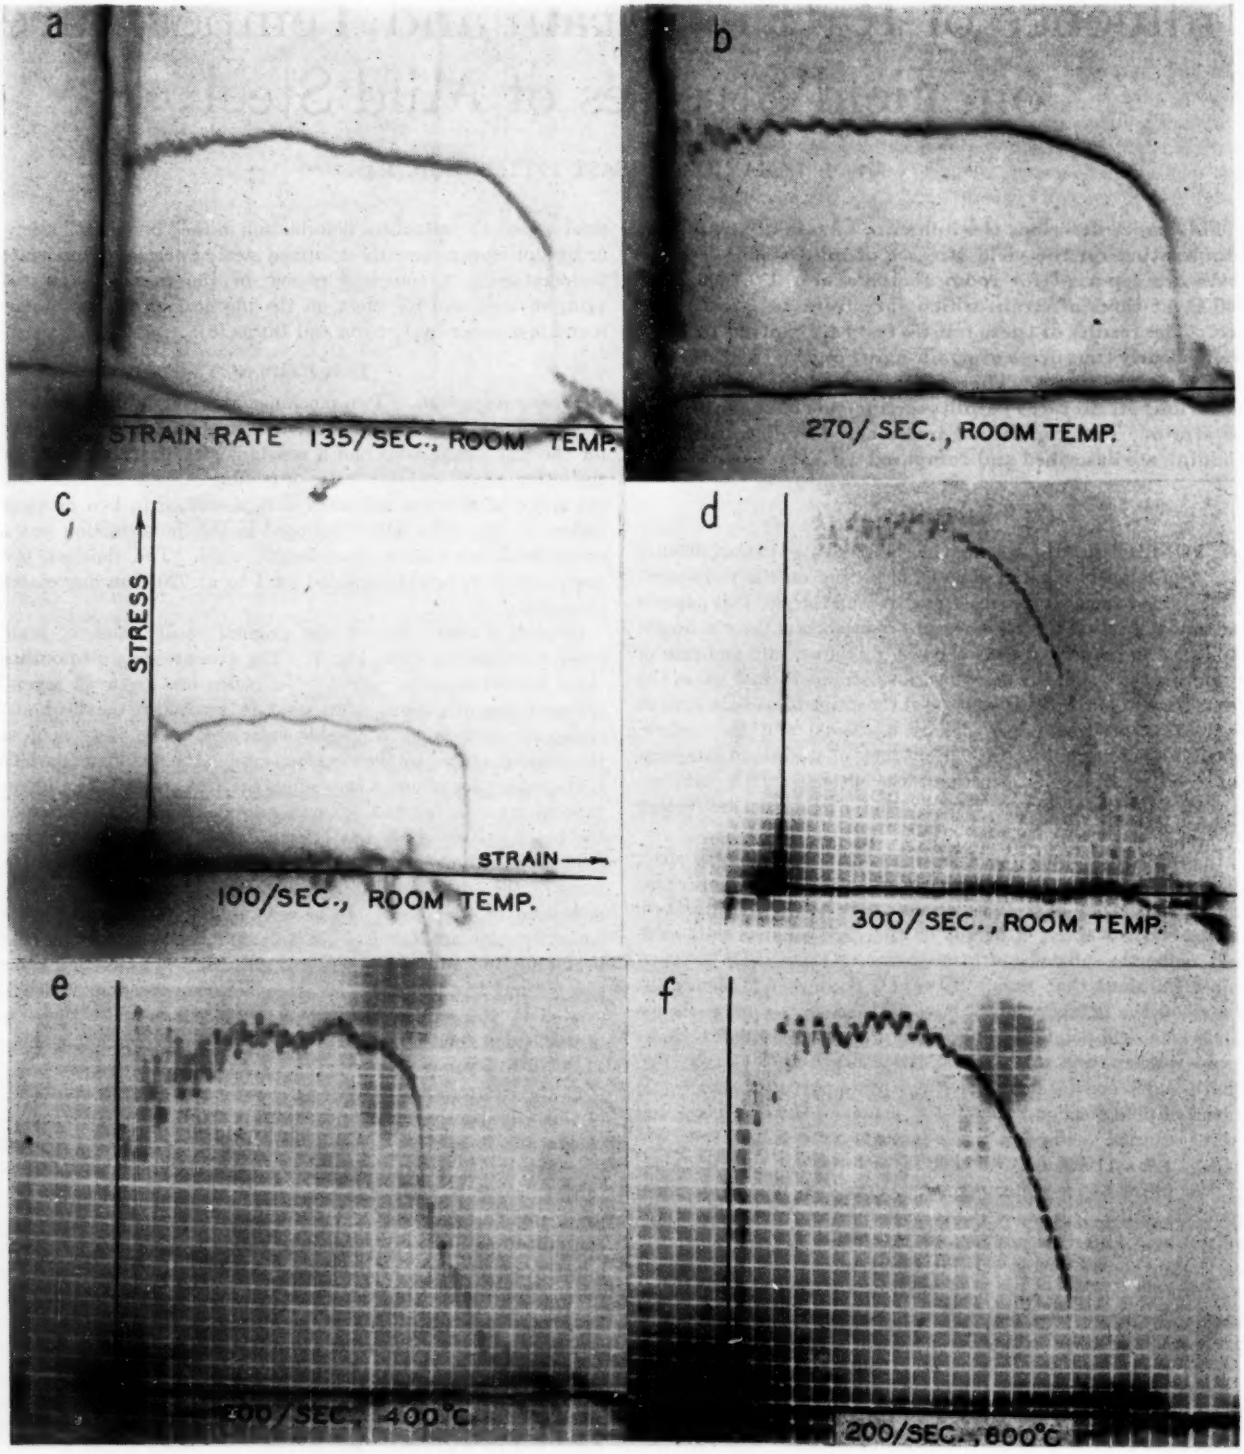

FIG. 1 ORIGINAL OSCILLOGRAMS OF SOME HIGH-SPEED STRESS-STRAIN CURVES

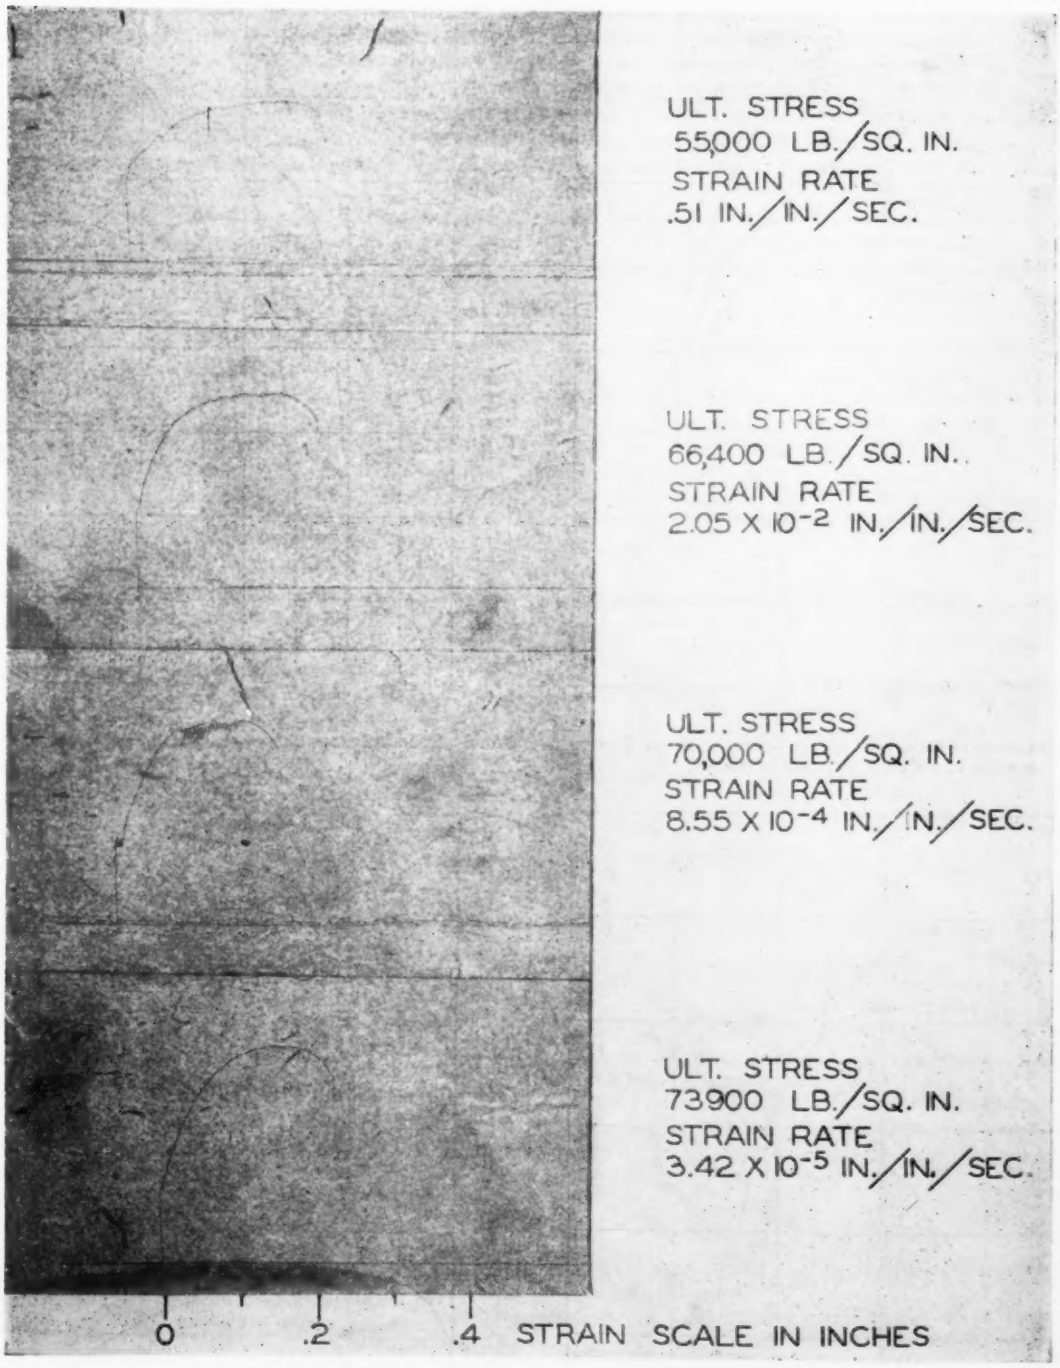

FIG. 2 EFFECT OF STRAIN RATE ON MILD STEEL AT 200 C

DISCUSSION OF STRESS - STRAIN CURVES

The original curves are a record of load versus elongation. Some of these curves have been replotted with stress as a function of strain and are shown in Figs. 3 to 6, inclusive. The stress is based on the original cross section, and strain is the total strain. In replotting the high-speed diagrams, an averaging curve has been drawn through the vibrations which occur on the original record.

The room-temperature stress-strain curves, given in Fig. 3, show the effect of the speed of testing on the shape of the curve. At a strain rate of 9.5×10^{-7} per sec, the time of the test is long enough to allow strain-aging at the higher strains, and therefore a greater ultimate strength is obtained than for the test made at a rate of 8.5×10^{-4} per sec. The yield-point stress is not noticeably affected by aging and shows a uniform increase with strain rate. The yield-point elongation increases with strain rate and reaches about 8 per cent strain at the rate of 300 per sec. The strain at the ultimate is about 20 per cent and changes very little with speed of testing. The first portion of the curve at 300 per sec is dashed because it represents the averaging curve of the

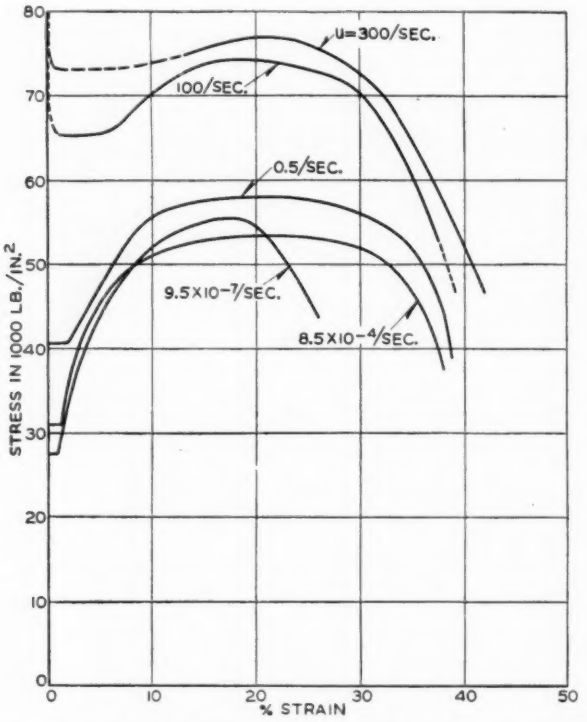

FIG. 3 STRESS-STRAIN CURVES OF MILD STEEL AT ROOM TEMPERATURE FOR VARIOUS RATES OF STRAIN

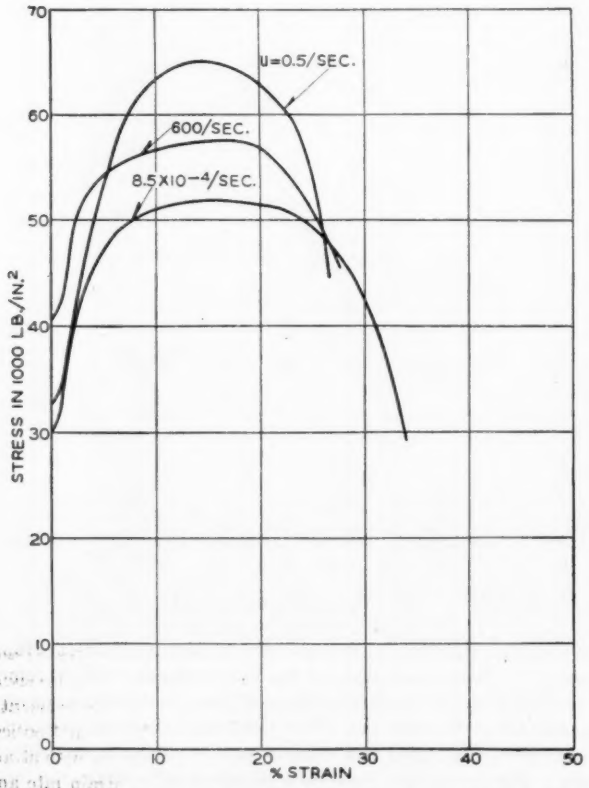

FIG. 5 STRESS-STRAIN CURVES OF MILD STEEL AT 400 C FOR VARIOUS RATES OF STRAIN

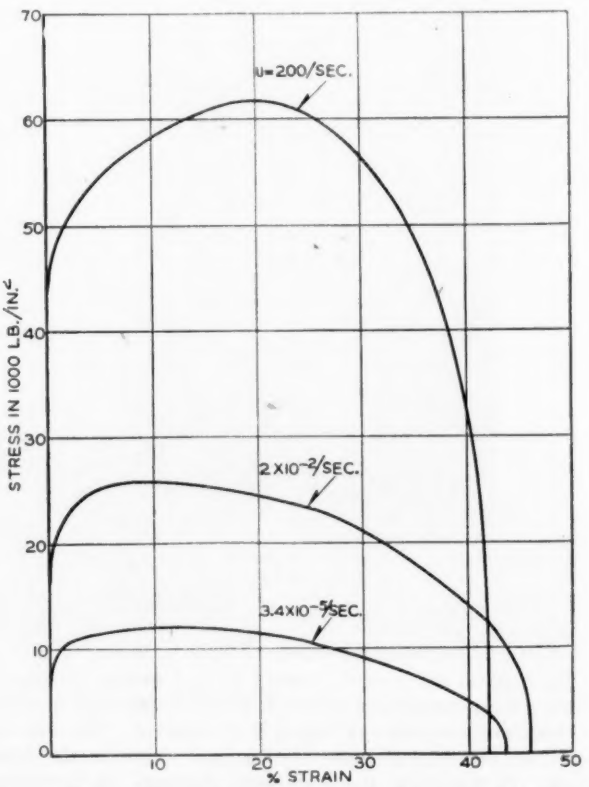

FIG. 6 STRESS-STRAIN CURVES OF MILD STEEL AT 600 C FOR VARIOUS RATES OF STRAIN

vibrations which occurred on the original diagrams. The specimen tested at a strain rate of 100 per sec necked down but was not broken.

The stress-strain curves for 200 C, Fig. 4, are plotted with the strain origin shifted 5 per cent to the right for each subsequent curve taken at a slower strain rate. The yield point, yield-point elongation, and ultimate strength increase with strain rate. The ultimate strength is also influenced by strain-aging. At a strain rate of 8.5×10^{-4} per sec, discontinuous yielding starts at about 8 per cent strain. The amplitude of the drop of the stress during yielding is about 5000 psi for our tensile machine. Discontinuous yielding also occurs at a strain rate of 2×10^{-2} per sec, but the amplitude of the drop in stress is only 800 psi.

At 400 C, Fig. 5, the yield point has practically disappeared, but a break in the curve is still present. The yield stress at 0.2 per cent increases with strain rate, but the ultimate strength increases at first and then decreases.

The curves for 600 C, Fig. 6, show the large increase in the strength for the higher strain rates. The yield point has completely disappeared at this high temperature.

Influence of Strain Rate on Tensile Properties of Mild Steel at Room Temperature

From the stress-strain curves for various rates at room temperature, the influence of strain rate on several of the tensile properties has been determined and is indicated in Fig. 7. This curve shows the dependence of the yield-point stress, the ultimate stress, and the total elongation on the rate of straining at room temperature. In addition, the ratio of the yield-point stress to the ultimate stress is given. The yield-point stress is taken as the stress at the lower yield point. This stress increases continuously with the rate of strain, while the ultimate stress shows a decrease for the lowest rates and an increase for the high rates. The ratio of yield stress to ultimate stress increases over the entire range of strain rates; at the lowest rate the ratio is 50 per cent while at the highest rate it is over 95 per cent. The elongation increases at the lower rates but is practically constant from a rate of 10^{-3} to 10^{3} per sec, a range of rates of 1 to 1,000,000.

Influence of Rate of Strain on Yield Stresses

To determine the effect of rate of strain on the yield stresses necessary to deform mild steel, the true yield stresses have been computed for various strains of the stress-strain curves in Figs. 3, 4, 5, and 6. The true yield stress is the load at a given strain divided by the actual area, or the load stress at a given strain multiplied by a factor (1 plus the unit strain).

The results of the room-temperature tests are given in Fig. 8. The true yield stresses are shown for the yield point and for the strains of 2, 4, 8, and 12 per cent; included in addition is the true stress at the ultimate load of the tensile test. The stress at the yield point is taken at the lower yield point where the material flows at practically a constant load throughout the yield-point elongation. Although the actual load is constant, the true stress in the mild steel must increase during the yield-point elongation; the amount of the increase depends upon the strain that takes place. Therefore, the values of the true stresses at the beginning and at the end of the yield-point elongation must be shown in a band. Since the yield-point elongation increases with rate of strain, this band increases in width for higher rates. No points can be shown within this band as stress and strain have little significance during the yield-point elongation.

The yield stresses at 2 and 4 per cent strain increase uniformly with rate; when the yield-point elongation reaches these strains the yield-stress curve is terminated. At higher strains and the slowest rates, however, the effect of strain-aging begins to show. The yield stresses for these higher strains decrease with rate, reach a minimum, and then increase uniformly at the higher rates. In the region where the slope of the stress versus strain-rate curve is negative, discontinuous yielding will occur. This effect will be described later in more detail. These curves are fortunately very flat in the region in which the ordinary short-time tensile tests are made (about 2×10^{-3} per sec).

The temperature of 200 C has always been considered a critical one for mild steel because at or near this temperature considerable strain-aging takes place during the ordinary short-time tensile test, and discontinuous yielding usually occurs. The reason for discontinuous yielding can be seen in Fig. 9, which shows the variation of the yield stresses with strain rate. As

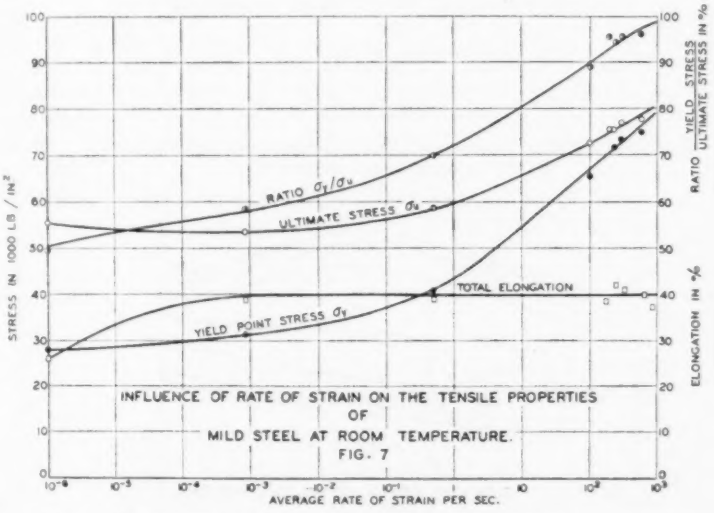

Fig. 7 Influence of Rate of Strain on Tensile Properties of Mild Steel at Room Temperature

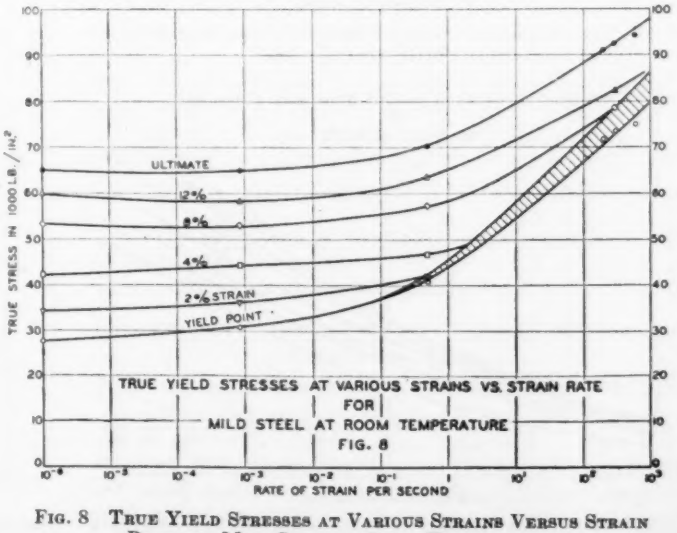

Fig. 8 True Yield Stresses at Various Strains Versus Strain Rate for Mild Steel at Room Temperature

stated before, discontinuous yielding can be expected when the stress versus strain-rate curve has a negative slope. This means that the material can yield more rapidly at a lower stress, as it does; to keep the average rate constant, the material will be stretched much more slowly during another part of the cycle; this causes the load to build up again and the cycle is repeated.

In Fig. 9, the yield stress at 8 per cent strain has a negative slope from a rate of 10^{-4} to 5×10^{-1} per sec. Referring to the curve for the strain rate of 8.5×10^{-4} per sec, which is in the range previously mentioned, Figs. 2 or 4, discontinuous yielding starts at a strain of about 8 per cent and continues up to the ultimate strength. The tension test at the rate of 2×10^{-2} per sec is also in this range of negative slope, and discontinuous yielding starts at a strain of 4 per cent and continues up to rupture of the specimen. The amplitude of the fluctuation in load during yielding, however, is about one fifth of that which occurred at the rate of 8.5×10^{-4} per sec. This can be accounted for by the fact that the mild steel strain-ages at the same rate in both tests, but at the higher average strain rate less time is available, and therefore less effect can be expected.

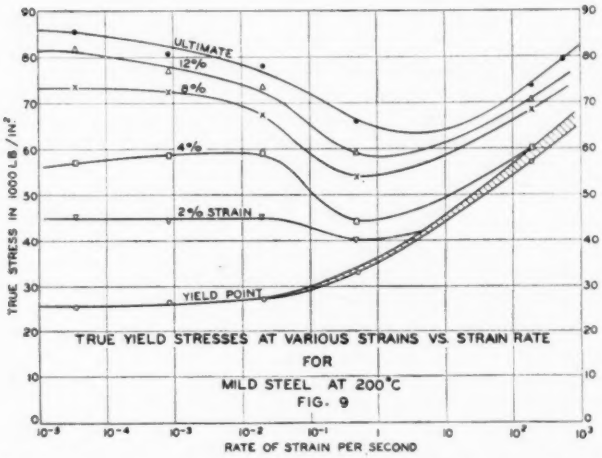

FIG. 9 TRUE YIELD STRESSES AT VARIOUS STRAINS VERSUS STRAIN RATE FOR MILD STEEL AT 200 C

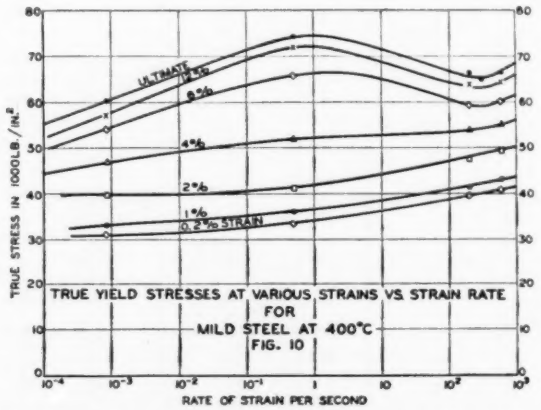

FIG. 10 TRUE YIELD STRESSES AT VARIOUS STRAINS VERSUS STRAIN RATE FOR MILD STEEL AT 400 C

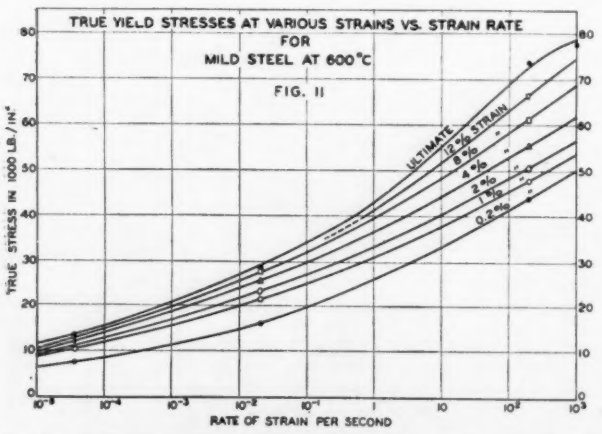

FIG. 11 TRUE YIELD STRESSES AT VARIOUS STRAINS VERSUS STRAIN RATE FOR MILD STEEL AT 600 C

Discontinuous yielding has been described by other investigators who gave aging as the only explanation. Among the first to show this rapid variation in load during deformation were Bach and Baumann (10), and Körber and Pomp (11). They found the effect for ferrous metals when tested at slightly elevated temperatures. Quinney (12) showed that discontinuous yielding may occur at room temperature for Yorkshire iron at very slow speed of testing (see Figs. 7 and 8, for the negative slope in the stress-strain-rate curve at the lowest rates). Elam (13) found the same thing for Armco iron and aluminum alloys at room temperature and compared discontinuous yielding with an aging effect which occurs in a test in which frequent rest periods are allowed.

Strain-aging is dependent upon time and temperature. Its effect may be either beneficial or, as in the case of overaging, deleterious. Since annealing or recrystallization may occur,

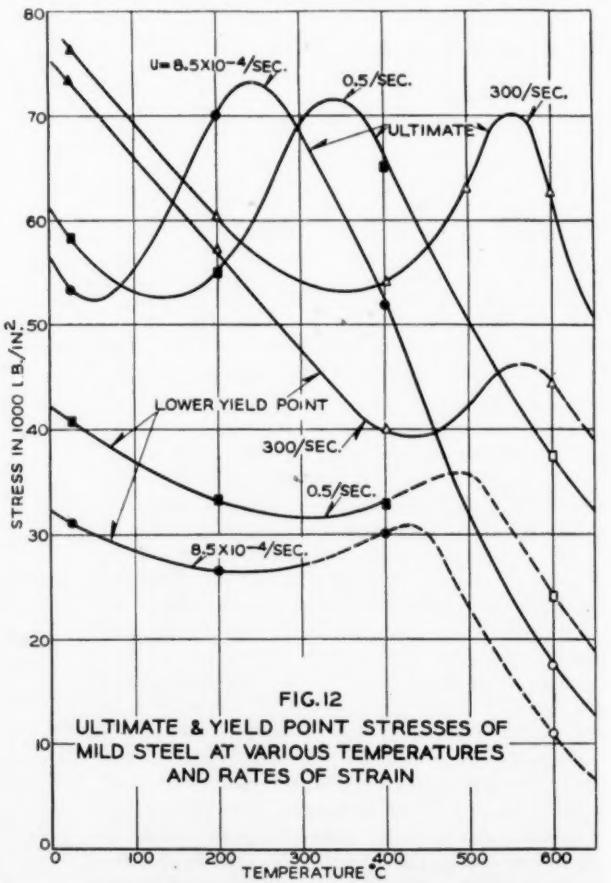

FIG. 12 ULTIMATE AND YIELD-POINT STRESSES OF MILD STEEL AT VARIOUS TEMPERATURES AND RATES OF STRAIN

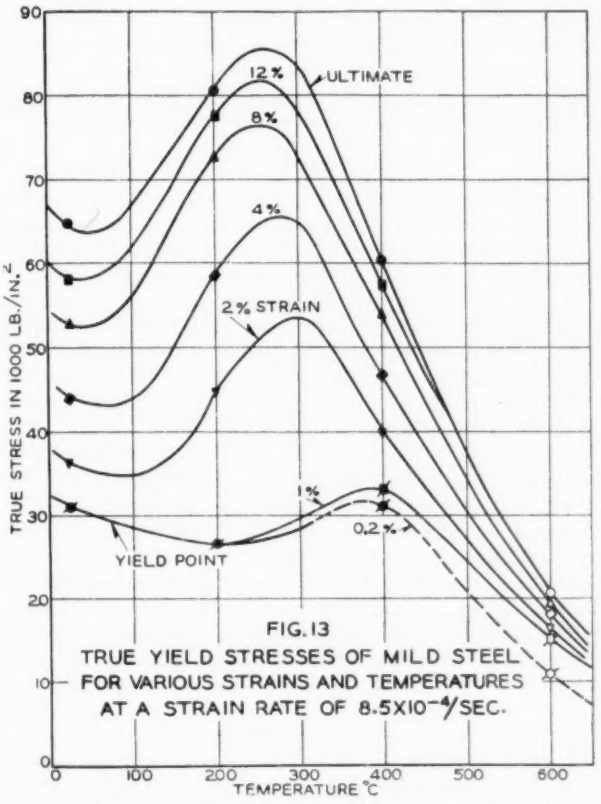

FIG. 13 TRUE YIELD STRESSES OF MILD STEEL FOR VARIOUS STRAINS AND TEMPERATURES AT A STRAIN RATE OF 8.5×10^{-4} PER SEC

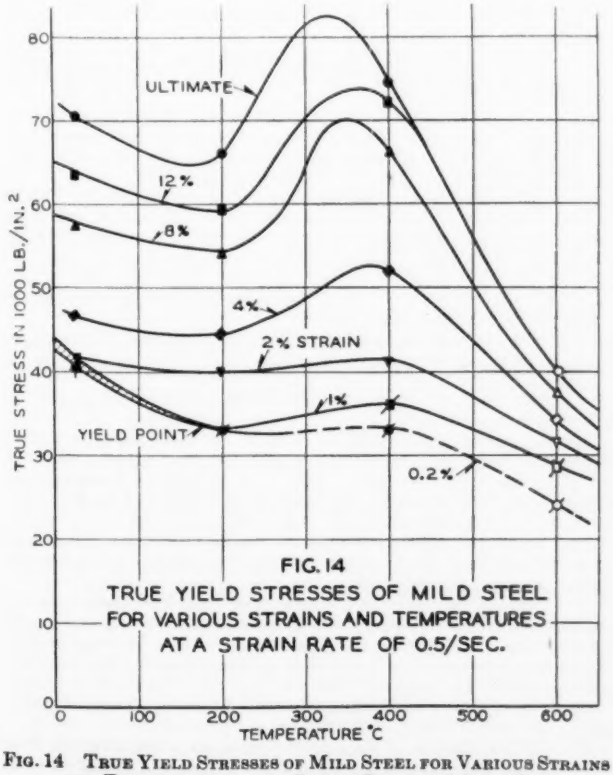

FIG. 14 TRUE YIELD STRESSES OF MILD STEEL FOR VARIOUS STRAINS AND TEMPERATURES AT A STRAIN RATE OF 0.5 PER SEC

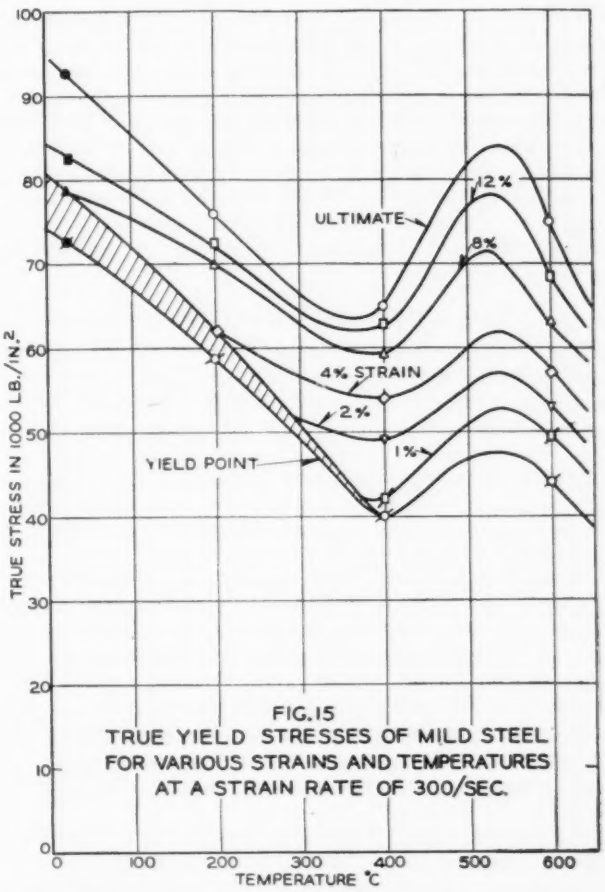

FIG. 15 TRUE YIELD STRESSES OF MILD STEEL FOR VARIOUS STRAINS AND TEMPERATURES AT A STRAIN RATE OF 300 PER SEC

which is also a function of time and temperature, the yield stresses for mild steel for high temperatures will be influenced by all these factors. At 400 C, Fig. 10, all the foregoing effects show up when tests are made over a large range of strain rates. At the higher strains, above 4 per cent, aging causes an increase in yield stress as the strain rate is decreased, thus allowing a longer time for a given strain. However, as the strain rate is further decreased, the time becomes great enough to allow overaging, annealing, and recrystallization; therefore the yield stress decreases with further decreases in strain rate. For strains below 4 per cent, the yield stresses increase with strain rate throughout the range investigated. At this temperature, the yield point is no longer observed at the slow strain rates, but a slight break in the stress-strain curve can still be seen.

At 600 C, Fig. 11, the speed effect is more pronounced. The yield stresses of all strains increase with rate of strain. The effect of strain-hardening increases with strain rate since the time for recrystallization and annealing decreases.

Influence of Temperature on Ultimate Strength and Yield-Point Stresses

The stresses at the ultimates of the loads and at the yield points have been taken from some of the stress-strain curves and are plotted as a function of temperature for the strain rates of 8.5×10^{-4}, 0.5 and 300 per sec, Fig. 12. The solid points are actual test points, while the open points are interpolated from other curves. At the higher temperatures, the lower yield-point curve is shown as a broken line; the stress for this portion

of the curve is taken at the yield stress for 0.2 per cent strain. The peak in the ultimate-strength curve is a result of aging and strain-hardening. Since these processes take time, the peak can be shifted to a higher temperature for increasing strain rates. The yield point is not noticeably affected by strain hardening and therefore undergoes a smaller shift as the strain rate is increased. The peak at the lowest rate occurs at about 400 C, which is 150 C higher than the peak of the ultimate stress at the same rate. However, at the high speeds, the peaks in the ultimate-stress and yield-point-stress curves occur at practically the same temperature.

True Yield Stress Versus Temperature

Based upon the preceding curves, Figs. 8 to 11, inclusive, the effect of temperature can now be better studied by comparing the yield stresses at several constant rates of strain. Comparisons are made at rates of 8.5×10^{-4}, 0.5, and 300 per sec in Figs. 13, 14, and 15. The solid points on the curves are actual test points, while the open points are interpolated from Figs. 8 to 11, inclusive. The yield-point curve is joined with the curve for 0.2 per cent strain but the latter portion of the curve is shown as a broken line.

At the strain rate of 8.5×10^{-4} per sec which is about the rate of a short-time tensile test, the yield-point elongation is about 1 per cent for the lower temperatures and vanishes for temperatures of about 400 C and higher. At this strain rate the strain-aging range extends from 100 to 400 C; at 1 per cent strain a much higher temperature is needed to strain-age the steel, the peak in the stress versus temperature curve coming at about 400 C. However, as the strain is increased, this peak shifts to lower temperatures and, at the ultimate of the load in the tension test, occurs at about 250 C.

The curves in Fig. 13 show that a sharp change in shape takes place in the curves between the strains of 1 and 2 per cent. This indicates that a strain of between 1 to 2 per cent is necessary to accelerate strain-aging and that further increase in stress for higher strains is caused by strain hardening. This statement can be better understood if we compare cross sections of the curves at room temperature and at 250 C. At room temperature, strain-aging occurs so slowly that it can be neglected at this strain rate. The increase in stress necessary to deform the mild steel at increasing strain is a result of strain hardening, and the amount of strain hardening can be seen from the spacing of the curves. At 250 C the spacing between the 1 and 2 per cent strain curves is much greater than the spacing at room temperature, but the spacings between the other curves are about the same for both temperatures. The difference in spacing between the curves is a result of strain aging. At temperatures of 400 C and above, strain aging and hardening occur, but their effect is reduced by annealing or recrystallization and is only noticeable at strains below 1 per cent.

When the strain rate is increased to 0.5 per sec, the peak in the curve for true stress at the ultimate load occurs at about 325 C, Fig. 14. The peaks of the yield-point and 1 per cent strain curves have not been changed in so far as temperature is concerned but have increased because of the increase in strain rate. To separate strain-hardening and strain aging, the difference in the spacing of the curves must be compared at room temperature and about 325 C. From this comparison it is evident that a much higher strain is necessary to accelerate strain aging; the actual strain lies somewhere between 4 and 8 per cent. We can therefore conclude that, as the speed is increased a higher temperature and strain are necessary to accelerate strain aging.

At a strain rate of 300 per sec, Fig. 15, the peak in the stress-temperature curves occurs at about 540 C for all strains. Very little time, less than 0.001 sec, is available for strain aging, but the temperature is so high that the aging takes place at a very high rate. The lack of data between 400 and 600 C prevents any accurate conclusion about the spacing of the curves. At this high rate, the yield-point elongation is about 8 per cent at room temperature and decreases to about 1 per cent at 400 C.

Conclusions

The influence of temperature and the rate of strain on the yield stresses of mild steel has been described for the range of strain rates from 10^{-6} to 10^{3} per sec, an increase of 1 to 1,000,000,000 and for temperatures from about 25 to 600 C.

At room temperature, the ultimate strength decreases slightly at the very low rates and then increases with strain rate, showing a 40 per cent increase at the highest rate. The lower yield point increases throughout the range of rates with an over-all increase of 170 per cent. The total elongation for the higher rates is practically constant at 40 per cent.

At the higher temperatures, the yield stresses are greatly affected by strain aging. In general, as the strain rate is increased, a higher temperature and strain are necessary to accelerate strain aging. When the yield stress - strain rate curve has a negative slope, discontinuous yielding can be expected. The fluctuations of the load which occur during discontinuous yielding decrease in amplitude as the strain rate is increased. At 600 C, the influence of strain aging is reduced or completely eliminated by annealing and recrystallization, and the yield stresses increase with strain rate over the entire range.

Acknowledgment

This analysis was made on tests previously reported (1) with Dr. A. Nadai to whom the writer expresses his appreciation for counsel and permission to use the results of these tests.

An Analytical Theory of Landing-Shock Effects on an Airplane Considered as an Elastic Body

By E. G. KELLER,[1] BUFFALO, N. Y.

An analytical method of determining the accelerations at any point P (x, y, z) of an airplane during landing is given. The method is applicable to any type airplane with either tricycle or conventional landing gear. The shock-strut forces are determined by a method previously published. A criterion for the mechanism of a broken spar is sought. Calculations are carried out for no particular airplane, but representative values of parameters for four-engined transports are employed.

Introduction

THE purpose of this investigation is the analytical determination of the accelerations during landing of any point on a large airplane considered to be an elastic or semi-elastic body.

The ever-increasing size of transports and bombers has rendered the problem a classical one[2] of the aircraft industry. Its solution is of use in various ways. Some of these are the following: (*a*) An underlying analytical theory tends to reduce landing strength specifications to a more rational basis. In the case of small aircraft, an arbitrary (substantiated by experience) strength specification of ng for the entire airplane was satisfactory. Increased size of transports, extremely nonuniform mass, and variable rigidity distributions throughout wings, fuselage, and empennage necessitate more careful design specifications for each part of the airplane. (*b*) An analytical theory furnishes a basis for the organization, correlation, and explanation of flight test data obtained in landing. (*c*) Destructive landings can be made economically by analytical methods. If the analytical theory is checked by flight tests in normal and moderately severe landings, and if the theory is sound, then reasonable extrapolations of the theoretical results may be made to show tendencies in destructive landings which cannot be carried out physically. (*d*) A generalized transport plane can be studied analytically in an economical manner by changes in system parameters. The twenty-four parameters of the fundamental matrix, Equation [35], along with the seven parameters of the applied force matrix, Equation [36], are sufficient to specify with considerable precision the behavior of a transport in landing. A change in any parameter corresponds to a physical change in the plane. For example, the variation of ϵ_0 from $+1$ to -1 shifts the points of application of the main landing gear forward by 34 in.

Certain Inherent Difficulties of the Problem

It may be of interest to list certain inherent difficulties of the problem.

(*a*) The foremost of these is the determination of the externally applied forces produced by the shock struts at their points of application to the airplane. Once the loads and requirements for a shock strut have been decided upon, shock-strut analysis is in a very definite sense an independent subject; that is, in the case of large aircraft, shock struts are designed and tested independently of the manufacture of the airplane. Usually the drop tests of a shock strut consist of free falls from prescribed heights onto horizontal or inclined planes. More often than not, there is in the drop tests no simulation of the air lift of the airplane during landing. This air lift is always present to some degree in the landing of any craft. The air lift greatly diminishes the intensity of the shock-strut nonlinear forces transmitted to the wing structure. In order that the problem of determining the accelerations over an elastic airplane during landing may be reduced to a linear one, it is necessary to obtain the strut forces as functions of the time. To so express these forces, and at the same time take into consideration the effect of air lift, it is necessary either to resort to expensive simulation of air lift during drop tests or to integrate the nonlinear differential equations of performance of the strut. The nonlinear differential equations of a shock strut, viewed as a body with 2 degrees of freedom, are easily shown to be

$$\left.\begin{aligned} M_2\ddot{s}_2 - nW_2 + \frac{p_0 S}{\left[1-\left(\frac{s_2-s_1}{D}\right)\right]^{1.2}} \\ + \frac{\rho\,(S-s_m)^3\,(\dot{s}_2-\dot{s}_1)^2}{2gc^2[A(r)]^2} = 0 \\ M_1\ddot{s}_1 - W_1 - \frac{p_0 S}{\left[1-\left(\frac{s_2-s_1}{D}\right)\right]^{1.2}} \\ - \frac{\rho(S-s_m)^3\,(\dot{s}_2-\dot{s}_1)^2}{2gc^2[A(r)]^2} + k_1\dot{s}_1 + k_0 s_1 = 0, \end{aligned}\right\} \quad . . [1]$$

where $A(r)$ is a function of $(s_2 - s_1)$ as given by the metering pin, s_2 and s_1 are, respectively, displacements of the airplane and piston of the strut, $\dot{s}_2$, $\dot{s}_1$, $\ddot{s}_2$, $\ddot{s}_1$ are time derivatives, and all other letters in the equations represent constant parameters. Since these equations have been integrated elsewhere,[3] no further dis-

[3] "Some Nonlinear Problems of the Electrical and Aircraft Industries" (Symposium Address, American Mathematical Society), E. G. Keller, Quarterly *Journal of Applied Mathematics*, vol. 2, April, 1944, p. 1.

cussion of them is necessary here. Of course, once s_2 and s_1 are found as functions of the time, both the load factors and strut forces are immediately obtainable.

(*b*) In the use of Equations [1], the values of M_1 and M_2 (equivalent masses to be dropped) must be determined. The determination of these masses, taking into consideration the moment of inertia and aerodynamic lift, is again a separate investigation. For this analysis refer to another paper[4] on this subject.

(*c*) The problem of determining the local accelerations over a plane is naturally one of infinitely many degrees of freedom. However, if the airplane is viewed as a semielastic body, it is sufficient to specify its behavior during landing in most practical cases by at most eight co-ordinates. The literal equations of motion are, however, derived for fourteen degrees of freedom. Six co-ordinates are employed to define the position of the center of gravity and eight to describe the torsion and bending of wings, fuselage, and stabilizer.

(*d*) Nonuniform mass and variable rigidity distributions introduce laborious numerical calculations. In order that a theory may be successful, from an engineering point of view, the labor required in applying it must be reduced to a minimum. Thus one of the first problems is the determination of how crudely

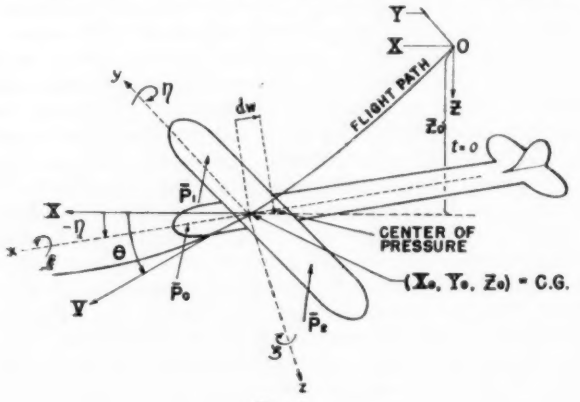

FIG. 1

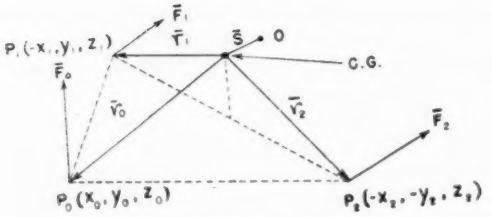

FIG. 2

the foregoing computations can be made without affecting significantly the coefficients in Equation [35].

(*e*) The number of initial conditions for the variables involved is very large.

(*f*) In the study of the generalized transport, each of the 24 system parameters of the general matrix, Equation [35], may take on several values. For each such change, the differential equations of performance (and hence their characteristic equations) are changed.

Difficulties (*a*) and (*b*) are eliminated by the material of footnote (3) and (4). A combination of proper co-ordinates along with the use of vector methods disposes of difficulty (*c*). Difficulty (*d*) is overcome by the method of exhaustion. The last two difficulties are entirely suppressed by use of the differential analyzer of the General Electric Company.

[4] "Determination of Equivalent Masses in Drop-Tests of Shock Struts Both With and Without Aerodynamic Lift Taken Into Consideration," by J. F. McBrearty and E. G. Keller, *Journal of the Aeronautical Sciences*.

PLAN OF THE ANALYSIS

The analysis consists of two divisions of which the first is concerned with the derivation of the equations of performance, while the second is devoted to the solution of the derived equations.

DERIVATION OF THE EQUATIONS OF PERFORMANCE

1 REFERENCE FRAME

Let the frame of reference be as follows: O-X, Y, Z are axes fixed in space such that the center of gravity of the airplane is at O at time $t = 0$, the first instant of contact of the plane with the ground. The axes G-x, y, z are fixed in the plane and move with the plane. X_0, Y_0, Z_0 are the co-ordinates of the center of gravity G at time t. The interval of time in which we are interested is at most 1 sec. The flight path is assumed to be a plane curve. (Bars over letters in the figures signify vectors.)

Let P_0, P_1, P_2 denote the points of contact of the airplane with the ground. Denote the vectors from the center of gravity to P_0, P_1, P_2 by

$$\left.\begin{aligned} \boldsymbol{r}_0 &= \boldsymbol{I}x_0 + \boldsymbol{J}y_0 + \boldsymbol{K}z_0 \\ \boldsymbol{r}_1 &= -\boldsymbol{I}x_1 + \boldsymbol{J}y_1 + \boldsymbol{K}z_1 \\ \boldsymbol{r}_2 &= -\boldsymbol{I}x_2 - \boldsymbol{J}y_2 + \boldsymbol{K}z_2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [2]$$

where $\boldsymbol{I}$, $\boldsymbol{J}$, $\boldsymbol{K}$ are unit vectors in the directions of X, Y, Z. Let the forces acting on the axles of the shock-strut wheels be

$$\left.\begin{aligned} \boldsymbol{F}_0 &= \boldsymbol{I}F_{0x} + \boldsymbol{J}F_{0y} + \boldsymbol{K}F_{0z} \\ \boldsymbol{F}_1 &= \boldsymbol{I}F_{1x} + \boldsymbol{J}F_{1y} + \boldsymbol{K}F_{1z} \\ \boldsymbol{F}_2 &= \boldsymbol{I}F_{2x} + \boldsymbol{J}F_{2y} + \boldsymbol{K}F_{2z} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [3]$$

In a successful landing, the angles between x, y, z and X, Y, Z do not exceed 10 or 12 deg. Hence the vectors $\boldsymbol{I}$, $\boldsymbol{J}$, $\boldsymbol{K}$, may be replaced by $\boldsymbol{i}$, $\boldsymbol{j}$, $\boldsymbol{k}$ the unit vectors along x, y, z. (See reference (5) for details.) The co-ordinates of reference points (Fig. 3) in equilibrium configuration are

$$\left.\begin{array}{llll} \boldsymbol{P}_0(x_0, 0, z_0) & P_3(-a_1, 0, c_2) & B_1(-a_1 + a, b, c_2) & \\ \boldsymbol{P}_1(-x_1, y_1, z_0) & P_4(-a_1, b_1, c_2) & B_2(-a_1 - a, b, c_2) & \\ \boldsymbol{P}_2(-x_1, -y_1, z_0) & P_5(-a_1, b_2, c_2) & B_3(-a_1 - a, -b, c_2) & \\ P_3(a_0, 0, c_0) & P_3'(-a_2, 0, -c_3) & B_4(-a_1 + a, -b, c_2) & \\ P_1[-(a_1 + a_3), b_1, c_2] & A_1(-a_1, b, c_3) & B_1'(-a_2 + a', b', -c_3) & \\ P_2[-(a_1 + a_3), -b_1, c_2] & A_2(-a_1 - b, c_2) & B_2'(-a_2 - a', b', -c_3) & \\ & B_3'(-a_2 - a', -b', -c_3) & B_4'(-a_2 + a', -b', -c_3) & \end{array}\right\} \quad \ldots [4]$$

where the lengths $x_0, z_0, \ldots, b', c_3$ are displayed in Fig. 3. No distortion is yet taken into account by the symbols $x_0, \ldots, c_3$.

2 CO-ORDINATE SYSTEM

The total displacement (rigid and distortional) of any point P is

$$\boldsymbol{S} = \boldsymbol{S}_0 + \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ \xi & \eta & \zeta \\ a_i & b_j & c_k \end{vmatrix} + \boldsymbol{k}\zeta^k \quad \ldots\ldots\ldots\ldots [5]$$

where $a_i = a_i(x)$, $b_j = b_j(y)$, $c_k = c_k(z)$ are functions, respectively, of x, y, z; $\boldsymbol{i}$, $\boldsymbol{j}$, $\boldsymbol{k}$ are unit vectors, and ξ, η, ζ are angular rotations indicated in Fig. 3, and ξ^k ($k = w$(wing), f, e) are the distortional co-ordinates presently specified.[5] Only distortions perpendicular to the x,y-plane are considered. The longitudinal distortions of wings, fuselage, and empennage are neglected, since

[5] Mathematics of Modern Engineering, vol. 2, by E. G. Keller, John Wiley & Sons, New York, N. Y., 1941, p. 47.

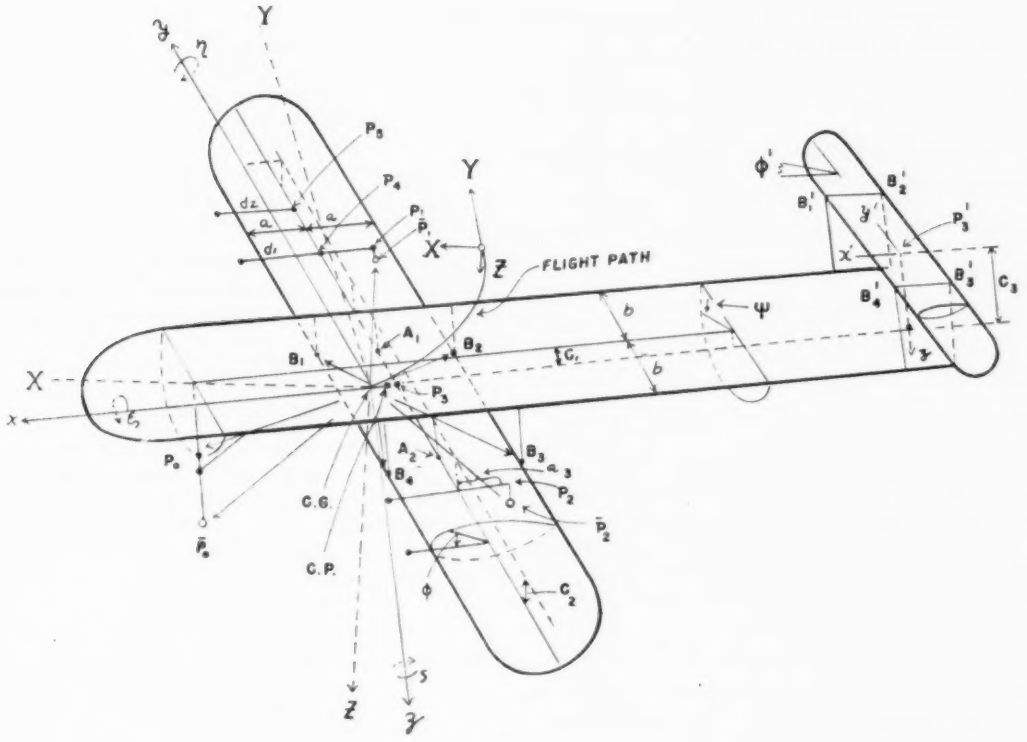

FIG. 3

during the motion considered no forces act which cause extensions.

Accordingly, let the distortional displacement of any point $P_w(x, y)$ on a wing be

$$\left.\begin{aligned}\zeta^w &= \eta^j(y, t) + x^i\varphi^j(y, t)\\ &= \eta_1(t)\eta(y) + x^i\varphi_1(t)\varphi(y)\end{aligned}\right\} \quad \ldots\ldots\ldots [6]$$

where x^i is the distance of $P_w(x, y)$ from the axis of rotation of the wing and $\varphi(x)$ is the torsional angle at (o, y). For the empennage

$$\left.\begin{aligned}\zeta^{rj} &= \eta^{rj}(y', t) + x^{ri}\varphi^{rj}(y', t)\\ &= \eta'_1(t)\eta'(y') + x^{ri}\varphi_1'(t)\varphi'(y')\end{aligned}\right\} \quad \ldots\ldots\ldots [7]$$

From special solutions and experimental results, it is a fact that, that portion of the wing interior to or intercepted by the fuselage may be taken as a rigid body. Consequently, the distortional co-ordinates for the fuselage are

$$\left.\begin{aligned}\zeta^f &= \xi_r{}^i(x, t) + \psi_r{}^i(x, t)\\ &= \xi_r(t)\xi_r(x) + y^j\psi_r(t)\bar{\psi}_r(x)\end{aligned}\right\} \quad \ldots\ldots\ldots [8]$$

where $r = 1, 2$ give the distortional displacement fore and aft, respectively, of the rigid section previously described. . For airplanes which possess no rigid sections, the procedure is clear from section (7).

3 Kinetic Energy

In view of the foregoing co-ordinate system we write the total kinetic energy of the airplane preparatory to deriving the equations of performance.

The velocity components (to the accuracy required) of any point P of the plane from Equation [5] are

$$\dot{X}_0 + \mathbf{i}\cdot\begin{vmatrix}\mathbf{i} & \mathbf{j} & \mathbf{k}\\ \xi & \dot{\eta} & \dot{\zeta}\\ a_i & b_j & c_k\end{vmatrix} = \dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta}$$

$$\dot{Y}_0 + \mathbf{j}\cdot\begin{vmatrix}\mathbf{i} & \mathbf{j} & \mathbf{k}\\ \xi & \dot{\eta} & \dot{\zeta}\\ a_i & b_j & c_k\end{vmatrix} = \dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi}$$

$$\dot{Z}_0 + \mathbf{k}\cdot\begin{vmatrix}\mathbf{i} & \mathbf{j} & \mathbf{k}\\ \xi & \dot{\eta} & \dot{\zeta}\\ a_i & b_j & c_k\end{vmatrix} + \dot{\zeta}_k = \dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta} + \dot{\zeta}^k$$

Thus the kinetic energies of the wings, fuselage, and empennage are, respectively

$$T_w = {}^1/_2\int_w \{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2 + [\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta} + \dot{\eta}^j + x^i\dot{\varphi}^j]^2\}dm \quad \ldots\ldots [9]$$

$$T_f = {}^1/_2\int_f \{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2 + [\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta} + \dot{\xi}_r{}^i + y^j\dot{\psi}_r{}^i]^2\}dm \quad \ldots\ldots [10]$$

$$T_e = {}^1/_2\int_e \{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2 + [\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta} + \dot{\eta}^{rj} + x^{ri}\dot{\varphi}^{rj}]^2\}dm \quad \ldots\ldots [11]$$

The addition of Equations [9], [10], and [11] gives for the total kinetic energy

$$\begin{aligned}T = {}^1/_2\int_{\text{plane}} &\{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2\\ &+ (\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})^2\}dm + \int_w (\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})\\ &(\eta^j + x^i)\dot{\varphi}^j dm + {}^1/_2\int_w (\dot{\eta}^j + x^i\dot{\varphi}^j)^2\, dm\\ &+ \int_f (\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})(\dot{\xi}_r{}^i + y^j\dot{\psi}_r)dm\\ &+ {}^1/_2\int_f (\dot{\xi}_r{}^i + y^j\dot{\psi}_r)^2 dm \quad \ldots\ldots\ldots\ldots [12]\\ + \int_e (\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})&(\dot{\eta}^{rj} + x^{ri}\dot{\varphi}^j)dm\\ &+ {}^1/_2\int_e (\dot{\eta}^{rj} + x^{ri}\dot{\varphi}^{rj})^2 dm,\ (r = 1, 2)\end{aligned}$$

cussion of them is necessary here. Of course, once s_2 and s_1 are found as functions of the time, both the load factors and strut forces are immediately obtainable.

(*b*) In the use of Equations [1], the values of M_1 and M_2 (equivalent masses to be dropped) must be determined. The determination of these masses, taking into consideration the moment of inertia and aerodynamic lift, is again a separate investigation. For this analysis refer to another paper[4] on this subject.

(*c*) The problem of determining the local accelerations over a plane is naturally one of infinitely many degrees of freedom. However, if the airplane is viewed as a semielastic body, it is sufficient to specify its behavior during landing in most practical cases by at most eight co-ordinates. The literal equations of motion are, however, derived for fourteen degrees of freedom. Six co-ordinates are employed to define the position of the center of gravity and eight to describe the torsion and bending of wings, fuselage, and stabilizer.

(*d*) Nonuniform mass and variable rigidity distributions introduce laborious numerical calculations. In order that a theory may be successful, from an engineering point of view, the labor required in applying it must be reduced to a minimum. Thus one of the first problems is the determination of how crudely

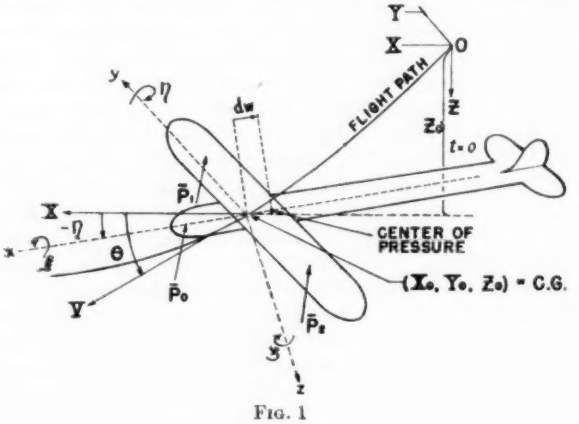

FIG. 1

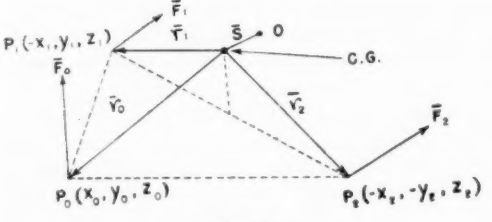

FIG. 2

the foregoing computations can be made without affecting significantly the coefficients in Equation [35].

(*e*) The number of initial conditions for the variables involved is very large.

(*f*) In the study of the generalized transport, each of the 24 system parameters of the general matrix, Equation [35], may take on several values. For each such change, the differential equations of performance (and hence their characteristic equations) are changed.

Difficulties (*a*) and (*b*) are eliminated by the material of footnote (3) and (4). A combination of proper co-ordinates along with the use of vector methods disposes of difficulty (*c*). Difficulty (*d*) is overcome by the method of exhaustion. The last two difficulties are entirely suppressed by use of the differential analyzer of the General Electric Company.

The axes G-x, y, z are fixed in the plane and move with the plane. X_0, Y_0, Z_0 are the co-ordinates of the center of gravity G at time t. The interval of time in which we are interested is at most 1 sec. The flight path is assumed to be a plane curve. (Bars over letters in the figures signify vectors.)

Let P_0, P_1, P_2 denote the points of contact of the airplane with the ground. Denote the vectors from the center of gravity to P_0, P_1, P_2 by

$$\left.\begin{aligned} \boldsymbol{r}_0 &= \boldsymbol{I}x_0 + \boldsymbol{J}y_0 + \boldsymbol{K}z_0 \\ \boldsymbol{r}_1 &= -\boldsymbol{I}x_1 + \boldsymbol{J}y_1 + \boldsymbol{K}z_1 \\ \boldsymbol{r}_2 &= -\boldsymbol{I}x_2 - \boldsymbol{J}y_2 + \boldsymbol{K}z_2 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [2]$$

where $\boldsymbol{I}$, $\boldsymbol{J}$, $\boldsymbol{K}$ are unit vectors in the directions of X, Y, Z. Let the forces acting on the axles of the shock-strut wheels be

$$\left.\begin{aligned} \boldsymbol{F}_0 &= \boldsymbol{I}F_{0x} + \boldsymbol{J}F_{0y} + \boldsymbol{K}F_{0z} \\ \boldsymbol{F}_1 &= \boldsymbol{I}F_{1x} + \boldsymbol{J}F_{1y} + \boldsymbol{K}F_{1z} \\ \boldsymbol{F}_2 &= \boldsymbol{I}F_{2x} + \boldsymbol{J}F_{2y} + \boldsymbol{K}F_{2z} \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [3]$$

In a successful landing, the angles between x, y, z and X, Y, Z do not exceed 10 or 12 deg. Hence the vectors $\boldsymbol{I}$, $\boldsymbol{J}$, $\boldsymbol{K}$, may be replaced by $\boldsymbol{i}$, $\boldsymbol{j}$, $\boldsymbol{k}$ the unit vectors along x, y, z. (See reference (5) for details.) The co-ordinates of reference points (Fig. 3) in equilibrium configuration are

$$\left.\begin{array}{llll} \boldsymbol{P}_0(x_0, 0, z_0) & P_3(-a_1, 0, c_2) & B_1(-a_1 + a, b, c_2) & \\ \boldsymbol{P}_1(-x_1, y_1, z_0) & P_4(-a_1, b_1, c_2) & B_2(-a_1 - a, b, c_2) & \\ \boldsymbol{P}_2(-x_1, -y_1, z_0) & P_5(-a_1, b_3, c_2) & B_3(-a_1 - a, -b, c_2) & \\ P_6(a_0, 0, c_0) & P_3'(-a_2, 0, -c_3) & B_4(-a_1 + a, -b, c_2) & \\ P_1[-(a_1 + a_3), b_1, c_2] & A_1(-a_1, b, c_2) & B_1'(-a_2 + a', b', -c_3) & \\ P_2[-(a_1 + a_3), -b_1, c_2] & A_2(-a_1 - b, c_2) & B_2'(-a_2 - a', b', -c_3) & \\ & B_3'(-a_2 - a', -b', -c_3) & B_4'(-a_2 + a', -b', -c_3) & \end{array}\right\} \quad \ldots [4]$$

where the lengths $x_0, z_0, \ldots, b', c_3$ are displayed in Fig. 3. No distortion is yet taken into account by the symbols $x_0, \ldots, c_3$.

2 CO-ORDINATE SYSTEM

The total displacement (rigid and distortional) of any point P is

$$\boldsymbol{S} = \boldsymbol{S}_0 + \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ \xi & \eta & \zeta \\ a_i & b_j & c_k \end{vmatrix} + \boldsymbol{k}\zeta^k \quad \ldots\ldots\ldots\ldots [5]$$

where $a_i = a_i(x)$, $b_j = b_j(y)$, $c_k = c_k(z)$ are functions, respectively, of x, y, z; $\boldsymbol{i}$, $\boldsymbol{j}$, $\boldsymbol{k}$ are unit vectors, and ξ, η, ζ are angular rotations indicated in Fig. 3, and ζ^k ($k = w$(wing), f, e) are the distortional co-ordinates presently specified.[5] Only distortions perpendicular to the x,y-plane are considered. The longitudinal distortions of wings, fuselage, and empennage are neglected, since

[5] Mathematics of Modern Engineering, vol. 2, by E. G. Keller, John Wiley & Sons, New York, N. Y., 1941, p. 47.

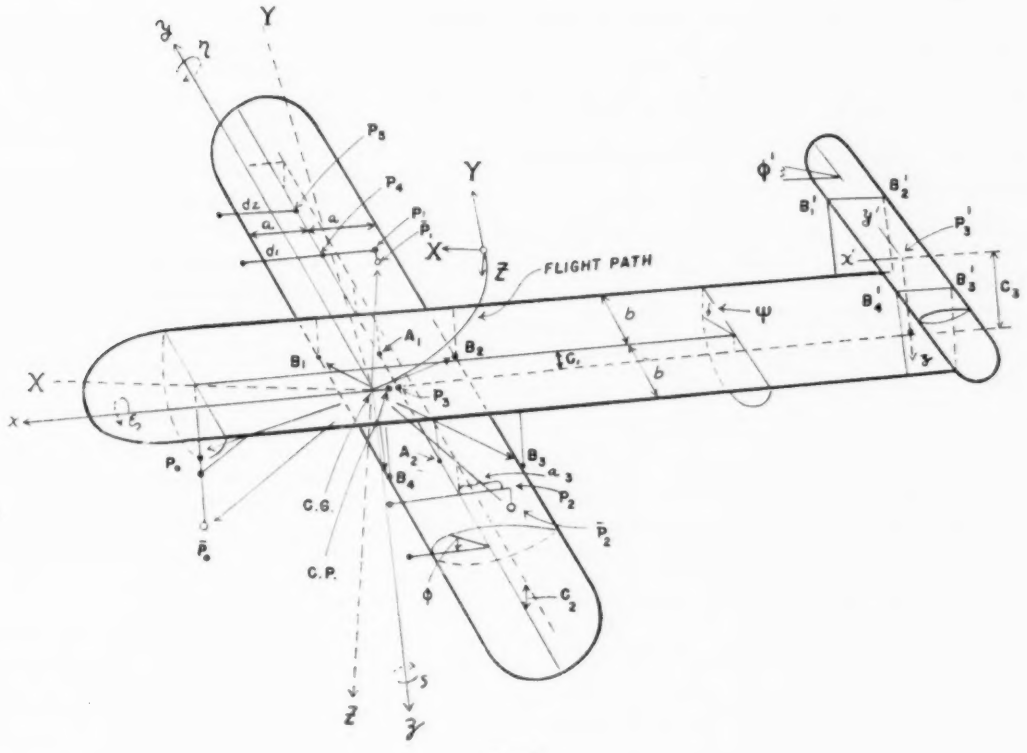

FIG. 3

during the motion considered no forces act which cause extensions.

Accordingly, let the distortional displacement of any point $P_w(x, y)$ on a wing be

$$\left.\begin{aligned}\zeta^w &= \eta^j(y, t) + x^i\varphi^j(y, t)\\ &= \eta_1(t)\eta(y) + x^i\varphi_1(t)\bar{\varphi}(y)\end{aligned}\right\} \quad \ldots\ldots\ldots [6]$$

where x^i is the distance of $P_w(x, y)$ from the axis of rotation of the wing and $\varphi(x)$ is the torsional angle at (o, y). For the empennage

$$\left.\begin{aligned}\zeta^e &= \eta'^j(y', t) + x'^i\varphi'^j(y', t)\\ &= \eta'_1(t)\eta'(y') + x'^i\varphi_1'(t)\varphi'(y')\end{aligned}\right\} \quad \ldots\ldots\ldots [7]$$

From special solutions and experimental results, it is a fact that, that portion of the wing interior to or intercepted by the fuselage may be taken as a rigid body. Consequently, the distortional co-ordinates for the fuselage are

$$\left.\begin{aligned}\zeta^f &= \xi_r^i(x, t) + \psi_r^i(x, t)\\ &= \xi_r(t)\bar{\xi}_r(x) + y^j\psi_r(t)\bar{\psi}_r(x)\end{aligned}\right\} \quad \ldots\ldots\ldots [8]$$

where $r = 1, 2$ give the distortional displacement fore and aft, respectively, of the rigid section previously described. For airplanes which possess no rigid sections, the procedure is clear from section (7).

3 Kinetic Energy

In view of the foregoing co-ordinate system we write the total kinetic energy of the airplane preparatory to deriving the equations of performance.

The velocity components (to the accuracy required) of any point P of the plane from Equation [5] are

$$\dot{X}_0 + \mathbf{i}\cdot\begin{vmatrix}\mathbf{i} & \mathbf{j} & \mathbf{k}\\ \dot{\xi} & \dot{\eta} & \dot{\zeta}\\ a_i & b_j & c_k\end{vmatrix} = \dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta}$$

$$\dot{Y}_0 + \mathbf{j}\cdot\begin{vmatrix}\mathbf{i} & \mathbf{j} & \mathbf{k}\\ \dot{\xi} & \dot{\eta} & \dot{\zeta}\\ a_i & b_j & c_k\end{vmatrix} = \dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi}$$

$$\dot{Z}_0 + \mathbf{k}\cdot\begin{vmatrix}\mathbf{i} & \mathbf{j} & \mathbf{k}\\ \dot{\xi} & \dot{\eta} & \dot{\zeta}\\ a_i & b_j & c_k\end{vmatrix} + \dot{\zeta}_k = \dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta} + \dot{\zeta}^k$$

Thus the kinetic energies of the wings, fuselage, and empennage are, respectively

$$T_w = {}^1/_2\int_w\{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2 + [\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta} + \dot{\eta}^j + x^i\dot{\varphi}^j]^2\}dm \quad \ldots\ldots [9]$$

$$T_f = {}^1/_2\int_f\{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2 + [\dot{Z}_0 + b_j\dot{\zeta} - a_i\dot{\eta} + \dot{\xi}_r^i + y^j\dot{\psi}_r^i]^2\}dm \quad \ldots\ldots [10]$$

$$T_e = {}^1/_2\int_e\{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2 + [\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta} + \dot{\eta}'^j + x'^i\dot{\varphi}'^j]^2\}dm \quad \ldots\ldots [11]$$

The addition of Equations [9], [10], and [11] gives for the total kinetic energy

$$\begin{aligned}T = {}^1/_2\int_{\text{plane}}&\{(\dot{X}_0 + c_k\dot{\eta} - b_j\dot{\zeta})^2 + (\dot{Y}_0 + a_i\dot{\zeta} - c_k\dot{\xi})^2\\ &+ (\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})^2\}dm + \int_w(\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})\\ &(\dot{\eta}^j + x^i)\dot{\varphi}^j dm + {}^1/_2\int_w(\dot{\eta}^j + x^i\dot{\varphi}^j)^2\,dm\\ &+ \int_f(\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})(\dot{\xi}_r^i + y^j\dot{\psi}_r)dm\\ &+ {}^1/_2\int_f(\dot{\xi}_r^i + y^j\dot{\psi}_r)^2dm \quad \ldots\ldots [12]\\ &+ \int_e(\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})(\dot{\eta}'^j + x'^i\dot{\varphi}'^j)dm\\ &+ {}^1/_2\int_e(\dot{\eta}'^j + x'^i\dot{\varphi}'^j)^2dm,\ (r = 1, 2)\end{aligned}$$

Now the first integral in Equation [12] is merely the kinetic energy of a rigid plane and may be written

$$\frac{M}{2}(\dot{X}_0^2 + \dot{Y}_0^2 + \dot{Z}_0^2) + {}^1/_2 I_x \dot{\xi}^2 + {}^1/_2 I_y \dot{\eta}^2 + {}^1/_2 I_z \dot{\zeta}^2 \quad [13]$$

It remains to carry out in detail the remaining six integrals. The second integral in Equation [12] is

$$\begin{aligned}
&\int_w (\dot{Z}_0 + b_j\dot{\xi} - a_i\dot{\eta})(\ddot{\eta}^j + x^i\ddot{\varphi}^j)dm \\
&= \dot{Z}_0 \int \ddot{\eta}^j dm + \dot{Z}_0 \int x^i\ddot{\varphi}^j\, dm + \ddot{\xi} \int b_j\dot{\eta}^j\, dm \\
&+ \dot{\xi} \int b_j x^i\ddot{\varphi}^j dm - \dot{\eta} \int a_i\dot{\eta}^j\, dm - \dot{\eta} \int a_i x^i\ddot{\varphi}^j\, dm \\
&= \dot{Z}_0\dot{\eta}_1 \int \bar{\eta} dm + \dot{Z}_0\dot{\varphi}_1 \int\int x^i\bar{\varphi}\, dm + \ddot{\xi}\dot{\eta}_1 \int b_j\bar{\eta} dm \\
&+ \dot{\xi}\dot{\varphi}_1 \int\int b_j x^i\bar{\varphi} dm - \ddot{\eta}\dot{\eta}_1 \int\int a_i\bar{\eta} dm - \ddot{\eta}\dot{\varphi}_1 \\
&\qquad \int\int a_i x^i\bar{\varphi} dm
\end{aligned} \quad \Big\} \quad [14]$$

where $a_i = -a + x^i$ and $-a \leqq x^i \leqq a$ (Fig. 3). The remaining five integrals in Equation [12] are carried out in a similar manner. The variable density or mass distributions for a transport are given by curves. The numerical evaluation of the forty-five integrals of Equation [12], of which those in Equation [14] are representative, yields the total kinetic energy of a semi-elastic plane.

4 Strain Energy

It is sufficient to consider the total strain energy as the sum of the energies of bending and torsion. The strain energies of bending and torsion of one wing are given by

$$W_b = \frac{\dot{\eta}_1^2}{2} \int_0^l E I_y \left[\frac{\partial^2\eta}{\partial y^2}\right]^2 dy,$$

$$W_t = \frac{\dot{\varphi}_1^2}{2} \int_0^l G \frac{[2A(y)\bar{\varphi}(y)]^2}{c(y)}\, t(y)dy \quad [15]$$

where

E = Young's modulus
I_y = moment of inertia
$t(y)$ = thickness of skin
$\bar{\varphi}(y)$ = angle of twist at y
G = torsion modulus
c = periphery at section y
$\bar{\eta}(y)$ = vertical displacement of bending of axis of wing
$A(y)$ = vertical cross-sectional area at y

The functions I_y, $A(y)$, $c(y)$, and $t(y)$, are given by curves, and in general the evaluation of Equation [15] is numerical. Integrals [15] are written for one wing. For the fuselage and stabilizer the symbols $\bar{\eta}$, $\dot{\eta}_1$, $\bar{\varphi}$, $\dot{\varphi}_1$, I_y, c, and the limits of integration in Equation [15] are replaced by those appropriate.

5 Work Done by Shock-Strut Forces

The nine components of $F_i (i = 0, 1, 2)$ are expressed in Equations [3]. The three components F_{iz} are given as functions of the time by the solution of Equations [1]. The method of obtaining the three components F_{ix} is indicated in section (9).

The element of work δW done by the struts during the interval from 0 to t is

$$\delta W = Q_1\delta X_0 + Q_2\delta Y_0 + \ldots,$$

where the Q_i are generalized forces. δW can be written also as

$$\delta W = \boldsymbol{F}_0 \cdot \delta\boldsymbol{R}_0 + \boldsymbol{F}_1 \cdot \delta\boldsymbol{R}_1 + \boldsymbol{F}_2 \cdot \delta\boldsymbol{R}_2 \quad [16]$$

where

$$\boldsymbol{R}_i = \int_0^t (\boldsymbol{S}_i + \omega \times \boldsymbol{r}_i)dt,\ \omega = \dot{\zeta}\boldsymbol{i} + \dot{\eta}\boldsymbol{j} + \dot{\xi}\boldsymbol{k},\ \boldsymbol{S}_i = X_i\boldsymbol{i} + Y_i\boldsymbol{j} + Z_i\boldsymbol{k}$$

The component displacements of $\boldsymbol{P}_0$, $\boldsymbol{P}_1$, $\boldsymbol{P}_2$, (transport considered as a rigid body) are

$$\begin{aligned}
(\boldsymbol{P}_0)\ & X_0 + \boldsymbol{i}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ x_0 & 0 & z_0\end{vmatrix} = X_0 + z_0\eta,\ Y_0 + \boldsymbol{j}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ x_0 & 0 & z_0\end{vmatrix} = Y_0 - z_0\xi + x_0\zeta \\
& Z_0 + \boldsymbol{k}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ x_0 & 0 & z_0\end{vmatrix} = Z_0 - x_0\eta \\
(\boldsymbol{P}_1)\ & X_0 + \boldsymbol{i}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ -x_1 & y_1 & z_1\end{vmatrix} = X_0 + z_1\eta - y_1\zeta,\ Y_0 + \boldsymbol{j}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ -x_1 & y_1 & z_1\end{vmatrix} = Y_0 - z_1\xi - x_1\zeta \\
& Z_0 + \boldsymbol{k}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ -x_1 & y_1 & z_1\end{vmatrix} = Z_0 + y_1\xi + x_1\eta \\
(\boldsymbol{P}_2)\ & X_0 + \boldsymbol{i}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ -x_2 & -y_2 & z_2\end{vmatrix} = X_0 + z_2\eta + y_2\zeta,\ Y_0 + \boldsymbol{j}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ -x_2 & -y_2 & z_2\end{vmatrix} = Y_0 - z_2\xi - x_2\zeta \\
& Z_0 + \boldsymbol{k}\cdot\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ \xi & \eta & \zeta\\ -x_2 & -y_2 & z_2\end{vmatrix} = Z_0 - y_2\xi + x_2\eta
\end{aligned} \quad \Big\} \quad [17]$$

From Equations [16] and [17], the element of work done by the shock struts against a rigid airplane is

$$\left.\begin{aligned}\delta W_0 = {} & (\boldsymbol{i}F_{0x} + \boldsymbol{j}F_{0y} + \boldsymbol{k}F_{0z}) \cdot \delta[\boldsymbol{i}(X_0 + z_0\eta) \\ & + \boldsymbol{j}(Y_0 - z_0\xi + x_0\zeta) + \boldsymbol{k}(Z_0 - x_0\eta)] + \dots \\ & + (\boldsymbol{i}F_{2x} + \boldsymbol{j}F_{2y} + \boldsymbol{k}F_{2z}) \cdot \delta[\boldsymbol{i}(X_0 + z_2\eta + y_2\zeta) \\ & + \boldsymbol{j}(Y_0 - z_2\xi - x_2\zeta) + \boldsymbol{k}(Z_0 - y_2\xi + x_2\eta)]\end{aligned}\right\} \dots\dots [18]$$

To Equation [18] is added the element of work performed against the elastic body. Thus the element of total work (to the accuracy required) done against the airplane by the forces $\boldsymbol{F}_i$ is

$$\left.\begin{aligned}\delta W = {} & F_{0x}(\delta X_0 + z_0\delta\eta) + F_{1x}(X_0 + z_1\delta\eta + y_1\delta\zeta) \\ & + F_{2x}(\delta X_0 + z_2\delta\eta + y_2\delta\zeta) + F_{0y}(\delta Y_0 - z_0\delta\xi + x_0\delta\zeta) \\ & + F_{1y}(\delta Y_0 - z_1\delta\xi\,1 - x_1\delta\zeta) + F_{2y}(\delta Y_0 - z_2\delta\xi - x_2\delta\zeta) \\ & + F_{0z}[\delta Z_0 - x_0\delta\eta + \xi_1(x_0)\delta\xi_1] \\ & + F_{1z}[Z_0 + y_1\delta\xi + x_1\delta\eta + \bar{\eta}_1(b_1)\delta\eta_1 + a_3\bar{\varphi}_1(b_1)\delta\varphi_1] \\ & + F_{2z}[\delta Z_0 - y_2\delta\xi + x_2\delta\eta + \bar{\eta}_1(b_2)\delta\eta_1 + a_3\bar{\varphi}_1(b_2)\delta\varphi_1] \\ & + n_1\xi_2(-a_3)\delta\xi_2\end{aligned}\right\} \dots [19]$$

From Equation [19] and section 6, the force matrix,[6] for a level landing, is shown in chart form in Equation [20]. In Equation [20], Mg is the weight of the plane, A_{z0} is the z component of the air lift, and A_η is the aerodynamic moment positive nose upward.

EQUATION [20]

$$\boldsymbol{F} = \begin{array}{|c|c|}\hline X_0 & F_{0x} + F_{1x} + F_{2x} \\ \hline Y_0 & F_{0y} + F_{1y} + F_{2y} \\ \hline Z_0 & F_{0z} + F_{1z} + F_{2z} + Mg - A_{z0} \\ \hline \xi & -z_0F_{0y} - z_1F_{1y} - z_2F_{2y} + y_1F_{1z} - y_2F_{2z} \\ \hline \eta & z_0F_{0x} + z_1F_{1x} + z_2F_{2x} - x_0F_{0z} + x_1F_{1z} + x_2F_{2z} + A_\eta \\ \hline \zeta & y_1F_{1x} + y_2F_{2x} + x_0F_{0y} - x_1F_{1y} - x_2F_{2y} \\ \hline \eta_1 & \bar{\eta}_1(b_1)F_{1z} + \bar{\eta}_1(-b_1)F_{2z} \\ \hline \varphi_1 & a_3F_{1z}\bar{\eta}_1(b_1) + a_3F_{2z}\bar{\eta}_1(-b_1) - z_0[\bar{\varphi}_1(b_1)F_{1x} + \bar{\varphi}_1(-b_1)F_{2x}] \\ \hline \xi_1 & F_{0z}\xi_1(x_0) \\ \hline \xi_2 & n_1\bar{\xi}_2(-a_2) \\ \hline \psi_1 & 0 \\ \hline \eta_1' & 0 \\ \hline \varphi_1' & 0 \\ \hline\end{array}$$

The explicit form of the components of the matrix $\boldsymbol{F}$ will be given presently.

[6] "The Use of Tensors in Mechanical Engineering Problems," *General Electric Review*, vol. 39, 1936, p. 335; also, "Elementary Matrices," by R. A. Frazier, W. J. Duncan, and A. R. Collar, Cambridge University Press, 1938; also, reference (5), p. 131.

6 Aerodynamic Forces

The equations of motion of a rigid airplane on a plane flight path are

$$\left.\begin{aligned} M\frac{dV}{dt} &= -D + Mg\sin\theta + D_0 \\ MV\frac{d\theta}{dt} &= -L + Mg\cos\theta \\ I_y\ddot{\eta} &= -M_\eta\end{aligned}\right\} \dots\dots [21]$$

where the symbols have their usual significance and the co-ordinates are shown in Fig. 4.

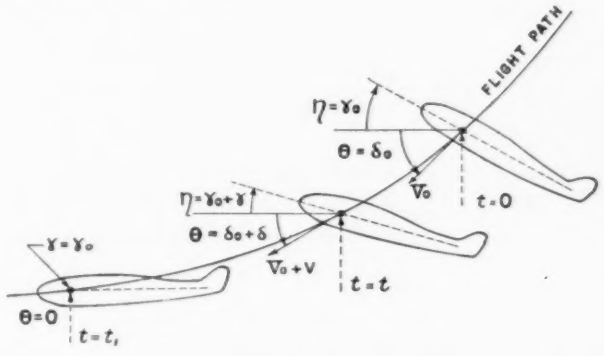

FIG. 4

It is necessary to transform the co-ordinates V, θ, η to the structural co-ordinates employed before. Let $V = V_0 + v$, where V_0 is the value of V at $t = 0$ and v is the change in velocity along the flight path during the impact interval. Then considering all angles to be less than 15 deg, Equations [21] for $D - D_0 = 0$ may be written

$$\left.\begin{aligned} M\dot{v} &= Mg\theta \\ MV\dot{\theta} &= -L + Mg \\ I_y\ddot{\eta} &= -M_\eta\end{aligned}\right\} \dots\dots [22]$$

The angle of attack α (Fig. 4) is

$$\alpha = \theta + \eta = \delta_0 + \gamma_0 + \delta + \gamma = \alpha_0 + \delta + \gamma$$

where α_0 is the angle of attack at $t = 0$. Then the numerical value of the lift is

$$L = \frac{e_0}{2}\rho(V_0 + v)^2(\alpha_0 + \delta + \gamma)SC_L$$

$$= \frac{e_0}{2}\rho V_0^2\alpha_0\left[\left(1 + \frac{2v}{V_0}\right) + \frac{\delta + \gamma}{\alpha_0}\right]SC_L$$

where $0 < e_0 < 1$ is an efficiency factor. Write

$$(\alpha_0/2)\rho V_0^2SC_L = n_0Mg$$

Then

$$L = n_0\left[\left(1 + \frac{2v}{V_0}\right) + \frac{\delta + \gamma}{\alpha_0}\right]Mg \dots\dots [24]$$

and

$$-L + Mg = \left[(1 - n_0) - n_0\frac{2v}{V_0} - \frac{n_0}{\alpha_0}(\delta + \gamma)\right]Mg \dots [25]$$

In view of Equation [25], Equations [22] become

$$\left.\begin{aligned} \dot{v} &= g\theta \\ V_0\dot{\theta} &= \left[(1-n_0) - \frac{2n_0 v}{V_0} - \frac{n_0}{\alpha_0}(\delta+\gamma)\right] \\ I_y\ddot{\eta} &= -\left[n_0(e_0'k_0c_2 - d_w)\left(1 + \frac{2v}{V_0} + \frac{\delta+\gamma}{\alpha_0}\right) + e_0'\frac{c_3^2 k_0'\dot{\eta}}{V_0}\right]Mg \end{aligned}\right\} \quad [26]$$

where d_w is shown in Fig. 1, k_0 and k_0' are dimensionless constants, and e_0' is the tail efficiency factor. The last term is that due to tail damping.

At time t

$$(V_0+v)^2 = \dot{Z}_0^2 + \dot{X}_0^2$$

or

$$\left.\begin{aligned} v &= \sqrt{\dot{Z}_0^2 + \dot{X}_0^2} - V_0 = \dot{X}_0\sqrt{1+\frac{\dot{Z}^2}{\dot{X}^2}} - V_0 \doteq \dot{X}_0 - V_0 \\ &\text{(in landing but not in steady flight), and also} \\ \dot{Z}_0 &= (V_0+v)\sin(\delta_0+\delta) \doteq (V_0+v)(\delta_0+\delta) \doteq V_0(\delta_0+\delta) \\ &\text{or} \\ \delta &= (\dot{Z}_0/V_0) - \delta_0 \text{ and } \dot{\delta} = \ddot{Z}_0/V_0,\ \gamma = \eta - \gamma_0 \end{aligned}\right\} \quad [27]$$

The first of Equations [26] and [27] give

$$\ddot{X}_0 = +g\left(\frac{\dot{Z}_0}{V_0}\right) \quad \text{or} \quad \dot{X}_0 = +g\left(\frac{Z_0}{V_0}\right) \quad [28]$$

In view of Equations [27] and [28], Equations [26] become

$$\left.\begin{aligned} \ddot{Z}_0 &= \left[1 + n_0\left(2 - \frac{2gZ_0}{V_0^2} - \frac{\dot{Z}_0}{\alpha_0 V_0} - \frac{\eta}{\alpha_0}\right)\right]g \\ I_y\ddot{\eta} &= -\left[n_0(e_0'k_0c_3 - d_w)\left(\frac{\dot{Z}_0}{\alpha_0 V_0} + \frac{\eta}{\alpha_0} + \frac{2gZ_0}{V_0^2} - 2\right) + \frac{e_0'c_2^2k_0'\dot{\eta}}{V_0}\right]Mg \end{aligned}\right\} \quad [29]$$

7 Deflection Functions

Thus far the deflection functions $\bar{\eta}_1, \bar{\varphi}_1, \bar{\xi}_1, \bar{\xi}_2, \bar{\psi}_1, \bar{\eta}_1', \ldots$ remain unspecified. From Rayleigh's principle it is reasonable to suppose that the instantaneous deflections are the product of a time function and the static deflections of the airplane under gravity. The static deflections are found by the principle of minimum energy. For example, in the case of wing the deflections in bending and torsion are first determined as power series in y by minimizing the functions

$$\left.\begin{aligned} H_1 &= \tfrac{1}{2}\int_0^l EI_y\left[\frac{d^2\bar{\eta}_1(y)}{dy^2}\right]^2 dy - \int_0^l w(y)\bar{\eta}_1(y)dy \\ H_2 &= \tfrac{1}{2}\int_0^l G\left[\frac{[2A\bar{\varphi}_1(y)]^2}{c(y)}\right]t(y)\,dy - \int^l\int_{-a}^{a} w(y)\,x^i\bar{\varphi}_1(y)\,dx^i\,dy \end{aligned}\right\} \quad [30]$$

where w is the (weight—air lift) per unit area. After power-series approximations are obtained for the deflection functions, these in turn may be approximated by elementary functions. For a wing, in spite of the variable mass and variable structural rigidity, the deflections in bending, from the fuselage as far as the outboard motor, are sufficiently approximated by a constant multiple of $(1 - \cos \pi x/2)$. Likewise, two straight-line segments approximate the total angle of twist in torsion over the same length.

The deflections at time t are then given by

$$\eta_1(t)\bar{\eta}_1(y),\ \xi_1(t)\bar{\xi}_1(x),\ \ldots,$$

where the time functions $\eta_1(t)$, $\xi_1(t)$, ... are given by the solution of the equations of motion, Equations [31]. The calculations, when done carefully, of the deflection functions involve a vast amount of labor. However, by trial, it is justified that these functions when calculated crudely give in all cases sufficiently accurate results. The mass distribution $\sigma(y)$ along a wing is represented by average constant values of σ over three segments of the wing as far out as the outboard motor.

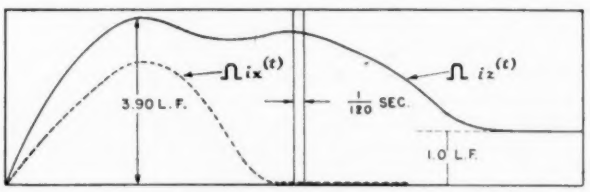
For an airplane such that the portion of the wing intercepted by the fuselage is significantly deformable, the functions $\bar{\xi}_1$ and $\bar{\xi}_2$ are replaced by a single deflection function $\bar{\xi}^i(x)$ which is first determined as a power series in x by means of the first of Equations [30].

8 Equations of Motion

The combination of Lagrange's equations and Equations [29] yield the equations of motion of an elastic airplane

$$\bar{\boldsymbol{Z}}\cdot\boldsymbol{X} = \boldsymbol{F} \quad [31]$$

where values are given in Table 1.



Vector $\boldsymbol{F}$ is given by Equations [20]. The elements of the matrix $\bar{\boldsymbol{Z}}$ are

$$Z_{ij} = M_{ij}p^2 + R_{ij}p + S_{ij}$$

where all R_{ij} vanish except R_{22} and R_{25}. That is, structural damping is neglected. This neglect is on the conservative side.

9 Explicit Strut Load Factors

When the equivalent drop-mass has been determined as shown in reference (4), then the solution of Equations [1], reference (3), yields the load-factor curves as functions of the time. As previously stated the load-factor curves for zero lift can be determined from test results, provided the strut exists. For the cases of fractional lift and for the case of nonexistence of the strut,

LOAD FACTOR CURVE, NO LIFT

Fig. 5

the solution of Equations [1] is the only recourse. Denote the vertical load factors, for zero aerodynamic lift, corresponding to the forces F_{is} by $\Omega_{is}(t)$, $(i = 0, 1, 2)$. A representative $\Omega_{is}(t)$ for zero lift is shown in Fig. 5. Write

$$F_{0s} = -\delta_0'\Omega_{0s}g,\ F_{is} = -\delta_0\Omega_{is}g,\ (i = 1, 2)$$

where the significance of δ_0' and δ_0 is given in Equation [32] and also in section 11.

The drag forces induced by the sudden rotation of the wheels of the landing gear are indeed significant. It is found both by solving the equation of motion for the sudden rotation of a wheel subject to a torque rF_{is}, where r is the radius of the wheel, and also by flight test that the drag force acting at the axle of the

		$Z_{13\,3}$	$Z_{13\,4}$	$Z_{13\,5}$								$Z_{13\,13}$	$Z_{14\,14}$	η_1'
		$Z_{14\,3}$	$Z_{14\,4}$	$Z_{14\,5}$								$Z_{14\,13}$	$Z_{14\,14}$	η_1'

wheel in landing on a level surface has a maximum value equal to approximately 0.75 F_{iz}. This force reaches its maximum value in 0.5 of the time period that F_{iz} reaches its maximum and the drag force vanishes at approximately the time of peak value of F_{iz}. Write

$$F_{iz} = -C\Omega_{iz}$$

where C is a positive constant and a typical $\Omega_{iz}(t)$ is represented by the dotted line in Fig. 5. All load factors are positive functions for all values of the time. For a level landing all F_{iy} of the vector $\boldsymbol{F}$ (Equation [20]) are zero. Since all components of $\boldsymbol{F}$ are thus determined, the vector $\boldsymbol{F}$ may be expressed as a time function.

By solution of Equations [1] the law of variation of load factor with aerodynamic lift may be stated

$$\text{[Peak load factor with lift]} = \left[1 - 0.40\left(\frac{\text{Per cent lift}}{100}\right)\right] \times \text{[Maximum load factor with no lift]} \equiv [\delta_0' \text{ or } \delta_0] \times \text{[Maximum load factor with no lift]} \quad [32]$$

SOLUTIONS OF THE EQUATIONS OF PERFORMANCE

10 Analytical Solution

Equations [31] are linear because they were so rendered by first solving Equations [1]. Moreover, Equations [1] were first solved independently to conform with manufacturing procedure. In the study of the landing of an elastic plane, the order of procedure is first to determine the values of M_1 and M_2 (equivalent drop-masses) under the assumptions that the plane is a rigid body. These values are determined from footnote (4). With these values of M_1 and M_2 the solutions of Equations [1] give the load factors for different fractions of air lift. Thus vector $\boldsymbol{F}$ is determined and Equations [31] are solvable for the deflections and rigid co-ordinates.

The solution[7] of Equation [31] is, in matrix notation

$$\boldsymbol{X} = \bar{\boldsymbol{Z}}^{-1}\cdot[Q\boldsymbol{F}(t) + (\bar{\boldsymbol{M}}p + \bar{\boldsymbol{R}})\cdot\boldsymbol{X}_0 + \bar{\boldsymbol{M}}\cdot\dot{\boldsymbol{X}}_0] \quad [33]$$

where

$$\boldsymbol{X}_0 = \boldsymbol{X}(0) = \text{displacements at } t = 0$$

$$\dot{\boldsymbol{X}}_0 = \dot{\boldsymbol{X}}(0) = \text{velocities at } t = 0$$

and

$$Q\boldsymbol{F}(t) \equiv \int_0^\infty e^{-pt}\,\boldsymbol{F}(t)\,dt$$

All elements of $\boldsymbol{X}_0$ are zero except $X_5(0) = \eta(0) = \eta_0$, and likewise all elements of $\dot{\boldsymbol{X}}$ are zero except

$$\dot{X}^3(0) = Z_0(0) = v_0$$

Denote the right-hand side of the operational matrix Equation [33] by $\boldsymbol{G}(p)$. The solution of Equation [33] is given by the contour integral

$$\boldsymbol{X}(t) = \frac{1}{2\pi i}\int_C e^{pt}\boldsymbol{G}(p)\,dp \quad [34]$$

where C is a circular contour enclosing all the poles of $G(p)$.

Since the determinant of $\bar{\boldsymbol{Z}}$ is a high-degree polynomial, the labor of computing the residues in Equation [34] is considerable.

A study of the behavior of the generalized elastic airplane in landing involves the study of the solution of Equation [34] as the system parameters M_{ij} and S_{ij} vary. Since it is especially

[7] Equation [34] is merely Van der Pol's extension of Heaviside's operational calculus written in matrix form. For the unextended theory see "The Heaviside Operational Calculus," by H. W. March, Bulletin, American Mathematical Society, vol. 33, 1927, p. 311; also reference (5), vol. 1, chapt. 4. For the extended theory see: "Simple Proof and Extension of Heaviside's Operational Calculus for Invariable Systems," *Philosophical Magazine*, vol. 7, 1929, p. 1153.

desirable, from a structural point of view, to study the cause of distortion (bending and torsion) of the front spar in a crash landing, it is of interest to vary fore and aft the location of the main landing gear on the wing. To study the mechanism of failure of a front spar in landing, it is necessary to vary the torsional rigidity of the wing. The location of the center of gravity has a pronounced effect on wing torsion in landing. Different loadings and different velocities of descent along with system parameter changes lead to a multitude of cases.

Of course, if only one particular landing with one set of system parameters is required then the solution of Equation [34] is carried out.

11 Differential-Analyzer Solutions

It is evident that the labor involved in a complete study of a generalized transport airplane in landing by means of Equation [34] is prohibitive. Certain particular cases must be selected which are most important and these solved by machine methods.

For a large transport with tricycle landing gear, its normal first impact is on the main gear. For this type of landing, the general deflections of the transport will be largest. Once the airplane rests on the main gear, the solution of the dynamical problem of lowering the nose gear is not a difficult one.

Accordingly, consider the deflections for the airplane landing on the main gear. Since there exists no differential analyzer sufficiently large to integrate Equation [31], it is necessary to proceed as follows: Since the weight of the empennage of a transport is but 3 to 5 per cent of the weight of the plane, it is clear that the bending and torsion of the stabilizer cannot, as far as mass considerations are concerned, affect the deflections of the wing and fuselage in landing. Consequently, as far as mass considerations are concerned in the motion of the airplane the empennage will be regarded as a concentrated mass. As far as its aerodynamic moments are concerned, the empennage will be regarded as a localized force. Once the motion of the points of attachment of the stabilizer are known from the general motion of the airplane, the behavior of the empennage under an applied *displacement* can be studied as an independent problem. If it is further supposed that the airplane lands on all wheels of the main gear simultaneously, then the co-ordinates in Equation [31] are reduced to Z_0, η, η_1, φ_1, ζ_1, ξ_2. This system is well within the range of a differential analyzer.

Since the time of impact during landing is of the order of 0.25 sec, it is assumed that the aerodynamic forces remain constant during this interval. These forces then are equivalent to a constant lift at the center of gravity and a constant moment. Solutions were carried out for a range of lifts and moments. Subsequently, the orientation of the transport and the position of its control surfaces which will produce the prescribed lift and moment are determined from Equations [29].

Under the conditions thus set forth, consider a numerical example. It is not feasible to publish data pertaining to any particular transport. Accordingly, the curves of distributed rigidity, distributed mass, and aerodynamic lift and moments are not displayed. All of the lengths represented in Fig. 3 are involved. Such data as are given are somewhat typical for large transports and do not necessarily pertain to a particular airplane.

Let the weight on the main gear be 62,000 lb. The center of gravity is in its most forward position. The main landing gear is 44 in. aft of the center of gravity and is 17 in. aft of the center line of the wing. The first two numbers change with the loading; only the last is descriptive of a particular airplane. However, when the main struts are moved fore and aft in the solutions, this number also will change. The units employed are inches, pounds, seconds; $E = 10^7$, $g = 386$.

Under the stated conditions and after the required integrals have been evaluated, the equation of performance for one set of values of the system parameters is

$$\bar{\boldsymbol{Z}}_s \cdot \boldsymbol{X}_s = \boldsymbol{F}_s \qquad [35]$$

where values are given in Table 2 and Equations [36].

Equation [35] is of a form suitable for use on the differential analyzer.

The structural matrix $\bar{\boldsymbol{Z}}$, for α_0 fixed, represents a particular transport with a definite loading and definite position of the center of gravity. The vector $\boldsymbol{F}$, through the variation of the parameters δ_0, δ_1, β_0, β_1, L_w, L_t, m, and n_1 determines an eightfold infinitude of landings. The variation of the twenty-four structural system parameters gives a twenty-fourfold infinitude of transports. The duration of the impact during landing has been shown to be (for the type of strut in question) of the order of 0.25 sec.

The variations of the $\boldsymbol{F}_s$ parameters are as follows: If

$0.5 < \alpha_0 < 7$ then $(0.5)2 \times 10^4 <$ torsional rigidity $< (7)\ 2 \times 10^4$

$0.6 < \delta_0 < 1$ then $0 <$ aerodynamic lift at C.G. < 1

$0 < \delta'_0 < 1$ then $0 <$ wheel drag $< 0.75F_{it}(2t)$

$0 < \beta_0 < 1$ then $0 <$ wing lift < 1 ($\beta_0 = 1$ signifies no stall)

$0 < \beta_1 < 1$ then $0 <$ negative tail lift < 1

$n_1 = 1$ This signifies a constant tail moment acting during impact such that the transport was balanced at the first instant of impact

$m = 0.1$ signifies that the wing moment is 0.1 of the tail moment

$\epsilon_0 = 1$ or -1 according as the struts of the main gear are located at 14 in. aft or fore of the center line of the wing

Results and Conclusions

(*a*) *Differential-Analyzer Solutions.* About 300 solutions were obtained on the differential analyzer. The applied-force parameters were varied as just indicated. One system parameter (i.e., parameters of the matrix $\bar{\boldsymbol{Z}})\alpha_0$ was varied. Two of these solutions are shown in Fig. 6. The initial sinking speed v_0 was 200 ips for the solutions shown.

(*b*) *Broken Front-Spar Criterion.* The value of α_0 in the solutions shown in Fig. 6 does not belong to any bomber or transport investigated. The value of α_0 is taken such that the period of the first half cycle of φ_1 agrees approximately with the period of application of the strut force. For this choice the peak value of φ_1 is the maximum obtainable and is approximately 14 times the static angular deflection. This is the only indication of the mechanism of a broken spar. The real value of α_0 belonging to modern transports and bombers with high wing loading is approximately 5 instead of 0.7. For the real value of α_0 the response of $p\varphi_1$ is shown approximately by the line of circles in Fig. 6(*b*). Both of the solutions given are for crash landings. The effect of 0.5 air lift is shown by comparing the dotted and continuous lines in Fig. 6. In Fig. 6(*a*), it is noted that the acceleration due to gravity of the C.G. is greater than the resistance of the struts for approximately 0.022 sec. The same initial hook appears in Figs. 6(*b*, *d*, *e*, *f*).

FIG. 6

(*c*) *Accelerations at Point* $P(x, y, z)$. The accelerations at $P(x, y, z)$ are given by

$$\ddot{P} = \ddot{Z}_0 + \boldsymbol{k} \cdot \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ \ddot{\xi} & \ddot{\eta} & \ddot{\zeta} \\ a(x) & b(y) & c(z) \end{vmatrix} + \ddot{\zeta}^{\boldsymbol{k}} \quad \ldots\ldots\ldots [37]$$

For example, from the no-lift solution in Fig. 6, the acceleration of the pilot is

$$\ddot{P}_0 = \ddot{Z}_0 + \boldsymbol{k} \cdot \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ \ddot{\xi} & \ddot{\eta} & \ddot{\zeta} \\ 400 & 0 & 0 \end{vmatrix} + \ddot{\xi}_1 \bar{\xi}(400)$$

$$= -\left(\frac{180}{0.12}\right) - 400\left(-\frac{0.01}{0.20}\right) + (600\,\pi \cos 10\pi t)(1/4)$$

$$= -(3.88 - 1.22 \cos 10\pi t)g = -2.66g \text{ (minimum)}$$

(The C.G. acceleration is —3.9.)

If the transport has an angular velocity nose downward of $^3/_4$ radian per sec, then the pilot will perceive no acceleration induced by the main landing gear in a crash landing. (It should be noted that the positive direction of η_1 is upward, the positive directions of ξ_1 and ξ_2 are downward, and φ_1 is as shown in Fig. 3.)

The maximum acceleration of the outboard motor is

$$\ddot{P}_{m2} = \ddot{Z}_0 + \boldsymbol{k} \cdot \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ \ddot{\xi} & \ddot{\eta} & \ddot{\xi} \\ -a_1 & -b_2 & c_2 \end{vmatrix} + \ddot{\eta}_1 \bar{\eta}(b_1) + d_1 \ddot{\varphi}_1 \bar{\varphi}(b_1)$$

$$= -\frac{180}{0.12} + 17\left(-\frac{0.01}{0.12}\right) + 490\,(1) + 1400\,(1/57.3)$$

$$= -2.55g$$

(The C.G. acceleration is —3.9.)

(*d*) *Maximum Deflections.* The crash landings just considered give high accelerations. (The term crash landing is used for a more severe landing than maximum blind landing.) For normal landings (velocity of descent = 60 ips and wing lift = 0.8) the accelerations are of the order of $1.3g$. The order of magnitude of measured accelerations are of the order of $1.1g$.

(*e*) *Configuration of Maximum Deflections.* The maximum deflections in landing due to the main gear occur for the space-time configuration given in Fig. 6, that is, when the tail is held down, the airplane is prevented from rolling away from the thrust exerted by the main gear.

(*f*) *Analytical Solutions.* Since the space-time configuration of maximum deflections is known, sufficient results are obtainable by one application of Equation [34], the tail moment being held as a symbol and its magnitude eventually determined such that $\eta = 0$ for all t during impact. In a crash landing, this moment must be very large to overcome the opposing moment induced by the sudden rotation of the landing wheels. Once this tail moment is known, the position of the control surfaces required to produce it can be obtained approximately from Equations [29].

(*g*) *Conventional Gear.* The method just given with slight changes is applicable to an airplane with conventional landing gear.

(*h*) *Impact Stress.* In the beginning, the electrical industry was primarily concerned with mere steady-state phenomena. Since there was a need for it, the Heaviside operational calculus developed rapidly for the handling of transient phenomena. In a like manner impact or dynamical stress is becoming of increasing importance. It is of course closely associated with fatigue.

(*i*) *Improved Accuracy.* The foregoing F_{ij} are calculated with the methods of references (3) and (4), which suppose M_2 to be a rigid mass. For more accurate F_{ij} the work of reference (3) can be carried out where M_2 is the mass of an elastic beam. This, however, is scarcely justifiable since the F_{ij} here employed are on the conservative side, i.e., they are slightly too large.

Acknowledgments

This paper is part of a general investigation on the behavior of an elastic airplane in landing, taxiing, and gusts which Mr. F. R. Shanley, chief structures engineer of the Lockheed Aircraft Corporation, with characteristic foresight, first seriously suggested to the author in 1942. The investigations on the two remaining subjects will appear presently. Appreciation is expressed to him for his many helpful ideas and his encouraging support during the rather long interval of this work. The author also expresses his appreciation to Mr. C. L. Johnson, chief research engineer, for his interest in the application of the theory to the Lockheed *Constellation* and the Lockheed-89, and to Mr. H. L. Hibbard, vice-president and chief engineer, for his abiding interest in theoretical work and for the liberal financial appropriation which made possible the use of the differential analyzer of the General Electric Company.

Studies in Three-Dimensional Photoelasticity Torsional Stresses by Oblique Incidence

By MAX M. FROCHT,[1] PITTSBURGH, PA.

In this paper a photoelastic method is described for the study of stresses in cylindrical shafts due to pure torsion. The basic photoelastic equation governing this case is derived. It is shown that the maximum stresses, i.e., the boundary stresses, can be determined from a single stress pattern, and that the two stress components which define the complete stress system in pure torsion at an interior point can be determined from two stress patterns obtained from one section of a shaft into which the pure-torsion system has been frozen, employing to this end the Drucker-Mindlin suggestion of oblique incidence. The method is applied to a circular shaft, and the experimental results are found to be in complete agreement with the theory.

1 THEORY

History of Three-Dimensional Photoelasticity

WITH the advent of three-dimensional photoelasticity, which was made possible by the process of freezing a stress pattern (1, 2, 3),[2] it was early recognized that the two-dimensional procedure employing a parallel beam of light at normal incidence to the plate was inadequate. In 1937, Hiltscher (4) employed a convergent beam of light in the determination of the directions of the principal stresses and the corresponding three principal shears. In 1938, Kuske (5) extended Hiltscher's work and showed the possibilities in this method for the determination of the actual principal stresses.

The next suggestion came from Weller (6), who in 1939, at the Ninth Eastern Photoelasticity Conference held at Cornell University, proposed the use of scattered light. This paved the way for the next step. In 1940, Drucker and Mindlin (7) in a theoretical study of the effect of rotation of the principal axes in three-dimensional problems suggested the use of oblique incidence of a parallel beam in contrast to the oblique incidence of the convergent beam employed by Hiltscher.

Although, theoretically, this procedure, which may be likened to that of a strain rosette, leads one to expect the complete determination of all the six stress components encountered in the most general three-dimensional case, the actual formulation of these equations shows that only in the simplest cases will they yield results of sufficient accuracy to be of practical value. This weakness is indirectly shown by Drucker's (8) paper of 1943, which to the best of the author's knowledge represents the first published application of this type of oblique incidence in photoelasticity. Drucker considers a two-dimensional problem, a diagonally compressed square plate, and determines the principal stresses at a point by a rotation of the model about one of the principal axes at the point. From his discussion of the accuracy of the results, it follows that even in a two-dimensional case rotation about an arbitrary axis in the plate would lead to gross errors.

The present paper is an application of oblique incidence to the solution of the three-dimensional problem of pure torsion, which because of its relative simplicity, promises to be of practical value and of high accuracy. Work with oblique incidence has been carried on in the photoelastic laboratory at the Carnegie Institute of Technology intermittently since 1940, and the present paper is one of the outgrowths (9).

Development of Theory

The Basic Equation for Pure Torsion. It is shown in the theory of elasticity (10) (Saint Venant's theory), that in cylindrical shafts subjected to pure torsion the general stress system is reduced to two shear components only, lying in planes parallel to those of the applied twisting couples. Choosing the axis of the shaft as the Z axis, Fig. 1, the stress components induced by pure torsion are τ_{zx} and τ_{yz}. All other stress components vanish, i.e.

$$\sigma_x = \sigma_y = \sigma_z = \tau_{xy} = 0$$

Assume now that a ray of polarized light lying in a plane

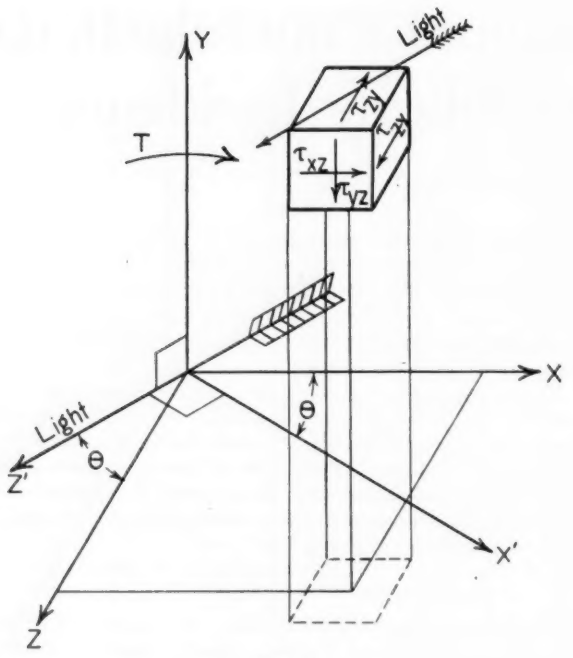

FIG. 2

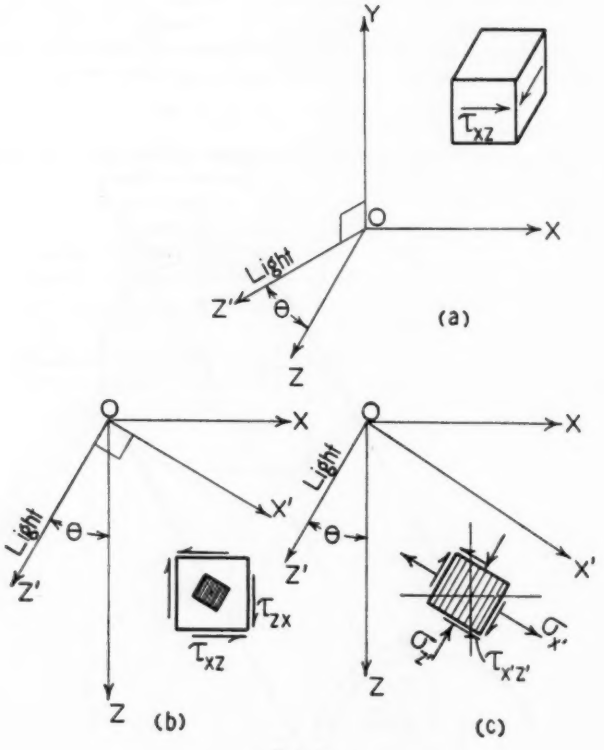

FIG. 3

parallel to the X, Z plane passes through an element subjected to pure torsion, the ray being inclined at an arbitrary angle θ to the axis of the shaft, the Z axis, Fig. 2. The direction of the light we designate by Z' and the line perpendicular to it and lying in the X, Z plane by X', Fig. 2. We now wish to determine the photo-elastic effect of the stresses resulting from pure torsion on the light passing through an element subjected to it. From the general stress-optic law we know that, neglecting rotation, this optical effect is produced by the difference between the secondary principal stresses $(p' - q')$ lying in a plane transverse to the assumed axis of propagation, i.e., in a plane parallel to the X', Y plane, Fig. 2. The problem thus reduces itself to one of determining the secondary principal stresses and their difference for the specified direction of the light.

To this end we consider each of the two stress systems τ_{zx} and τ_{yz}, separately. The first of these components τ_{zx} is shown in Fig. 3(*a*). Consider next an element with faces parallel and perpendicular to the ray, the shaded element, Figs. 3(*b*) and (*c*). The stresses $\sigma_{x'}$, $\sigma_{z'}$, and $\tau_{x'z'}$ induced on such an inclined element by the component τ_{zx} are given by the expressions

$$\sigma_{x'} = \tau_{zx} \sin 2\theta \quad [1a]$$

$$\sigma_{z'} = -\tau_{zx} \sin 2\theta \quad [1b]$$

$$\tau_{x'z'} = \tau_{zx} \cos 2\theta \quad [1c]$$

The secondary principal stresses for this case are therefore completely determined by the horizontal stress component $\sigma_{x'}$. Hence

$$p' = \sigma_{x'} = \tau_{zx} \sin 2\theta \quad [2a]$$

$$q' = 0 \quad [2b]$$

We next turn our attention to the second stress component τ_{yz} which is shown in Fig. 4(*a*). On an inclined element whose faces are parallel and perpendicular to the ray, Figs. 4(*b*) and (*c*), this stress gives rise to two shear systems

$$\tau_{x'y} = \tau_{zy} \sin \theta \quad [3a]$$

$$\tau_{z'y} = \tau_{zy} \cos \theta \quad [3b]$$

Of these only the component $\tau_{x'y}$ will influence the secondary principal stress for the given ray.

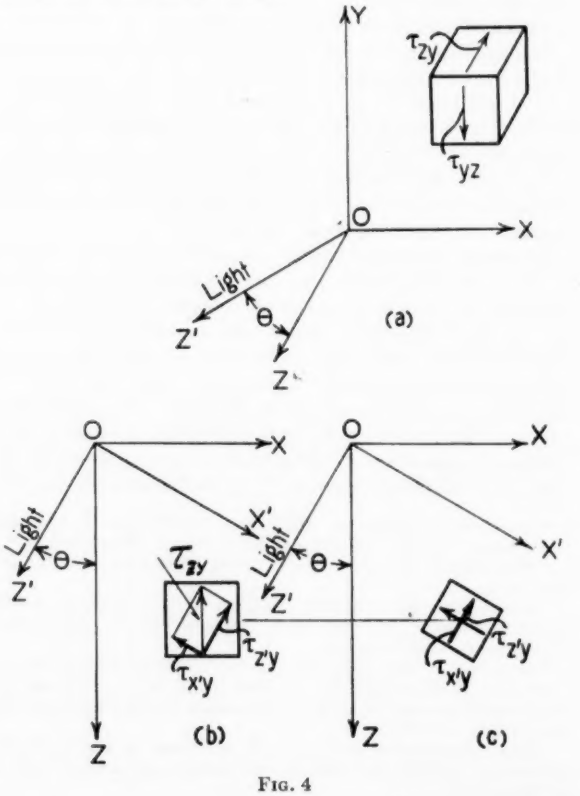

FIG. 4

By superimposing the two stress systems given by Equations [2*a*] and [3*a*], we obtain the secondary principal stresses resulting from pure torsion.

From elementary consideration, it then follows that the secondary principal stresses p' and q' are given by

$$p', q' = \frac{\sigma_{x'}}{2} \pm \frac{1}{2}\sqrt{\sigma_{x'}^2 + 4\tau_{x'y}^2}$$

$$= \frac{1}{2}(\tau_{zz}\sin 2\theta \pm \sqrt{\tau_{zz}^2 \sin^2 2\theta + 4\tau_{zy}^2 \sin^2\theta}) \ldots [4]$$

Hence

$$p' - q' = \sqrt{\tau_{zz}^2 \sin^2 2\theta + 4\tau_{zy}^2 \sin^2\theta}$$

or

$$p' - q' = 2\sin\theta\sqrt{\tau_{zz}^2\cos^2\theta + \tau_{zy}^2} \ldots [5]$$

The photoelastic effect, i.e., the retardation n in fringes, is given by

$$n = Ct'(p' - q') \ldots [6]$$

in which C is the usual stress-optic coefficient, which is related to the shear fringe value of the material f by the expression

$$C = \frac{1}{2f} \ldots [7]$$

From Equations [5], [6], and [7] we obtain

$$n'f = \sin\theta\sqrt{\tau_{zz}^2\cos^2\theta + \tau_{yz}^2} \ldots [8]$$

in which

$$n' = n/t'$$

i.e., n' is the fringe intensity, or the number of fringes per inch of length measured parallel to the ray, and the units of τ_{zz} and τ_{yz} are those of the fringe value f, that is, pounds per square inch. If the constant f be omitted from Equation [8], the effect of this

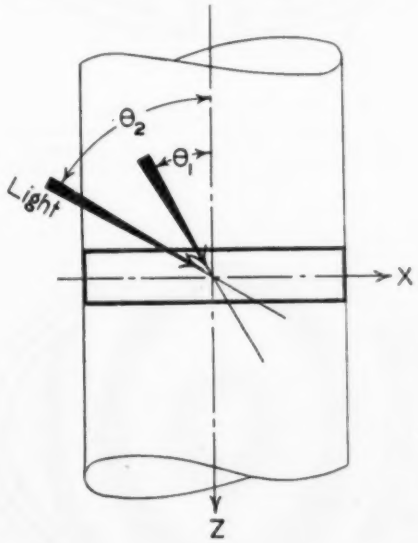

FIG. 5

omission is merely to change the units of the stress components to fringes per inch. Dropping this constant we obtain

$$n' = \sin\theta\sqrt{\tau_{zz}^2\cos^2\theta + \tau_{yz}^2} \ldots [9]$$

This is the fundamental stress-optic equation for pure torsion of cylindrical shafts.

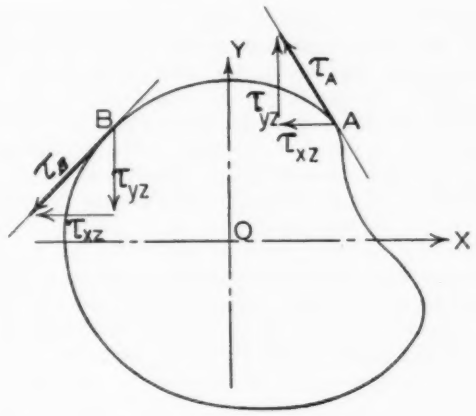

FIG. 6

Inspection of Equation [9] shows that the stress components τ_{zz} and τ_{yz} can be determined from two stress patterns of an arbitrary slice or plate cut from the shaft for which the light has different inclinations θ_1 and θ_2, (θ not equal to zero). To make the idea concrete, let us assume that we cut a transverse slice AB, Fig. 5, out of the shaft into which pure-torsion stresses have been fixed. Two stress patterns in which the light has different and arbitrary directions θ_1 and θ_2, Fig. 5, will give the necessary and sufficient experimental data to evaluate the stress components τ_{zz} and τ_{yz} at any point in the cross section. By inserting the angles θ_1 qnd θ_2 and the fringe intensities n_1' and n_2' at a given point into Equation [9], we obtain the two equations

$$n_1' = \sin\theta_1\sqrt{\tau_{zz}^2\cos^2\theta_1 + \tau_{yz}^2} \ldots [10a]$$

$$n_2' = \sin\theta_2\sqrt{\tau_{zz}^2\cos^2\theta_2 + \tau_{yz}^2} \ldots [10b]$$

which upon solution give the required stress components τ_{zz} and τ_{yz}, and from these the total shear stress can be found.

Boundary Stresses. The maximum shear stresses generally occur on the boundary, and these are of special practical significance. The method under consideration is even simpler for the determination of boundary stresses. These can be evaluated from only one stress pattern for an arbitrary value of θ, not equal to zero. This simplification is made possible by the well-known property of boundary stresses, which states that at the boundary the stresses are tangent to the boundary, Fig. 6. At each point of the boundary the relation between the components τ_{zz} and τ_{yz} is therefore completely determined by the geometry, i.e., the shape of the cross section. It follows that one stress pattern is sufficient to determine the boundary stresses. Denoting the fringe intensity at the boundary by N', we have from the fundamental Equation [9]

$$N' = \sin\theta\sqrt{\tau_{zz}^2\cos^2\theta + \tau_{yz}^2} \ldots [11]$$

Also from the contour of the cross section, we have

$$\tau_{yz} = r\tau_{zz} \ldots [12]$$

in which r is a known ratio. Substituting into Equation [11], we obtain

$$N' = \sin\theta\tau_{zz}\sqrt{\cos^2\theta + r^2} \ldots [13]$$

which gives τ_{zz} directly.

An alternative procedure for the determination of boundary stresses is possible. From Equation [9], it follows that for θ = 90 deg

$$n' = \tau_{yz} \ldots [14]$$

This means that a stress pattern obtained from a ray perpendicular to the axis of the shaft gives directly the component τ_{yz} at every point of the cross section, including the boundary. Since at the boundary the direction of the total shear is known, it follows that this boundary stress can be determined from the one component τ_{yz}. In this method, however, the slice cannot be a transverse section but has to be inclined to the axis of the shaft at some convenient angle α, Fig. 7. It should also be noted that at the boundary the thickness t' is no longer constant, but varies linearly and this variation must be considered when calculating n'. However, there will always be boundary regions at which the ray is parallel to the surface and these yield the most reliable results. It is therefore advisable to orient the model so that the rays are parallel to the most highly stressed parts.

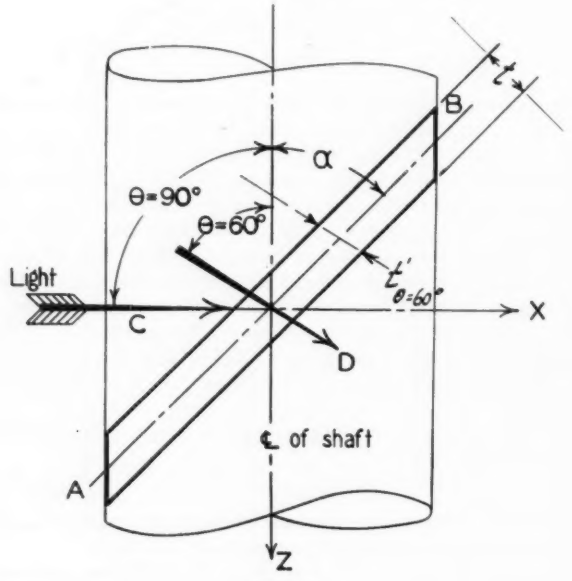

FIG. 7

Theoretically the two methods are equally effective. Practical considerations, however, make the first method, in which a transverse slice may be used, generally preferable. This is due to the relatively large distortions which must be given to a bakelite shaft in order to obtain sufficiently large stresses for optical observation. If the section is inclined as in Fig. 7, the shape of the boundary at the ends of the plate may be considerably distorted from the normal shape. This may lead to certain difficulties which are avoided by the use of a transverse section. However, for circular shafts the method based on Equation [14] is very effective.

The second procedure, in which $\theta = 90$ deg, may also be used to determine the shear stress at any point, provided the stress contour through that point is known or can be approximated.

2 APPLICATION TO CIRCULAR SHAFT

Since the state of stress in a circular shaft in pure torsion is known with precision, the proposed method is first tested on such a shaft. To this end a circular shaft made of Bakelite BT-61-893 and approximately 1 in. diam was subjected to a pure torque, and the shear system frozen into it in the usual manner.

In order to obtain a fair measure of the efficacy of the method, it would be desirable to have a material free from time stresses, which Bakelite is not. Here again the circular shaft proved advantageous because the time stresses in such a shaft can be readily removed by machining after weeks or even months. The machinist was instructed to remove a thin skin. Due to an error, he reduced the diameter to 0.908 in., which was far in excess. It had, however, the effect of relieving the time stress completely. It is recognized that in a general case this remedy cannot be applied with the same ease or effect, although in many cases it is possible and advisable to remove a thin skin. While admittedly a source of error and highly undesirable, it should not be concluded that the presence of time stresses seriously impairs the final results. With proper technique and efficient work these stresses can be kept to very low values. We have obtained stress patterns from plates cut from circular shafts with transverse holes in tension in which the boundary stresses were nearly as good as those found in a freshly cut two-dimensional plate (11).

From this reduced shaft a slice 0.119 in. thick and inclined at 45 deg to the axis of the shaft, Fig. 7, was carefully cut out. In this cutting process the axis of the shaft was kept horizontal and the face of the cutter vertical, so that the axis of the shaft and the minor axis of the elliptical slice were perpendicular to each other.

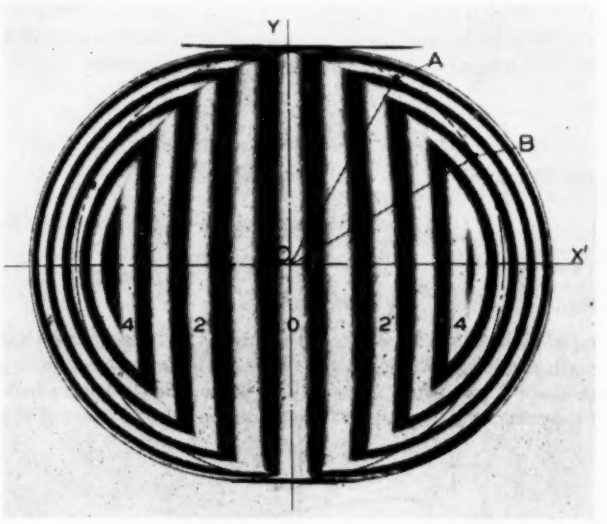

FIG. 8 STRESS PATTERN OF PLATE FROM SHAFT IN PURE TORSION MAKING AN ANGLE OF 45 DEG WITH AXIS OF SHAFT

(Light normal to axis, i.e., $\theta = 90$ deg. Diameter = 0.908 in.; $t' = 0.1685$ in.; N on X' axis at boundary = 5.5 fringes. Edges of plate have been marked for clarity.)

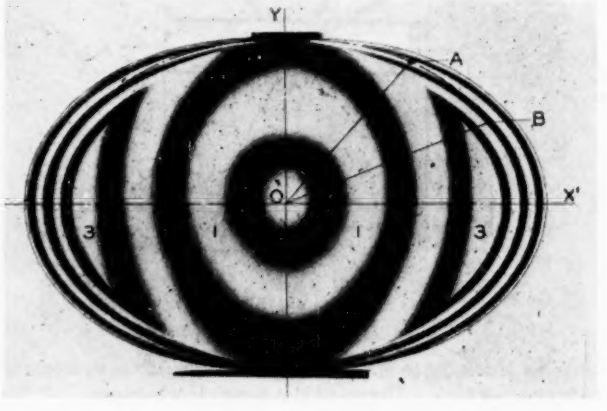

FIG. 9 STRESS PATTERN OF PLATE FROM SHAFT IN PURE TORSION MAKING AN ANGLE OF 45 DEG WITH AXIS OF SHAFT

(Light at an angle of 60 deg with axis of shaft. Diameter = 0.908 in.; $t = 0.119$ in.; $t' = 0.123$ in.; N on X' axis at boundary = 3.72 fringes, by extrapolation. Edges have been marked for clarity.)

Two stress patterns of this plate were taken, Figs. 8 and 9. In one, Fig. 8, $\theta = 90$ deg, i.e., the axis of the circularly polarized beam was perpendicular to the axis of the shaft; and in the other, Fig. 9, this angle was 60 deg, Fig. 7. The customary procedure of immersing the slice in a bath of Halowax oil was followed. The general dimensions, nomenclature, and relevant data are as follows:

Material—Bakelite BT-61-893

D = diameter of shaft, 1.005 in. both before and after twisting
D' = diameter of shaft after removal of time stresses, 0.908 in.
L = length between couples, 6 in.
Over-all length, 7 in.
Time and temperature of heating, 3 hr at 260 F
θ = angle of twist, 107 deg or 1.867 radians in 6 in.
T = applied torque, 11.42 lb-in.
α = angle between axis of shaft and plate, 45 deg
θ = angle between axis of shaft and ray
t = thickness of plate, 0.119 in.
t' = effective light path, $t' = t/\cos(\alpha - \theta)$, Fig. 7
n = fringe order at an interior point
n' = fringe intensity, i.e., fringes per inch of thickness at an interior point
N = fringe order at boundary
N' = fringe intensity at boundary
E = modulus of elasticity, 1100 psi
G = modulus of rigidity, 366 psi
ν = Poisson's ratio, $1/2$
f = shear-fringe value of material, 1.6 psi per in. of thickness

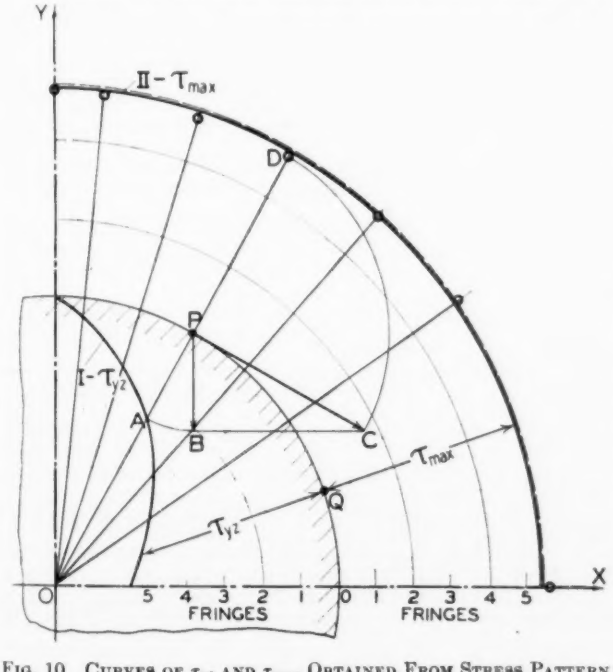

FIG. 10 CURVES OF τ_{yz} AND τ_{max} OBTAINED FROM STRESS PATTERN FIG. 9; METHOD OF OBTAINING τ_{max} IS ALSO SHOWN

Curve I is curve of fringe orders from Fig. 8. Curve II is mean value of τ_{max} derived from curve I, $N = 5.33$ fringes. Dashed curve is theoretical fringe order as calculated from applied torque of 11.42 lb-in., $N = 5.46$ fringes.)

Boundary Stresses. The boundary stresses were determined by means of Equation [14], and the fringe orders N from the stress pattern shown in Fig. 8.

Fig. 10 shows the actual procedure in the numerical evaluation of all boundary stresses. Curve I represents the values of τ_{yz} along the circumference of the shaft, laid off radially, which are obtained from the stress pattern in Fig. 8. For example, on the Y axis, $\tau_{yz} = 0$, and on the X' axis $\tau_{yz} = 5.5$ fringes. At some general point P, $\tau_{yz} = PA$. From P as a center, we draw an arc of radius PA, to obtain point B, so that

$$PB = PA = (\tau_{yz})_P$$

In order to obtain the total boundary shear stress at P, we draw a tangent at P and a horizontal line through B to obtain the point of intersection C. The length PC gives the required boundary stress.

For purposes of comparison of the magnitudes of the boundary stresses, we lay off radially $PD = PC$, so that PD is equal to the maximum or boundary stress at point P. In a circular shaft, these boundary stresses are clearly of equal magnitude, and they should therefore fall on a circle, with center at 0. Curve II, Fig. 10, represents the mean experimental value of the maximum shears, which is 5.33 fringes, and shows the degree of deviation of the experimental values from a circular locus. It is seen that the theoretical requirement that the boundary stresses in a circular shaft be of constant magnitude is completely satisfied.

The dashed curve in Fig. 10 falling slightly outside curve II represents the theoretical boundary shears based upon the applied torque of 11.42 lb-in.; thus

$$\tau_{max} = \frac{11.42 \times 0.502 \times 32}{\pi \times 1.005^4} = 57.4 \text{ psi}$$

From Equations [6] and [7]

$$N = \frac{\tau_{max}\, t'}{f}$$

$$= \frac{57.4 \times 0.1685}{1.6} = 6.05 \text{ fringes (approximately).}$$

Remembering that in Fig. 10, the diameter is only 0.908 in., as compared with 1.005 in. diameter of shaft, we obtain

$$N = \frac{6.05 \times 0.908}{1.005} = 5.46 \text{ fringes (approximately).}$$

This is the fringe order which corresponds to the mean experimental value of 5.33 given by curve II of Fig. 10, giving an error of about $2\frac{1}{2}$ per cent.

The maximum shear stress was also determined from five additional stress patterns obtained from two thicker plates. One of these was a transverse section 0.245 in. thick, the other was a section inclined at 45 deg to the axis and 0.246 in. thick. The mean value of the maximum shear from these plates is also 57.4 psi, and agrees completely with the value given by the applied torque.

We thus see that the boundary stresses not only satisfy the requirement that they be of constant magnitude but these magnitudes also agree with the required theoretical values. It should be emphasized that the complete story of the boundary stresses was determined from the one stress pattern shown in Fig. 8.

Stresses Across Radial Lines. We next determine the stresses across two arbitrary radial lines OA and OB, inclined, respectively, at 60 deg and 30 deg to the X axis. To this end two stress patterns with different angles of incidence of the light are needed. We choose those shown in Figs. 8 and 9 in which $\theta = 90$ deg and $\theta = 60$ deg, respectively; Fig. 8 being chosen because it gives τ_{yz} directly which can then be used to calculate τ_{zz}. The final stresses for section OA are given by the curve in Fig. 11, and those for OB (not shown) were quite similar. We note that at A the resultant stress is 5.35, and at B, 5.46 fringes, which provides an additional corroboration for the boundary stresses. The fringe-order curves which are necessary for the calculation of τ_{yz} and τ_{zz} across section OA are shown in Fig 12.

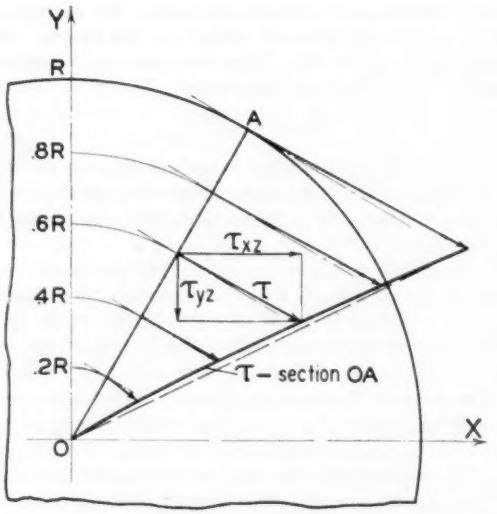

FIG. 11 CURVE OF τ ACROSS SECTION OA OBTAINED PHOTOELASTICALLY FROM THE TWO STRESS PATTERNS IN FIGS. 8 AND 9

(Deviation from theoretical direction is indicated by tangents drawn at each point. Deviation from linearity is indicated by straight dashed line drawn through origin.)

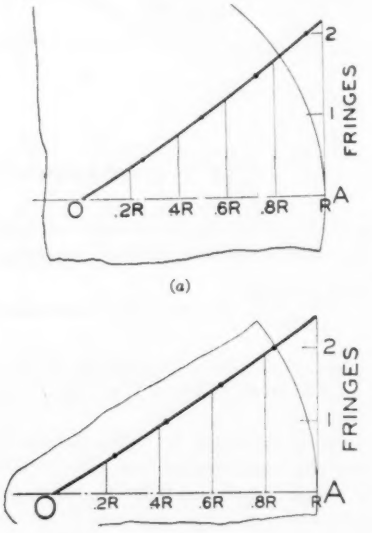

FIG. 12 CURVES OF FRINGE ORDERS FOR SECTIONS OA OBTAINED FROM FIGS. 8 AND 9

(Curve a, θ = 60 deg; curve b, θ = 90 deg.)

Two further checks can now be made. First the distribution of the resultant stresses must be linear, and second the stresses must be normal to the radius vector OA. Inspection of Fig. 11 shows that the experimental results essentially satisfy both conditions. All theoretical requirements for the stress system in a circular shaft are thus met.

Preliminary work on rectangular shafts and circular shafts with grooves further demonstrates the practicability of the proposed method.

Although the present discussion is confined to pure Saint Venant torsion, it is altogether reasonable to believe that the method will yield satisfactory boundary stresses even when warping is prevented.

ACKNOWLEDGMENT

The author expresses his appreciation to the administration of the Carnegie Institute of Technology for its support of this work. Special acknowledgment is made to Mr. John R. McDowell, mechanician in the photoelastic laboratory, now in the U. S. Air Corps, for his co-operation and assistance.

Stresses in a Reinforced Monocoque Cylinder Under Concentrated Symmetric Transverse Loads

By N. J. HOFF,[1] BROOKLYN, N. Y.

The stresses in the sheet covering, stringers, and rings of a reinforced monocoque cylinder of circular cross section are calculated for the case of a loading consisting of concentrated symmetric forces applied to the rings in the planes of the rings. The conventional assumptions of a linear normal stress distribution and a corresponding shear-stress distribution in the bent cylinder are replaced by a least-work analysis. Application of the theory to the numerical example of a cantilever monocoque cylinder yields a maximum shear stress in the sheet covering and a maximum bending moment in the ring amounting to 900 per cent and 33 per cent, respectively, of the values obtained by the conventional analysis.

Introduction and Summary

ONE of the problems most commonly encountered in aircraft structural analysis is the determination of the bending-moment distribution in a transverse frame, or ring, of a reinforced monocoque fuselage. The external loads acting upon the ring consist of concentrated forces, for instance, the weight of and the inertia forces due to passengers, cargo, and equipment, and the balancing distributed forces transmitted through the rivets from the sheet covering of the fuselage. In the sheet covering, the reactions to these distributed forces give rise to the shearing stresses associated with bending and torsion, and it is customary to calculate the distribution of the shearing stresses according to the Bernoulli-Navier theory of bending and the Saint Venant theory of torsion. Since it is generally known that these theories are valid only at some distance from the load application, the only justification for such a procedure has been the lack of better information. In the case of a beam of solid cross section, the distance beyond which the Bernoulli-Navier theory applies is usually taken as a small multiple of the cross-sectional dimensions. Because of the comparatively low degree of redundancy of a thin-walled monocoque cylinder, the predictions of the theory are likely to be valid only at a distance from the application of the concentrated loads equal to several times the diameter of the cylinder.

It is the object of this paper to investigate the distribution of the shearing stresses in the sheet covering and of the bending moments in the rings, through a least-work analysis. Calculations are carried out only for the case of symmetric loading, but they can be easily extended to cover cases of antisymmetric loading. In the numerical example of a typical cantilever monocoque cylinder of three fields, it is found that the maximum shearing stress in the sheet covering amounts to 900 per cent, the maximum bending moment in the ring to 33 per cent of the values obtained through a conventional analysis.

The Monocoque Cylinder

The fuselage underlying this analysis is a cantilever monocoque cylinder of circular cross section, as shown in Fig. 1. The formulas developed in the paper permit, however, the determination of the stresses in cylinders having different end conditions. The cylinder is made of thin sheet metal and is reinforced with m transverse rings, each one of which has a constant though in general a different cross section. The longitudinal reinforcing elements of the cylinder are referred to as stringers. In conformity with general practice in aircraft stress analysis the part of the cross-sectional area of the sheet covering considered effective in carrying normal stresses is added to the cross-sectional area of the stringers to form the total cross-sectional area resisting normal stresses. Since through this artifice the load-carrying capacity of the sheet in tension and in compression is taken into account, it is permissible to assume in the ensuing calculations that the sheet carries shear alone. To simplify further the calculations, the differences in the effective width of sheet on the tension and the compression side of the cylinder are disregarded. Through this device, and by the assumption of an even spacing of stringers of the same cross section around the perimeter of the cylinder, a high degree of uniformity and symmetry is achieved. It may then be assumed that the stringers are distributed continuously around the perimeter. Because of the great number of stringers in modern monocoque fuselages, the accuracy of the stress analysis is not impaired by this assumption. The imaginary thickness of sheet resisting normal stresses, obtained through division of the sum of the cross-sectional areas of all the stringers and the effective area of sheet by the perimeter of the cylinder, is denoted by the symbol t'.

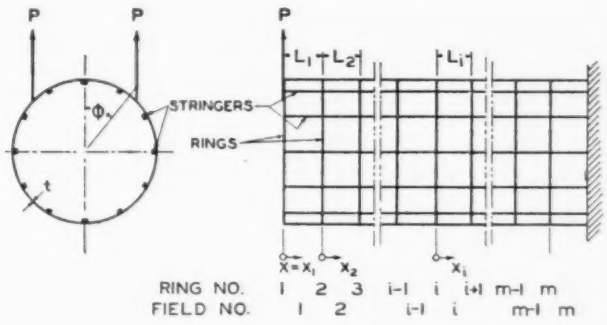

FIG. 1 MONOCOQUE CYLINDER

It follows from the conditions of membrane equilibrium that the shear stress must be constant in each panel bounded by two

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1945, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

adjacent rings and two adjacent stringers if the sheet does not carry direct stress. Because of this requirement, and because of the assumption of an infinite number of stringers and a finite number of rings, in the present problem the shear stress must be constant between two adjacent rings but may vary around the circumference of the cylinder. The shear flow q_i in the ith field, that is, the product of shear stress and sheet thickness, can be represented consequently by the infinite series

$$q_i = \sum_{n=1}^{\infty} a_{in} \sin n\varphi \quad \ldots\ldots [1]$$

The sine series satisfies the requirements of symmetry if the shear flow is taken positive when it points in the direction of increasing φ. Because of the symmetry of both structure and loading only one half of the structure will be considered in all the calculations to follow.

In addition to the foregoing assumptions, the stringers are considered as offering negligibly small resistance to bending. This may be true enough in the case of many monocoque fuselages having strong rings and weak stringers. The rings are assumed to have finite rigidity in bending in their plane and vanishing rigidity in bending out of their plane as well as in torsion. Moreover, the validity of Hooke's law and of the principle of superpositions is also assumed.

Analysis of First Ring

Fig. 2 shows the first ring with its loading and the sign convention used. The shear flow acting upon the first ring may be written as

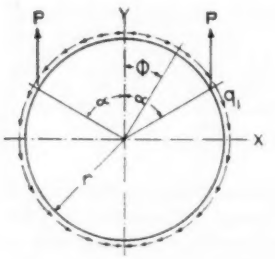

Fig. 2 Diagram of Ring and Loading

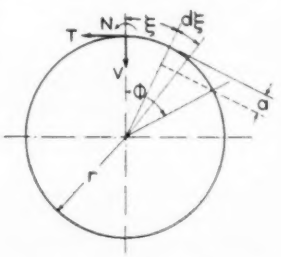

Fig. 3 Notation Used in Calculating Moments

$$q_1 = \sum_{n=1}^{\infty} a_{1n} \sin n\varphi \quad \ldots\ldots [1a]$$

It is easily verified that the requirements of equilibrium of moments and of forces in the x direction are satisfied by each term of the series. The condition of equilibrium of forces in the y direction is

$$P = \int_0^{\pi} qr \sin \varphi d\varphi = (\pi/2) r a_{11}$$

Consequently, the value of the first coefficient of the series is

$$a_{11} = (2/\pi)(P/r) \quad \ldots\ldots [2]$$

If the ring is assumed to be cut at $\varphi = 0$, the unknown moment N and the unknown forces T and V must be applied in the cut as shown in Fig. 3. However, V is zero because of the symmetry. The moments M_N and M_T caused by the other two unknowns may be written in the form

$$M_N + M_T = N + Tr(1 - \cos \varphi) \quad \ldots\ldots [3]$$

if moments are considered positive when they tend to increase the original curvature of the ring. The moment M_q caused by the distributed shear flow q_1 is given by the integral

$$M_q = \int_0^{\varphi} q_1 r^2 [1 - \cos(\varphi - \xi)] d\xi$$

$$= r^2 \int_0^{\varphi} \left[(1 - \cos\varphi \cos\xi - \sin\varphi \sin\xi) \sum_{n=1}^{\infty} a_{1n} \sin n\xi \right] d\xi$$

Integration gives

$$(M_q/r^2) = (2/\pi)(P/r)[1 - \cos\varphi - (1/2)\varphi \sin\varphi] + \sum_{n=2}^{\infty} (a_{1n}/n) - \cos\varphi \sum_{n=2}^{\infty} [a_{1n} n/(n^2 - 1)] + \sum_{n=2}^{\infty} [a_{1n}/n(n^2 - 1)] \cos n\varphi \quad \ldots\ldots [4]$$

The external force P causes the bending moment

$$M_P = Pr(\sin\alpha - \sin\varphi) \quad \ldots\ldots [5]$$

provided that

$$\alpha \leqq \varphi \leqq \pi \quad \ldots\ldots [5a]$$

In reality Equation [5] is valid up to $\varphi = (2\pi - \alpha)$, but because of the symmetry it is not necessary to consider it beyond $\varphi = \pi$.

The total bending moment is the sum of those given in Equations [3], [4], and [5]

$$(M/r^2) = A - B\cos\varphi - (P/\pi r)\varphi \sin\varphi + \sum_{n=2}^{\infty} [a_{1n}/n(n^2 - 1)] \cos n\varphi \quad \ldots\ldots [6]$$

if

$$0 \leqq \varphi \leqq \alpha \quad \ldots\ldots [6a]$$

and

$$(M/r^2) = A + (P/r)\sin\alpha - B\cos\varphi - (P/r)\sin\varphi - (P/\pi r)\varphi \sin\varphi + \sum_{n=2}^{\infty} [a_{1n}/n(n^2 - 1)] \cos n\varphi \quad \ldots\ldots [7]$$

if

$$\alpha \leqq \varphi \leqq \pi \quad \ldots\ldots [7a]$$

In these equations the symbols A and B stand for

$$\left.\begin{aligned} A &= (2/\pi)(P/r) + (T/r) + (N/r^2) + \sum_{n=2}^{\infty} (a_{1n}/n) \\ B &= (2/\pi)(P/r) + (T/r) + \sum_{n=2}^{\infty} [a_{1n} n/(n^2 - 1)] \end{aligned}\right\} \quad \ldots\ldots [8]$$

The strain energy U_r stored in one half of the ring is (if the strain energy due to shear and tension is neglected)

$$U_r = (r/2EI) \int_0^{\pi} M^2 d\varphi$$

According to Castigliano's theorem

$$\left.\begin{aligned}(\partial U_r/\partial N) &= 0 = \int_0^\pi M(\partial M/\partial N)d\varphi \\ (\partial U_r/\partial T) &= 0 = \int_0^\pi M(\partial M/\partial T)d\varphi\end{aligned}\right\} \quad \ldots\ldots [9]$$

From Equations [6], [7], and [8]

$$\left.\begin{aligned}(\partial M/\partial N) &= 1 \\ \text{and} \qquad (\partial M/\partial T) &= r(1 - \cos\varphi)\end{aligned}\right\} \quad \ldots\ldots [10]$$

Consequently, the conditions for a minimum of the strain energy originally given in Equations [9] may be expressed in the form

$$\left.\begin{aligned}&\int_0^\pi (M/r^2)d\varphi = 0 \\ \text{and} \qquad &\int_0^\pi (M/r^2)\cos\varphi\, d\varphi = 0\end{aligned}\right\} \quad \ldots\ldots [11]$$

After integration and manipulations the first of Equations [11] becomes

$$Tr + N = (Pr/\pi)[\cos\alpha - (\pi - \alpha)\sin\alpha] - r^2 \sum_{n=2}^{\infty} (a_{1n}/n) \quad \ldots\ldots [12]$$

Similarly, the second of Equations [11] becomes

$$Tr = -(Pr/2\pi)(3 + 2\sin^2\alpha) - r^2 \sum_{n=2}^{\infty} [a_{1n}n/(n^2 - 1)]. \quad \ldots\ldots [13]$$

Solving for N

$$N = (Pr/2\pi)[3 + 2\cos\alpha - 2(\pi - \alpha)\sin\alpha + 2\sin^2\alpha] + r^2 \sum_{n=2}^{\infty} [a_{1n}/n(n^2 - 1)] \quad \ldots\ldots [14]$$

If the right-hand members of Equations [13] and [14] are substituted into Equations [6] and [7], and use is made of Equations [8], the bending moment becomes

$$M = (Pr/\pi)\left\{[2 + \cos\alpha - (\pi - \alpha)\sin\alpha] - (1/2)\cos 2\alpha\cos\varphi - \varphi\sin\varphi\right\} + r^2 \sum_{n=2}^{\infty} [a_{1n}/n(n^2 - 1)]\cos n\varphi. \quad \ldots\ldots [15]$$

when

$$0 \leqq \varphi \leqq \alpha \quad \ldots\ldots [15a]$$

and

$$M = (Pr/\pi)\left\{[2 + \cos\alpha + \alpha\sin\alpha] - (1/2)\cos 2\alpha\cos\varphi - (\pi + \varphi)\sin\varphi\right\} + r^2 \sum_{n=2}^{\infty} [a_{1n}/n(n^2 - 1)]\cos n\varphi \quad \ldots [16]$$

when

$$\alpha \leqq \varphi \leqq \pi \quad \ldots\ldots [16a]$$

Bending Moments and Stresses in Other Structural Elements

As stated previously, the sheet covering is assumed to carry shearing stresses only. It follows from Equation [1], which gives the shear flow in the ith field, that the equilibrium condition of the forces in the y direction requires that

$$a_{11} = a_{21} = \ldots = a_{i1} = \ldots = a_{m1} = (2/\pi)(P/r) \quad \ldots\ldots [17]$$

While the loading of the first ring consisted of the concentrated forces P and the shear flow in the first field, upon the ith ring only the difference in the shear flow of the adjacent ith and $(i + 1)$st fields is acting, and no concentrated load is present. The distributed load can be written as

$$q_i - q_{(i-1)} = \sum_{n=2}^{\infty} (a_{in} - a_{(i-1)n})\sin n\varphi \quad \ldots\ldots [18]$$

Hence the bending moment in the ith ring is

$$M_i = r^2 \sum_{n=2}^{\infty} [(a_{in} - a_{(i-1)n})/n(n^2 - 1)]\cos n\varphi \quad \ldots [19]$$

The stress in the distributed stringers can be calculated from the equilibrium condition

$$t'(\partial\sigma/\partial x) + t(\partial\tau/r\partial\varphi) = 0$$

Consequently, the normal stress is

$$\sigma = -(1/rt')\int_0^x (\partial q/\partial\varphi)dx + f(\varphi)$$

With the rings assumed infinitely weak in bending out of their plane, and in the absence of external axial loads at the first ring

$$f(\varphi) = 0$$

In the stringers of the pth field the direct stress is

$$\sigma_p = -(1/rt')\left\{\sum_{i=0}^{p-1}\int_0^{L_i} (\partial q_i/\partial\varphi)dx_i + \int_0^{x_p} (\partial q_p/\partial\varphi)dx_p\right\} \quad \ldots\ldots [20]$$

if x_i and x_p denote the distances measured parallel to the axis of the cylinder from the ith and pth ring, respectively.

Condition for Minimum Strain Energy

The coefficients a_{in} of the Fourier series of Equation [1], with the exception of the first coefficient a_{i1} in each series, can be determined from Castigliano's theorem by equating to zero the derivatives with respect to the coefficients of the total strain energy stored in the structure. The value of the first coefficients is given in Equation [17].

The total strain energy stored in all the rings is denoted by $U_{r,\text{tot}}$. It may be given as

$$U_{r,\text{tot}} = \sum_{i=1}^{m} (1/EI_i)\int_0^\pi M_i^2 r d\varphi \quad \ldots\ldots [21]$$

Differentiating with respect to a_{1n}

$$(\partial U_{r,\text{tot}}/\partial a_{1n}) = (2r/EI_1)\int_0^\pi M_1(\partial M_1/\partial a_{1n})d\varphi + (2r/EI_2)\int_0^\pi M_2(\partial M_2/\partial a_{1n})d\varphi$$

where n is an integer greater than unity. As may be seen, only terms containing I_1 and I_2 figure in this equation. Terms containing I_i with $i \neq 1, 2$ are independent of a_{1n}. With

$$(\partial M_1/\partial a_{1n}) = [r^2/n(n^2 - 1)] \cos n\varphi$$

and

$$(\partial M_2/\partial a_{1n}) = -[r^2/n(n^2 - 1)] \cos n\varphi$$

where n is an integer greater than unity, integration gives

$$(\partial U_{r.\text{tot}}/\partial a_{1n}) = a_{1n}[\pi r^5/n^2(n^2 - 1)^2][(1/EI_1) + (1/EI_2)] - a_{2n}[\pi r^5/n^2(n^2 - 1)^2](1/EI_2) + P[2r^4/n(n^2 - 1)^2][\cos \alpha \cos n\alpha + (1/n) \sin \alpha \sin n\alpha + 2(-1)^n](1/EI_1) \quad [22]$$

Differentiating with respect to a_{in}

$$(\partial U_{r.\text{tot}}/\partial a_{in}) = (2r/EI_i) \int_0^\pi M_i(\partial M_i/\partial a_{in})d\varphi + (2r/EI_{i+1}) \int_0^\pi M_{i+1}(\partial M_{i+1}/\partial a_{in})d\varphi$$

since all the other terms in the summation of Equation [21] are independent of a_{in}. With

$$(\partial M_i/\partial a_{in}) = [r^2/n(n^2 - 1)] \cos n\varphi$$

and

$$(\partial M_{i+1}/\partial a_{in}) = -[r^2/n(n^2 - 1)] \cos n\varphi$$

where n and i are integers greater than unity, integration gives

$$(\partial U_{r.\text{tot}}/\partial a_{in}) = [\pi r^5/n^2(n^2 - 1)^2]\left\{(-a_{(i-1)n}/EI_i) + (a_{in}/EI_i) + (a_{in}/EI_{i+1}) - (a_{(i+1)n}/EI_{(i+1)})\right\} \quad [23]$$

The strain energy stored in the entire sheet covering is denoted by U_s. It may be given as

$$U_s = (r/tG) \sum_{i=1}^{m} L_i \int_0^\pi q_i^2 d\varphi \quad [24]$$

The differential coefficient of the strain energy stored in the sheet with respect to a typical Fourier coefficient is

$$(\partial U_s/\partial a_{in}) = (2r/tG)L_i \int_0^\pi \sin n\varphi \sum_{p=1}^{\infty} a_{ip} \sin p\varphi d\varphi = (\pi r L_i/tG)a_{in} \quad [25]$$

The total strain energy U_{str} stored in the stringers is

$$U_{str} = (t'r/E) \sum_{p=1}^{m} \int_0^\pi d\varphi \int_0^{L_p} \sigma_p^2 dx_p \quad [26]$$

With

$$L = \sum_{i=1}^{m} L_i \quad [27]$$

the differential coefficient of U_{str} with respect to a typical Fourier coefficient may be written in the form

$$(\partial U_{str}/\partial a_{in}) = (n^2\pi L_i/Ert')\left\{a_{1n}L_1\left[L - (1/2)L_i - \sum_{p=1}^{i-1} L_p\right] + a_{2n}L_2\left[L - (1/2)L_i - \sum_{p=1}^{i-1} L_p\right] + \ldots + a_{(i-1)n}L_{(i-1)n}\left[L - (1/2)L_i - \sum_{p=1}^{i-1} L_p\right] + a_{in}L_i\left[L - (2/3)L_i - \sum_{p=1}^{i-1} L_p\right] + a_{(i+1)n}L_{(i+1)}\left[L - (1/2)L_{(i+1)} - \sum_{p=1}^{i} L_p\right] + a_{(i+2)n}L_{(i+2)}\left[L - (1/2)L_{(i+2)} - \sum_{p=1}^{i+1} L_p\right] + \ldots + a_{mn}(1/2)L_m^2\right\} \quad [28]$$

provided $i < m$

Similarly

$$(\partial U_{str}/\partial a_{mn}) = (n^2\pi L_m/Ert')\left\{a_{1n}L_1(1/2)L_m + a_{2n}L_2(1/2)L_m + \ldots + a_{(m-1)n}L_{(m-1)}(1/2)L_m + a_{mn}(1/3)L_m^2\right\} \quad [28a]$$

The condition of a minimum of the total strain energy stored in the structure is

$$(\partial U_{\text{tot}}/\partial a_{in}) = (\partial U_{r.\text{tot}}/\partial a_{in}) + (\partial U_s/\partial a_{in}) + (\partial U_{str}/\partial a_{in}) = 0 \quad [29]$$

This condition holds for all integral values of n greater than unity, and for integral values of i from 1 to m, inclusive. Consequently, Equation [29] represents an m times infinite number of linear equations from which the Fourier coefficients can be determined.

Application to Cantilever Having Three Fields

The problem is now worked out in greater detail for the case when the monocoque cylinder has three fields ($m = 3$), and the length L_i of each field is the same, the moment of inertia I_i of each ring is the same, and the material of each structural element is the same. The 3 times infinite number of equations corresponding to Equation [29] can now be written in the following form

$$\left.\begin{aligned}(\partial U_{\text{tot}}/\partial a_{1n}) &= a_{1n}(14n^2 + 2A\gamma + B) + a_{2n}(9n^2 - A\gamma) + a_{3n}3n^2 + nA\gamma f(\alpha, n) = 0\\ (\partial U_{\text{tot}}/\partial a_{2n}) &= a_{1n}(9n^2 - A\gamma) + a_{2n}(8n^2 + 2A\gamma + B) + a_{3n}(3n^2 - A\gamma) = 0\\ (\partial U_{\text{tot}}/\partial a_{3n}) &= a_{1n}3n^2 + a_{2n}(3n^2 - A\gamma) + a_{3n}(2n^2 + A\gamma + B) = 0\end{aligned}\right\} \quad [30]$$

where n is an integer greater than unity.

The new nondimensional symbols introduced in these equations are defined as follows

$$\left.\begin{aligned} A &= 6r^6t'/I_xL'^3 \\ B &= 6(E/G)(t'r^2/tL'^2) \\ \gamma &= 1/[n^2(n^2-1)^2] \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [30a]$$

and L' is the uniform distance between adjacent rings.

The function $f(\alpha, n)$ of the concentrated load may be written as

$$f(\alpha, n) = (2P/\pi r)[\cos\alpha\cos n\alpha + (1/n)\sin\alpha\sin n\alpha + 2(-1)^n] \quad \ldots\ldots\ldots\ldots\ldots\ldots [30b]$$

It is evident from Equations [30] that all the Fourier coefficients a_{in} that have the same subscript n are interdependent, while all those with different subscripts n are independent of each other. For this reason, in the case of the cantilever having three fields, the coefficients can be calculated by solving groups of simultaneous equations, each of which consists of three equations and contains three unknowns.

Numerical calculations have been carried out for the case when the external load is a concentrated radial force of magnitude $2P$ applied at the lowest point of the ring. With $\alpha = \pi$, Equation [30b] becomes

$$f(\alpha, n) = (-1)^n(2P/\pi r) = (-1)^n a_{11} \quad \ldots\ldots\ldots\ldots [31]$$

For the nondimensional parameters A and B, the following values were chosen

$$\left.\begin{aligned} A &= 10^7 \\ B &= 500 \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots\ldots [32]$$

The values of the first 3 times 12 Fourier coefficients were calculated from Equations [30]. They are given in Table 1.

TABLE 1 FOURIER COEFFICIENTS

n	a_{1n}/a_{11}	a_{2n}/a_{11}	a_{3n}/a_{11}
1	1	1	1
2	−1.987	−1.979	−1.975
3	2.711	2.533	2.452
4	−2.433	−1.605	−1.288
5	1.631	0.395	0.099
6	−0.950	0.088	0.142
7	0.507	−0.162	−0.095
8	−0.265	0.124	0.048
9	0.141	−0.080	−0.024
10	−0.078	0.050	0.013
11	0.045	−0.031	−0.007
12	−0.027	0.020	0.004

Values of the shear flow obtained from the numerical calculations are plotted in Fig. 4. For the sake of comparison the half sine wave, corresponding to the Bernoulli-Navier assumptions, is also shown. The results of the present paper indicate a high concentration of the shear flow in the neighborhood of the point of application of the load. This shear-flow concentration has a beneficial effect upon the bending moments in the first ring, as may be seen from Fig. 5. Fig. 6 presents the bending moments in rings 2 and 3. The shape of these moment curves is similar to that shown in Fig. 5, but the values are very much smaller. According to conventional assumptions, these rings are not bent at all. The normal stress distribution in the fixed end section of the cantilever monocoque cylinder is shown in Fig. 7. The straight-line distribution, according to conventional calculations, is also given in order to demonstrate the great difference between the two curves.

Moment-Distribution Analysis for Three-Dimensional Pipe Structures

By R. C. DeHART,[1] WOOD RIVER, ILL.

This paper presents a moment-distribution procedure for determining the moments and shears produced in a three-dimensional pipe structure subjected to expansion resulting from temperature change. From the shears existing in the various members, end reactions can be easily determined. The method offers an advantage over virtual-work methods in that fewer calculations are required, consequently reducing the time involved and the danger of omitting some item in the solution.

THE Cross method of moment distribution will be utilized in the present analysis for three-dimensional pipe structures, with the exception that the effect of rotation of the members due to torsion must be included. The steps involved in the method are as follows:

1 Computation of the joint translations, allowing no joint rotation and neglecting deformation of the members resulting from direct stress and shear.

2 Computation of fixed end moments due to the joint translations determined in (1).

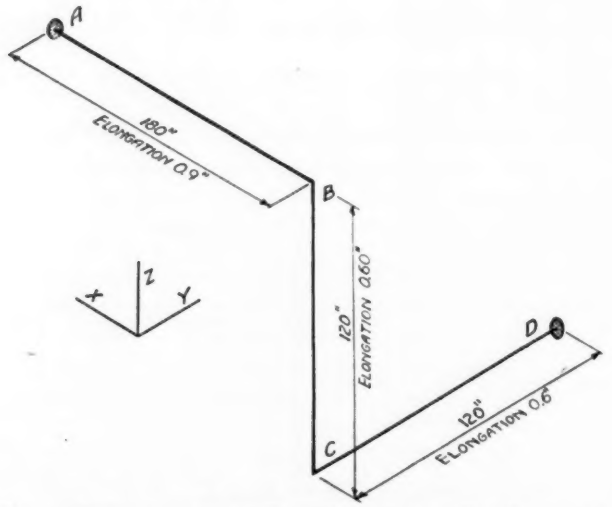

FIG. 1 CHARACTERISTICS OF THREE-DIMENSIONAL PIPE STRUCTURE TO BE ANALYZED

3 With joint translation prohibited, the fixed end moments of (2) are balanced, based upon flexural and torsional stiffness and carry-over factors.

4 Unbalanced shears are calculated, based upon the balanced moments of (3).

5 Elimination of the unbalanced shears of (4) by the process of applying a unit load in the direction of each unbalanced shear. The unbalanced shears due to these unit loads are used to write linear equations, the solution of which gives the forces required to remove the unbalanced shears found in (4).

6 Combination of the moments of (3) with the moments produced by the joint forces found in (5). From this combination the final joint moments and shears are obtained.

To illustrate the method, a three-dimensional structure of three members is chosen. In Fig. 1, dimensions and change in length of each member are given.

COMPUTATION OF JOINT TRANSLATIONS AND FIXED END MOMENTS

Allowing no rotation at the joints, the 0.6-in. elongation in the Z direction in member BC, Fig. 1, is distributed to members AB and CD in relation to their flexibilities. The relation between the deflection in AB and BC is determined as follows:

The shear in AB must equal the shear in CD in order that equilibrium conditions may be satisfied. These conditions are expressed by

$$S_{AB} = S_{CD} = \frac{2M_{AB}}{L_{AB}} = \frac{2M_{CD}}{L_{CD}} \quad \ldots\ldots [1]$$

where

M_{AB} is fixed end moment in AB caused by deflection Δ_{AB} in Z direction
M_{CD} is fixed end moment in CD caused by deflection Δ_{CD} in Z direction
L_{AB} and L_{CD} are lengths of members AB and CD

Substitute

$$M_{AB} = \frac{6EI_{AB}\Delta_{AB}}{L_{AB}^2} \qquad M_{CD} = \frac{6EI_{CD}\Delta_{CD}}{L_{CD}^2}$$

in Equation [1], and obtain

$$\frac{\Delta_{AB}}{\Delta_{CD}} = \frac{I_{CD}L_{AB}^3}{I_{AB}L_{CD}^3} \quad \ldots\ldots [2]$$

where

I_{AB} and I_{CD} are moments of inertia of members AB and CD
E is modulus of elasticity in tension and compression

The other deflections of the members are calculated using a relation developed in the same manner as Equation [2]. These deflections are given in Fig. 2(*a*). The fixed end moments due to these deflections are given in Fig. 2(*b*). A positive moment indicates that the joint is rotating the member clockwise, and a negative moment indicates that the joint is rotating the member counterclockwise. Fixed end moments are given in inch-pounds divided by 10^4.

Presented at the National Meeting of the Applied Mechanics Division, Chicago, Ill., June 16-17, 1944, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until January 10, 1945, for publication at a later date. Discussion received after the closing date will be returned.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

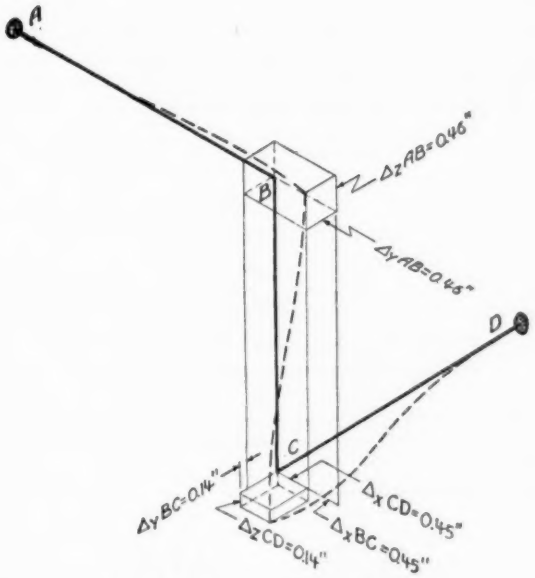

FIG. 2(a) DEFLECTION OF MEMBERS

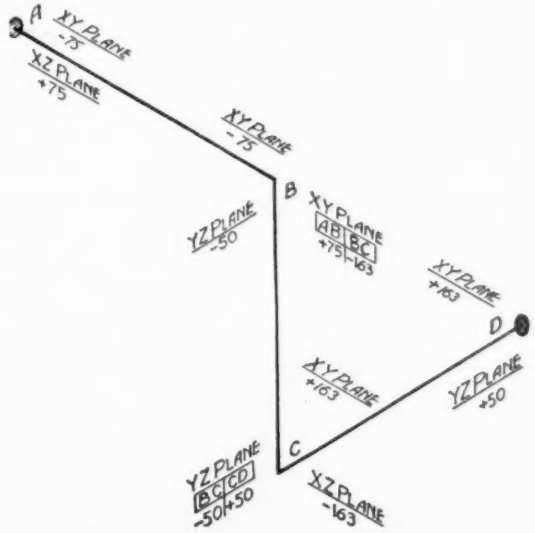

FIG. 2(b) FIXED END MOMENTS DUE TO DEFLECTIONS IN FIG. 2(a)

STIFFNESS AND CARRY-OVER FACTORS

Since moments exist in the X, Y-, Y, Z-, and X, Z-planes it is necessary to make a moment distribution in each plane. The carry-over factor for a member in torsion is minus 1 and for a member in flexure is plus $^1/_2$. At a joint such as B in the Y, Z-plane, one member rotates as a result of torsion, and the other as a result of flexure. The moment to be distributed to each member when the joint is allowed to rotate will depend upon the resistance of each member to rotation. This resistance to rotation is termed "stiffness."

The rotation due to an applied torque is

$$\theta = \frac{TL}{GJ} \quad \ldots\ldots [3]$$

and for unit θ

$$T = \frac{GJ}{L} \quad \ldots\ldots [4]$$

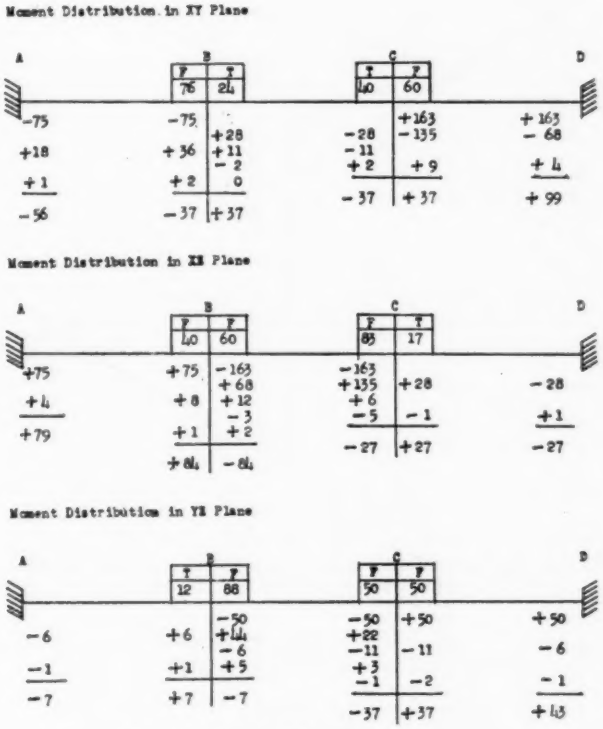

FIG. 3(a) INITIAL MOMENT DISTRIBUTION

(Moment-distribution factors are given below the letters T and F which indicate moment distribution for torsion and flexure.)

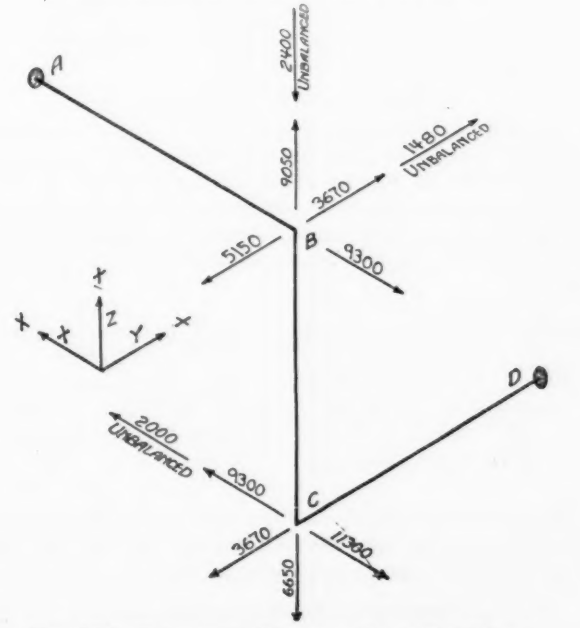

FIG. 3(b) UNBALANCED SHEARS AT B AND C IN POUNDS

where

T is applied torque
G is modulus of elasticity in shear
J is polar moment of inertia
L is length of member
θ is rotation in radians

The moment required to produce unit rotation at the simply

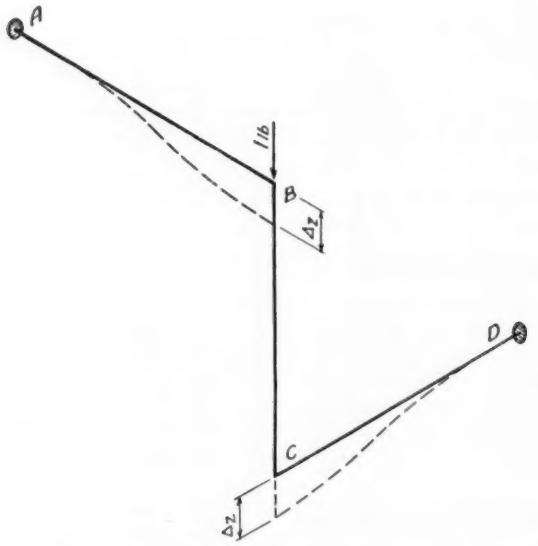

FIG. 4 PROPORTIONATE DISTRIBUTION IN MEMBERS AB AND CD OF 1 LB APPLIED AT B IN Z DIRECTION

supported end of a member fixed at one end and simply supported at the other is determined from the relation

$$M = \frac{4EI\theta}{L} \quad \ldots\ldots [5]$$

for unit θ

$$M = \frac{4EI}{L} \quad \ldots\ldots [6]$$

INITIAL MOMENT DISTRIBUTION

The moment-distribution factors for joints with one member rotating in torsion and the other in flexure will be based upon Equations [4] and [6]. Distribution factors at joints, involving both members in flexure, are determined in the usual manner using I/L values. Table 1 gives the moment required to produce unit θ in torsion, unit θ in flexure, and I/L values for each member.

TABLE 1 MOMENT TO PRODUCE UNIT θ IN TORSION AND IN FLEXURE, AND I/L VALUES FOR MEMBERS

Member	Moment producing unit θ in torsion, in-lb	Moment producing unit θ in flexure, in-lb	I/L
AB	40×10^6	$192 \times 10\theta$	2
BC	60×10^6	$288 \times 10\theta$	3
CD	60×10^6	$288 \times 10\theta$	3

The moment distribution for the fixed end moments of Fig. 2(b) is given in Fig. 3(a). Shears in the members calculated from these distributed moments are shown in Fig. 3(b).

ELIMINATION OF UNBALANCED SHEARS

At B and C, Fig. 3(a), there are unbalanced shears the values of which are shown in Fig. 3(b). These unbalanced shears must be removed before equilibrium in the structure is established. Their removal is accomplished by means of determining the unbalanced shears at the joints produced by a unit load acting in the direction of each unbalanced shear of Fig. 3(b). Linear equations based upon these unbalanced shears can then be written. The solution of these equations determines the forces necessary to remove the unbalanced shears of Fig. 3(b).

In Fig. 4, 1 lb applied at B in the Z direction is distributed to members AB and CD in proportion to their flexibilities,[2] or L^3/EI values; no joint rotation allowed. Member AB deflects the same as CD, the shear in AB plus the shear in CD is 1 lb, therefore the following equations are obtained

$$S_{AB} + S_{CD} = 1 \quad \ldots\ldots [7]$$

$$\frac{S_{AB}}{S_{CD}} = \frac{I_{AB}L_{CD}^3}{I_{CD}L_{AB}^3} \quad \ldots\ldots [8]$$

$$S_{CD} + \frac{L_{AB}^3}{L_{CD}^3} S_{CD} = 1 \quad \ldots\ldots [9]$$

S_{CD} = 0.77 lb shear in member CD
S_{AB} = 0.23 lb shear in member AB

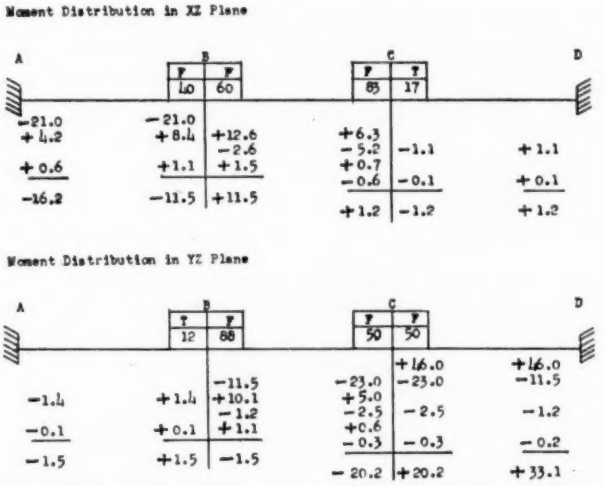

FIG. 5(a) MOMENT DISTRIBUTION IN X, Z- AND Y, Z-PLANES FOR 1 LB APPLIED AT B IN Z DIRECTION

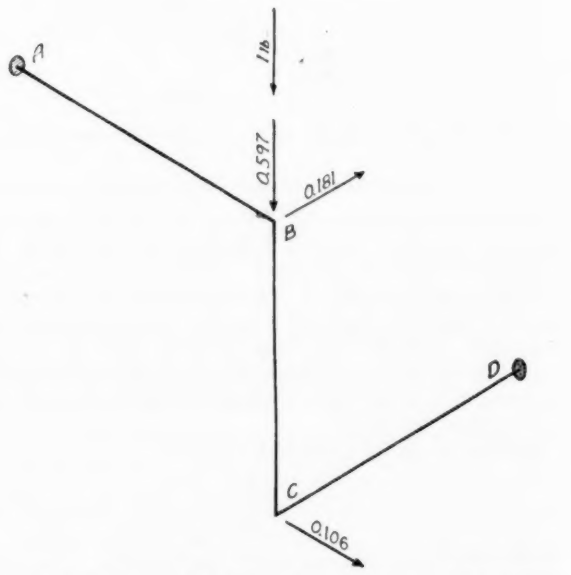

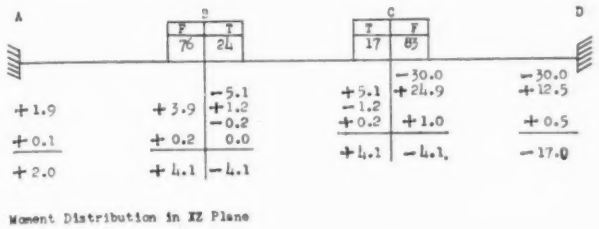

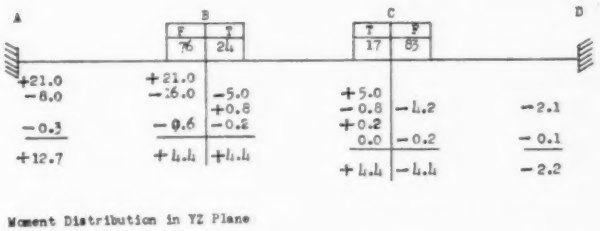

FIG. 5(b) UNBALANCED SHEARS AT B AND C DUE TO 1 LB APPLIED IN THE Z DIRECTION AT B

Moment Distribution in XZ Plane

Moment Distribution in YZ Plane

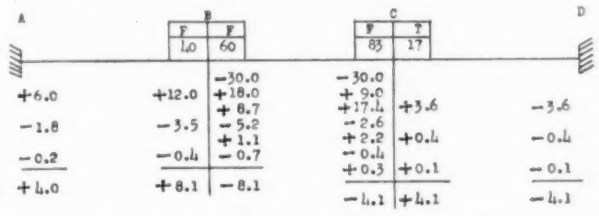

Fig. 6(*a*) Moment Distribution in *X*, *Y*- and *X*, *Z*-Planes for 1 Lb Applied at *C* in *X* Direction

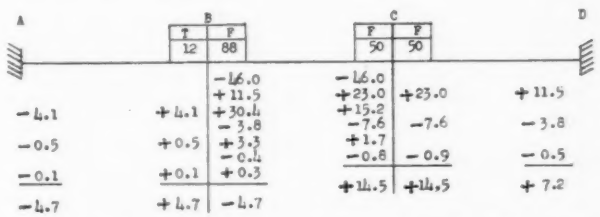

Fig. 7(*a*) Moment Distribution in *X*, *Y*- and *Y*, *Z*-Planes for 1 Lb Applied at *B* in *Y* Direction

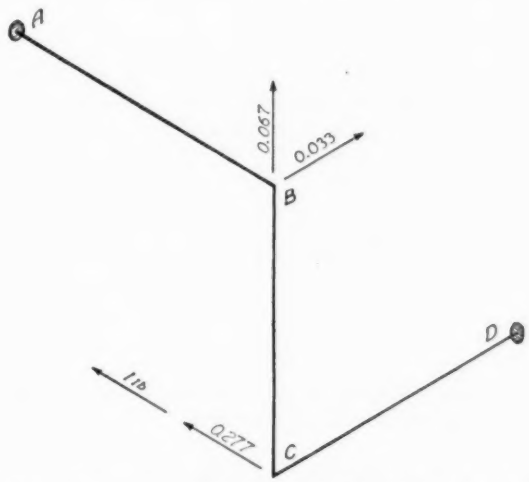

Fig. 6(*b*) Unbalanced Shears at *B* and *C* Due to 1 Lb Applied in *X* Direction at *C*

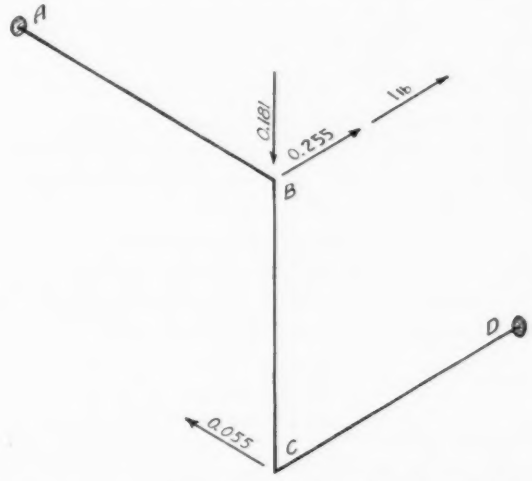

Fig. 7(*b*) Unbalanced Shears at *B* and *C* Due to 1 Lb Applied in the *Y*-Direction at *B*

The fixed end moments due to these shears are balanced in Fig. 5(*a*), and the shears produced by the distributed moments are calculated and shown in Fig. 5(*b*). It is seen in Fig. 5(*b*) that 1 lb in the *Z* direction at *B* produces unbalanced shears in the *Z* and *Y* directions at *B*, and in the *X* direction at *C*.

The same procedure is carried out for 1 lb in the *Y* direction at *B*, Figs. (6*a*) and 6(*b*); and 1 lb in the *X* direction at *C*, Figs. 7(*a*) and 7(*b*).

The unbalanced shears of Fig. 3(*b*) can now be removed by writing the following equations:

$(yB)(yB)F_{yB} + (yB)(zB)F_{zB} + (yB)(xC)F_{xC}$ = unbalanced shear in *Y* direction at *B*.....[10]

$(zB)(yB)F_{yB} + (zB)(zB)F_{zB} + (zB)(xC)F_{xC}$ = unbalanced shear in *Z* direction at *B*.....[11]

$(xC)(yB)F_{yB} + (xC)(zB)F_{zB} + (xC)(xC)F_{xC}$ = unbalanced shear in *X* direction at *C*.....[12]

$(yB)(yB)$ is the force in the *Y* direction at *B* due to 1 lb in the *Y* direction at *B*.

$(yB)(zB)$ is the force in the *Y* direction at *B* due to 1 lb in the *Z* direction at *B*.

$(yB)(xC)$ is the force in the *Y* direction at *B* due to 1 lb in the *X* direction at *C*; (and so on).

F_{yB} is the force in the *Y* direction at *B* required to remove the unbalanced shears of Fig. 3(*b*).

F_{zB} is the force in the *Z* direction at *B* required to remove the unbalanced shears of Fig. 3(*b*).

F_{xC} is the force in the *X* direction at *C* required to remove the unbalanced shears of Fig. 3(*b*).

Using quantities determined in Figs. 3(*b*), 5(*b*), 6(*b*), and 7(*b*); Equations [13], [14], and [15] are obtained.

$+0.255F_{yB} + 0.181F_{zB} + 0.033F_{xC} = +1480$.....[13]

$-0.181F_{yB} - 0.597F_{zB} + 0.067F_{xC} = -2400$.....[14]

$+0.055F_{yB} - 0.106F_{zB} + 0.277F_{xC} = +2000$.....[15]

from which

$F_{xC} = +8650$ lb
$F_{zB} = +4500$ lb
$F_{yB} = +1450$ lb

The force F_{yB} multiplied by the moments produced by 1 lb in the *Y* direction at *B*, Fig. 7(*a*), the force F_{zB} multiplied by the

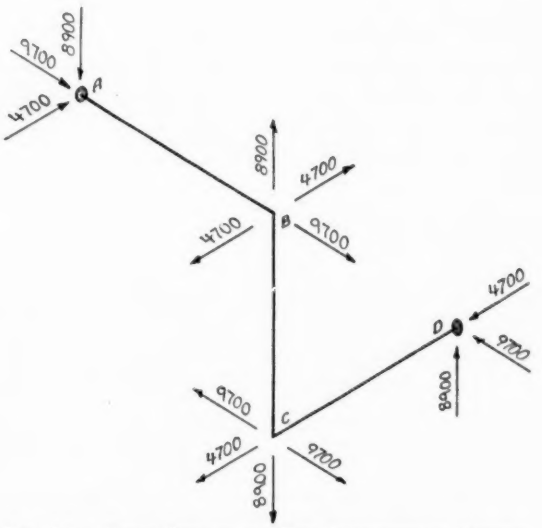

FIG. 8(b) FINAL SHEARS AND END REACTIONS IN POUNDS

While the solution given is for square corners, the method can be applied to pipe structures with bends at the corners. This necessitates modifying the stiffnesses and flexibilities of the members and also the carry-over factors. However, for the three-dimensional structure with bends at the corners having a radius of $1^1/_2$ pipe diameters or less, the assumption that the structure has square corners seems to be as accurate as is essential, in view of the fact that the end conditions of the structure can seldom be exactly dete.mined.

Discussion

The Strength of Cylindrical Dies[1]

BENJAMIN MILLER.[2] The behavior of metal under combined stresses is of great practical as well as theoretical importance, particularly in the case which the authors have investigated, i.e., the thick-walled tube under internal pressure. There are two solutions to be obtained, i.e., the equation for the pressure which will cause the inner skin to yield, and that relating the pressure to the spreading of the plastic region through the tube. The energy-of-distortion theory may be used to develop both equations. The equation for first yielding has been published by the writer;[3] in the authors' notation it is

$$p = K \frac{1 - (a/b)^2}{\sqrt{3 + (a/b)^4}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1a]$$

Presumably Equation [1*a*] could be obtained from Equation [37] of the paper by substituting a for r.

It has not yet been possible to verify Equation [1*a*] experimentally because it is so difficult to detect the first yield. Consider the hot-rolled steel cylinder tested by the authors with the results shown in Fig. 10 of the paper. According to Equation [1*a*], the pressure for first yield is 19,370 psi, and the corresponding load is 1490 lb. But the pressure of 25,000 psi and the corresponding load of 1900 lb predicted by the maximum-strain theory are as well supported by Fig. 10.

The equation for yield of the entire tube published previously[3] becomes in the authors' notation

$$\left(\frac{a}{b}\right)^2 = \frac{\sqrt{3}\, e^{\sqrt{3}\,(A_a - \pi/6)}}{2 \cos A_a} \quad \ldots\ldots\ldots\ldots [2a]$$

in which

$$p = (2K/\sqrt{3}) \sin (\pi/6 - A_a) \quad \ldots\ldots\ldots\ldots [3a]$$

Comparison indicated an error in Equation [39] of the paper; the expression under the radical within the brackets should be $(1 - 3p^2/4K^2)$. There may be a similar error in Equation [37].

The pressure for full yield in the test of Fig. 10 is calculated by Equations [2*a*] and [3*a*] to be 39,000 psi, and the corresponding load is 3000 lb. The calculated and experimental loads thus agree closely. Nevertheless, the equations are not entirely satisfactory.

The paper points out that "a cylinder under internal pressure is a case of biaxial stress, consisting of tension in the circumferential direction and compression in the radial direction." As the internal pressure increased from zero in the test of Fig. 10, the circumferential tension at the inner skin increased until it became 28,000 psi. Then, according to Equation [1*a*] of this discussion, yielding took place. Thereafter, as the pressure increased from 19,370 psi to 39,000 psi, the circumferential tension at the inner skin *decreased* to 4150 psi. The ratio of outside to inside diameter in this test was 2.35.

If the ratio of outside to inside diameter had been slightly greater, the circumferential tension at the inner skin for total yield would have been less; if the ratio had been 2.48, the circumferential tension at the inner skin for total yield would have been zero. If the ratio of outside to inside diameter had been slightly greater than 2.48, the circumferential stress at the inner skin for total yield would have been a compression rather than a tension. This result is one reason for considering that the equation is not entirely satisfactory; it is not easy to accept the idea that a radial pressure can develop a circumferential compression.

If the ratio of outside diameter to inside diameter had been 2.96, the internal pressure would have been 15.5 per cent greater than the yield strength, and no higher pressure can be attained, according to the theory. If the ratio of outside diameter to inside diameter had been greater than 2.96, total yielding in accordance with the equation would not have been possible. This conclusion was reached by Nadai.[4]

Equation [2*a*] can therefore be used only for cylinders having ratios of outside to inside diameters between 1 and 2.96. If b/a is greater than 2.96, the plastic region cannot extend throughout the tube, that is, r/a will have a maximum value less than b/a. The maximum value of r/a will obtain when the pressure has its maximum theoretical value of 15.5 per cent greater than the yield strength; it is given by

$$\left(\frac{r}{a}\right)^2_{\max} = \frac{e^{\sqrt{3}\, A_r}}{0.3259 \cos A_r} \quad \ldots\ldots\ldots\ldots [4a]$$

in which

$$\left(\frac{r}{b}\right)^2 = \sqrt{3} \tan A_r \quad \ldots\ldots\ldots\ldots [5a]$$

As b/a increases, $(r/a)_{\max}$ decreases, approaching 1.75 as a limit.

The writer cannot accept the conclusion that the outer layers of a cylinder cannot be caused to yield by internal pressure if the ratio of the outside to the inside diameter exceeds 2.96, and prefers to consider that the theory is incomplete. However, it is hoped that the authors will investigate this point by testing cylinders of hot-rolled steel having b/a values greater than 2.96. The heat-treated die-steel cylinders tested did have b/a values greater than 3 (except in test No. 20), but since they broke before the outer skin yielded it is suggested that similar experiments be run using hot-rolled-steel cylinders.

The authors have correctly pointed out that the theory cannot be expected to apply exactly to a metal which is subject to strain hardening, and have described a method of extrapolation to correct for slight strain hardening. There is also implicit in the theory the assumption that the yield strength in tension and the yield strength in compression have the same absolute value. It appears from the paper that the heat-treated steel, hardened to 60 Rockwell, withstood a compressive stress of 600,000 psi, but failed by fracture under very much lower tensile stress. It is therefore not quite clear that the theory may be properly applied to the heat-treated steel, or that a K value calculated from a load-expansion curve in the manner described is a yield strength in tension.

The use of rubber as the fluid to transmit the pressure to the

cylinder under test seems to offer great advantage. In experiments carried out under the writer's direction with water it was found that plotting the pressure against the corresponding volume of water pumped into the cylinder gave a better stress-strain diagram than could be obtained by using the expansion of the tube as a strain measure. With the authors' method, it may be that there will be an advantage in plotting the position of the testing machine head against the load.

R. L. Templin.[5] The authors have pointed out certain differences observed in the calibration of the extensometer used in their experimental work. A dial gage graduated to 0.0001 in. and apparently sensitive to ±0.00001 in. was part of the extensometer. While such gages are generally sensitive within the limits indicated, yet experience in actual calibration of such gages, using precision gage blocks having dimensional errors less than 0.000005 in. per in., shows much greater errors than might be suspected from the readily observed sensitivity.

Errors of 1 to 1½ full divisions (0.0001 to 0.00015 in.) are often found in gages of this type and occasionally larger errors. Unfortunately, there are no government or A.S.T.M. specifications covering the accuracy and sensitivity of dial gages. The British Standards Institution[6] issued such specifications in 1939, and these indicated permissible errors for dial gages 1¾ in. to 2 in. diam, having 100 divisions of 0.0001 in., and a magnification factor of 550 to 630, as follows:

Interval of reading	Permissible error over interval stated, in.
Any 0.001 in.	0.00005
Any half revolution	0.00007
Any one revolution	0.00010
Any two revolutions	0.00020
Any ten revolutions	0.00030
Any twenty revolutions	0.00040

Any such gage is required to repeat its readings to within one fifth of one unit division.

The accuracy of the apparatus used by the authors would appear to be quite satisfactory for determination of yield values, but any modulus-of-elasticity values, based upon the gage readings, would presumably contain errors corresponding to those in the gage in addition to those of lever ratio, observation, and manipulation.

Authors' Closure

The authors appreciate Mr. Miller's careful study and helpful comments and suggestions. The work on dies is being pursued further at the present time, and, consequently, such a discussion as that by Mr. Miller is very valuable to us.

If $r = a$ is inserted in Equation [37] of the paper, an implicit expression for P/K is obtained that is equivalent to Equation [1a] of Mr. Miller's discussion, as he presumes. However, Equation [1a] may be obtained much more directly and simply by substituting the stresses from Equations [5] and [6] for $x = a$ in Equation [12].

His Equation [2a] corresponds to Equation [37] of the paper, for the condition of $r = b$ (Equation [39]), except for the sign in the quantity $1 + \frac{3p^2}{4K^2}$ in both equations. This sign should have been negative, as pointed out by Mr. Miller. The error is not carried over into the numerical work, such as curve B of Fig. 4 of the paper, since it occurred only in copying the original equations for publication.

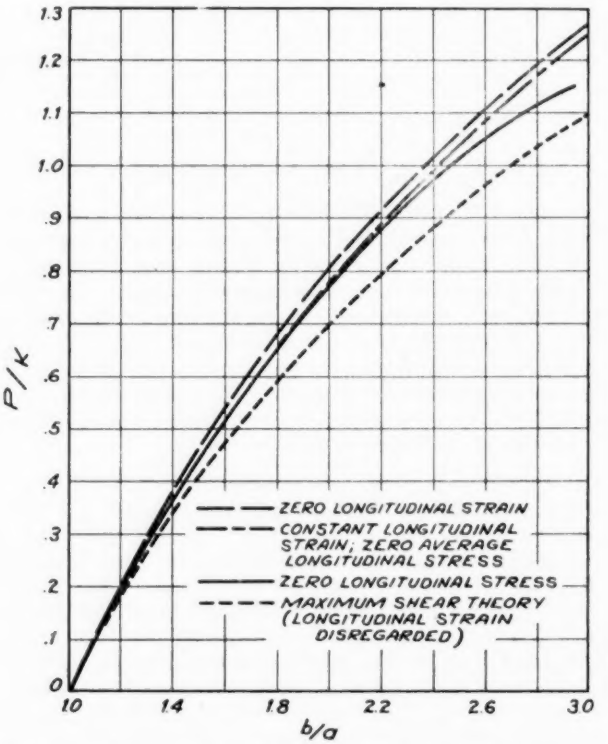

Fig. 1 (*a*) Effect of Wall Thickness on Pressure Necessary for Complete Plastic Flow, for Various Assumptions

The presence of a maximum possible pressure, equal to 1.155 times the flow stress, is a result of the assumption that the longitudinal stress (S_2) is zero. This condition actually occurs in a very short cylinder, or flat ring, under internal pressure. It is to be expected that in such a ring, having a large ratio of outside to inside diameter, a high internal pressure will cause yielding of the material near the hole in the longitudinal direction without causing yielding of the metal farthest from the hole. The existence of this limiting pressure can be shown more clearly in a qualitative way, at least, by the use of the maximum-shear theory. Longitudinal plastic flow at the surface of the hole occurs when $P = K$, since in this case the difference of the radial and longitudinal stresses equals the flow stress. However, complete plastic flow, extending to the outside surface of the cylinder, may not have occurred if b/a is greater than 2.72 (see Equation [24] of the paper). Thus, according to the maximum-shear theory for flat rings, no greater pressure than K can be developed, even though complete plastic flow throughout the tube has not occurred. The presence of a maximum pressure without total yielding in short thick cylinders has been observed also in recent experiments.

In a very long cylinder, on the contrary, longitudinal plastic flow is restricted by the necessary condition that the longitudinal strain is constant. Again, using the maximum-shear theory to develop a qualitative conception regarding the behavior of the cylinder, the longitudinal stress becomes unimportant in so far as the plastic flow is concerned, according to the foregoing assumptions. Then, by Equation [24] it can be seen that there is no limit to the pressure that might be developed in producing complete plastic flow. Likewise, by the energy-of-distortion theory, there is no limiting value of internal pressure for total plasticity assuming no longitudinal strain.[7]

[7] Reference 4, Equation [20], p. 188.

Since the publication of the original paper, the theory has been redeveloped using the energy-of-distortion theory and assuming constant longitudinal strain and zero average longitudinal stress. These assumptions correspond more nearly to the experimental conditions than the previous assumption of zero longitudinal stress, which was thought at the time to be the simplest possible. Actually the more correct assumptions have proved to be no more complicating, as can be seen by the expression for the pressure for total plasticity, which is

$$\frac{P}{K} = \frac{1}{\sqrt{\frac{1}{\frac{4}{3}\left(\ln\frac{b}{a}\right)^2} + \frac{1}{\left[\left(\frac{b}{a}\right)^2 - 1\right]^2}}} \quad \ldots\ldots\ldots [6a]$$

for the assumptions of constant longitudinal strain and zero average longitudinal stress, as contrasted with

$$\frac{\sqrt{3}}{2}\arcsin\frac{p\sqrt{3}}{2K} + \frac{1}{2}\ln\left[\sqrt{1-\frac{3p^2}{4K^2}} + \frac{p}{2K}\right] - \ln\frac{b}{a} = 0 \ldots [7a]$$

for the previous assumption of zero longitudinal stress.

The results of the more recent analysis have been compared in Fig. 1(*a*) of this closure, with results based on various other assumptions, and bring out the following facts: Assuming the most correct analysis to be that which assumes plane strain in a cylinder with unrestrained ends, the previous analysis gives nearly correct values for b/a values up to those investigated experimentally (2.4). For thicker cylinders the previous analysis deviates rapidly from the more correct analysis and becomes completely inapplicable for b/a values greater than 2.96. The energy-of-distortion theory, assuming zero longitudinal strain, is a good approximation, while the maximum-shear theory, although more simple, is less exact. In view of the foregoing discussion, it seems unnecessary to make any experiments on very thick cylinders.

The experimental fact that the fracture stress in tension is considerably less than the yield strength in compression, as referred to by Mr. Miller, in no way interferes with the conception that the yield strengths in tension and compression are nearly equal. This is generally accepted for the softer metals; and there is no reason why this relation should change with increasing hardness, even though the fracture stress in tension passes through a maximum and becomes smaller again. It is well known that a brittle steel can be made to flow plastically if a sufficiently high hydrostatic pressure is superimposed upon the tension.[8] In these cases, the yield strength is certainly considerably higher than the fracture stress in tension. Furthermore, under conditions of biaxial stress, the flow stress can no longer be identified with the yield strength in tension or compression.

We appreciate Mr. Miller's suggestion of using as a strain measure the change in the volume of fluid necessary to compensate for changes in the size of the hole. Successful tests have been made recently using this same principle, but with lead as the fluid rather than rubber. The compressibility and leakage characteristics of rubber are such as to make it unsuitable for such an experimental technique. The use of the change in fluid volume as a measure of strain is particularly valuable for those cases where longitudinal flow occurs at the surface of the hole without great progress of plastic flow in the radial direction.

Regarding Mr. Templin's remarks on the accuracy of dial gages, it should be noted that for a total measured strain of $^1/_2$ or 1 revolution, the accuracy of the gage is 1.0 to 1.5 per cent, according to the standards reproduced. On the contrary, the errors in the modulus-of-elasticity values, obtained by the use of the gage, are as high as 25 per cent. Consequently, the errors inherent in the dial gage are not sufficient to account for the observed discrepancies.

On Cutting and Hobbing Gears and Worms[1]

ALLAN H. CANDEE.[2] The writer has had experience with detailed calculations of the shapes of worm threads, gear-generating hobs, and thread-milling cutters for a good many years and is acquainted with a number of papers, articles, books, and patents dealing with the problems treated in the paper. Some of these are worthy of notice.

The earliest references to the shapes in involute worms and hobs of which the writer knows are by Trbojevich (1),[3] who demonstrated clearly that a hob to generate involute spur and helical gears must represent a worm of involute form. His articles present geometrical and analytical descriptions, as well as diagrams of involute helicoidal surfaces and their principal sections.

Buckingham (2) has employed the envelope method in analyzing the shapes of screw threads produced by thread-milling hobs, which at the present time are called multiple-thread-milling cutters. His tabulation of calculated co-ordinates, and diagrams showing paths of individual cutting points, together with the resultant envelope profile, are similar in kind to those in the paper. The envelope method, however, except for the more general information which it may yield, is too laborious for regular use, because it requires calculating several curves instead of only one.

Buckingham (3) also furnished specific equations for calculating co-ordinates of points in the axial profile of a worm thread produced by the usual straight-sided conical milling cutter. The effect of different diameters of cutter or grinding wheel was clearly illustrated.

A book by Cormac (4) gives an extensive mathematical treatment of worms and cutters. Most of the usual cases are covered, although only a few practical examples are included.

Wildhaber (5) has presented an original method of dealing with the contact between cutter and thread surfaces. He gives a table of formulas for radii of curvature of the cutter profile and of the surfaces of helical gear teeth and worm threads in the principal directions for the most usual cases.

There have been other articles in English, and of course there are many in German. Those mentioned have been most interesting to the writer. They indicate that the problem of profile shape in worms, hobs, and cutters has long been recognized and that answers have been known to some individuals at least.

The writer (6) has dealt with the correction of pressure angle and the determination of correct shape of the surfaces of relieved teeth in involute hobs.

The methods of solution adopted in the paper are based on

the kind of mathematics taught to engineers and on the advanced higher mathematics which is essential to progress in many fields. Analytic geometry, differentiation, vectors, transformations to successive sets of co-ordinate axes are all resorted to. Yet the problems dealt with are purely geometrical, and according to the writer's experience they can be solved most directly and simply by old-fashioned solid geometry, which seems to be an almost forgotten science.

The authors have applied concepts involving time, velocity, and even relativity with an observer placed first on one and then on the other of two moving bodies. Of course correct results can be obtained in this way; but it is simpler to consider merely the conditions of tangent contact, first between a helicoidal surface and a surface of revolution, and second between two helicoids. A surface of revolution and a helicoid can touch each other along a curve of contact, which can be established on the given surface and then determines the other surface. Two rotating helicoids can touch only at a single point, which during rotation lies at different positions on a curve determined from the given surface and serving to describe the other surface. Exact dimensions can be calculated by triangulation and by determining the intersection points of curves and lines.

The paper presents so-called deviation curves based upon a reference line which in some cases intersects the calculated profile. It is preferable and more usual in the treatment of curves in this way to refer the co-ordinates to the tangent and normal at the selected mean point. The amount of curvature is then most directly apparent, and in shop practice gaging is more readily accomplished.

The authors have based their determination of cutter pressure angle on a formula which gave noticeably inaccurate results. Thus under 6 "Example" the pressure angle specified was 25 deg; but in Fig. 9, a very considerable error is apparent. In order to determine as accurately as possible the pressure angle of the axial profile calculated in the paper, the writer took the following dimensions from a tabulation in Part I of the paper:[4]

r	z
1.64999	0.27101
1.75681	0.32301
1.86593	0.37750

By using a parabola passing through these three points and with its axis in the z direction, the pressure angle at the worm-pitch radius where $r = 1.750$ in. is estimated to be 26 deg 13 min to the nearest minute. This is 73 min more than the specified pressure angle of 25 deg. A difference of any such amount between a worm and its gear, for instance, would be far outside any manufacturing tolerance.

It is common in machine-shop practice to require an accuracy of pressure angle within 1 to 3 min; and it is therefore necessary to know how to specify correctly the pressure angle of a thread-milling cutter of either small or large diameter to produce a desired pressure angle in a worm.

The authors state[5] in Part I of their paper that the pressure angle of their cutter was determined in the following manner:

$$\tan \phi_n = \cos \lambda \tan \phi_x$$

$$\phi_c = \phi_n + \frac{90 \text{ deg} \sin^3 \lambda}{n}$$

It is seen that the final term is intended to represent the difference between the cutter pressure angle and the normal pressure angle of the worm thread; but no consideration is given to size of the cutter. The writer has derived and used the following approximate formula which includes the effect of the cutter and worm radii

$$\Delta\phi = \frac{90}{n} \cdot \frac{r}{R \cos^2 \lambda + r} \cdot \sin^3 \lambda \text{ deg}$$

$$= \frac{5400}{n} \cdot \frac{r}{R \cos^2 \lambda + r} \cdot \sin^3 \lambda \text{ min}$$

where $\Delta\phi$ is the difference between the normal pressure angle and the cutter pressure angle, n is the number of threads, r is the worm pitch radius, R is the cutter pitch radius, and λ is the lead angle. It is assumed that the cutter thickness is one half the normal circular pitch and that the cutter is set to the worm lead angle. The derivation of the formula is too long to be included here.

For the example already discussed, the foregoing approximate formula gives $\Delta\phi = 65.2$ min. A longer but mathematically exact method gives $\Delta\phi = 65.07$ min. Thus even with the lead angle as large as 30 deg, the writer's formula is almost exact and so is much more satisfactory than the one used by the authors.

Calculations of the kind indicated in the paper are not likely to be adopted even occasionally unless they are arranged so as to be as direct and brief as possible. The writer believes that considerable improvement in that direction can be made.

When the departure of the cutter or thread profile from a straight line is only slight, the calculation of point co-ordinates can be dispensed with and instead the amount of curvature estimated. In worm-thread grinding it is not even necessary to make this estimate, when means are provided to vary the curvature of the grinding-wheel profile until the thread profile conforms to a straight or slightly curved gage shape.

The paper is to be particularly commended for calling attention to the importance of a more widespread knowledge about shapes in worms, hobs, and cutters. Too many designers, mechanics, and even engineers responsible for gearing still suppose that worms, hobs, and cutters should all be straight-sided. This is not so, but correct shapes can be exactly determined; and proper specifications must be furnished by the gear calculator and tool designer, and used in the shop, if present-day requirements for the tooth contact in gears and worms are to be met.

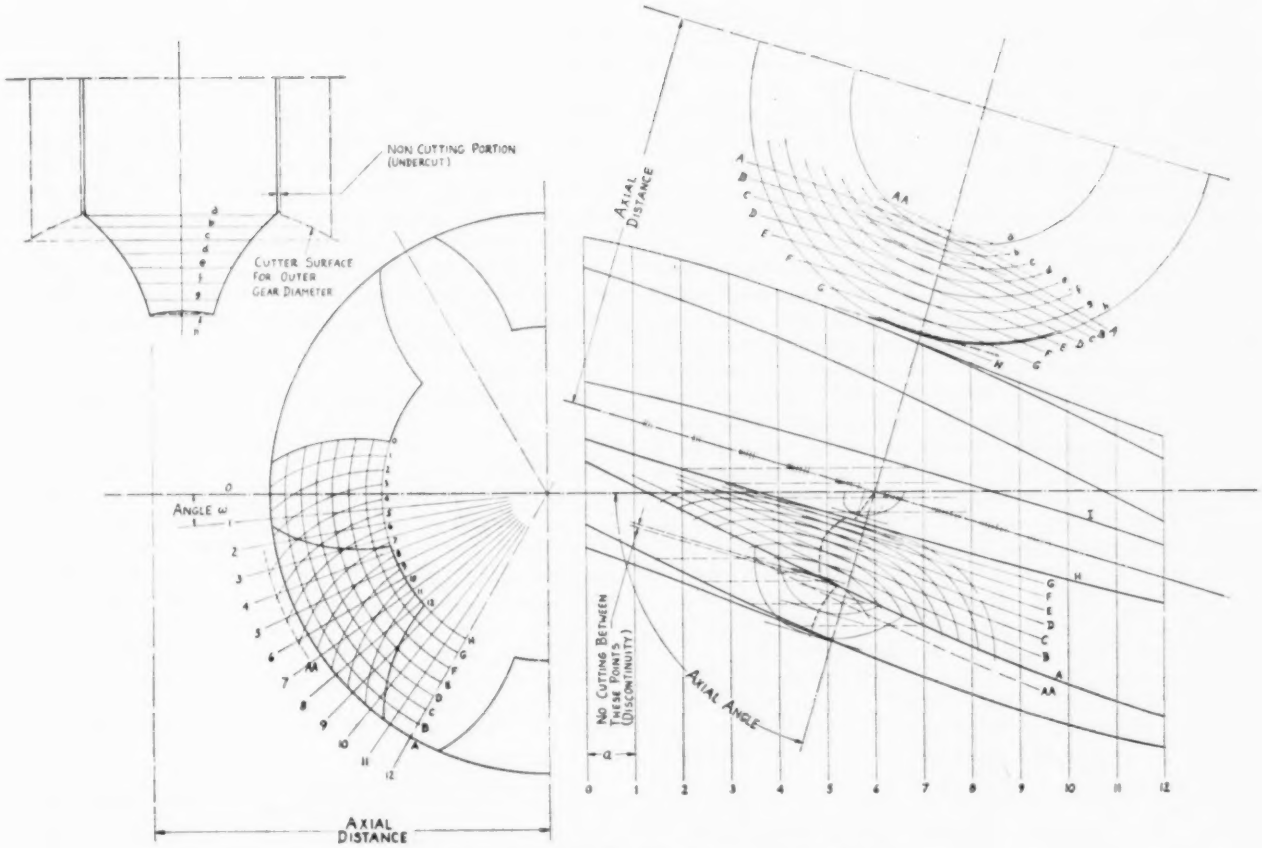

FIG. 1 LAYOUT OF "ALL-MILLING" CUTTER FOR A WORM

(Lines of deepest cutting are shown dashed. Cutter profile in upper-left corner.)

mined accurately without any guesswork, thus saving a tremendous amount of money, time, and materials.

This discussion will treat the problem: Given the worm, to find the cutter.

A few fundamental facts are worth noting in connection with the correct location, i.e., axial distance $R_p + r_p$ and axial angle λ, of milling cutters for new ideas of worms which have not been milled before. For a given worm, there is within certain limits an infinite number of possible cutter diameters. As for the case of straight grooves, the lower limit of the cutter diameter is given by the depth of the groove to be cut and by the diameter of the arbor and spacers holding the cutter.

However, while there is no theoretical upper limit of cutter diameters for straight grooves, the cutter for worms is limited by the requirement of free cutting. The cutter surface must fall away from the worm at a sufficient rate in order to prevent interference with the worm teeth. For smaller cutter diameters, this rate of falling away is greater than for larger diameters. The angle λ (Fig. 3 of paper) too, must be selected very carefully, particularly if the transverse worm section has some sharp corners at the bottom of the groove. In that case the "axial angle" λ must be identical with the lead angle at the bottom of the groove, because, as the authors state correctly, the helix cut must be tangent to the cutter surface. Where both cutter and worm come to a sharp corner, the requirement of tangential surfaces can be met only if the axial angle λ is equal to the lead angle at the bottom of the groove. If it were smaller or larger, the cutter could not reach deep enough. This, too, is a problem of interference. Accordingly if in Fig. 3 of the paper the axial angle λ were actually

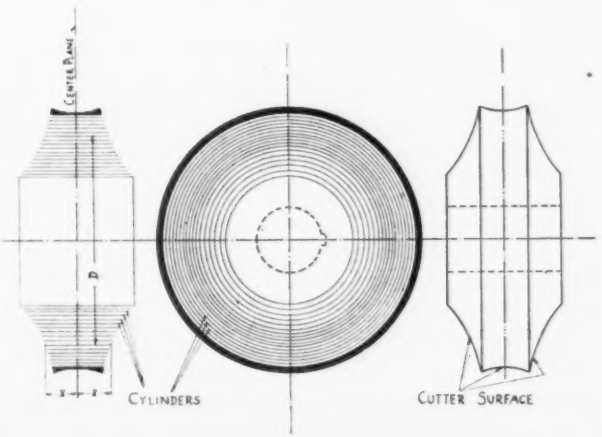

FIG. 2 FICTITIOUS MILLING CUTTER BUILT UP OF CONCENTRIC THIN CYLINDERS

the lead angle of the pitch helix, the profile as shown could not be cut, but fillets would result at the bottom of the groove.

It is possible to mill the entire worm rather than to turn the outer cylindrical surface on a lathe, thus eliminating one operation in mass production. The layout of a cutter for such an "all-milling" operation is shown in Fig. 1 of this discussion. This cutter was designed by a graphical method. The cutter can be thought of as consisting of a great number of concentric thin cylinders, Fig. 2 of this discussion. The intersection lines of

these cylinders with the worm surface will then determine the correct length of each cylinder at the point of tangency with a plane parallel to the center plane of the cutter. This point is then a point of deepest cutting, and the line of deepest cutting or "contact line" passes through it. The contact lines are shown as dashed curves in Fig. 1. It can be seen that the contact lines are discontinuous at the sharp corners of the worm section. This condition is analogous to the discontinuity of the slope of a curve with a sharp corner. In the discontinuous region, the helix H runs in the direction of the cutter motion, and the cutter comes to a sharp edge. In contrast to helix H, helix A does not run in the direction of the cutter motion between the discontinued contact lines. The result is a noncutting part of the cutter between the point cutting helix A on the tooth flank portion of the cutter, and the point cutting helix A on the tooth-top portion of the cutter. These two points will be on different diameters of the cutter, and to assure noninterference and free chip motion, the cutter should be undercut between these two points. The cutter profile is shown in the upper left, with the undercut and the tooth top portions drawn in dash-dot lines.

An alternative method of finding points of the contact line directly has been described graphically by O. Baier,[7] and analytically by K. Okusima.[8] This method is based on the fact that the cutter surface and the finished worm surface are tangential surfaces, contacting each other along the contact line. Consequently, the cutter and worm surfaces have common normals through all points of the contact line. Since the cutter surface is a surface of rotation with respect to the cutter axis a_c, all cutter normals intersect the cutter axis, and the problem becomes one of ascertaining a number of those normals of the worm surface which intersect the cutter axis. The foot points of these common normals are then points of the contact line.

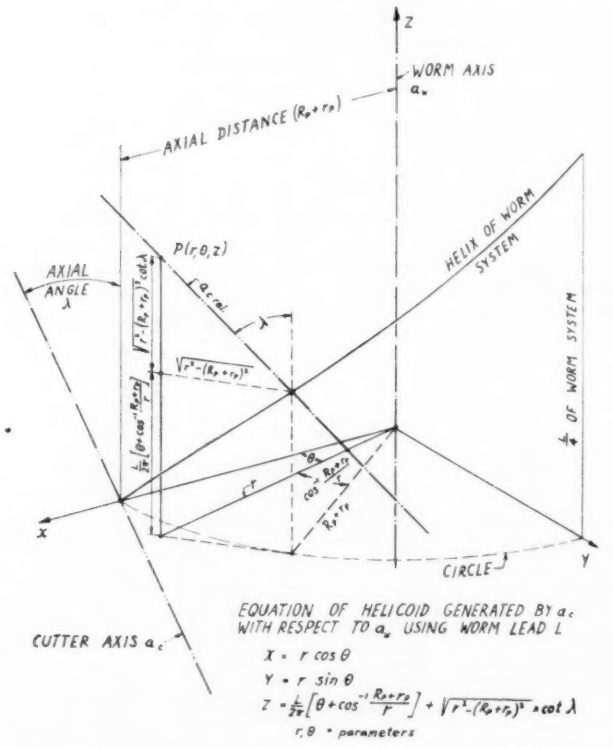

FIG. 3 HELICOID GENERATED BY THE CUTTER AXIS WITH RESPECT TO THE WORM AXIS DURING RELATIVE MOTION

The concept of relative motion of the cutter with respect to the worm is again used; during this motion the cutter axis a_c generates a helicoid H_{ac}. Now an intersection of a normal n of the worm surface W with the helicoid H_{ac} will give the exact relative position of the cutter as it cuts the foot point of that normal. The actual position of that contact point is then found by moving back the normal n along its foot helix of W through the same angle by which the relative cutter position is displaced from the actual cutter position. Mathematically, this operation may be performed as follows:

The helicoid H_{ac} is represented (Fig. 3 of this discussion) by

$$\left.\begin{aligned} x &= r \cdot \cos\theta \\ y &= r \cdot \sin\theta \\ z &= \frac{L}{2\pi}\left\{\theta + \cos^{-1}\left(\frac{R_p + r_p}{r}\right)\right\} + \sqrt{r^2 - (R_p + r_p)^2}\cdot \\ &\qquad\qquad\qquad\qquad\qquad\qquad \cot\lambda \end{aligned}\right\} \quad \ldots [1]$$

where r, θ are parameters.

The normal n may be represented by

$$\left.\begin{aligned} x &= r \cdot \cos\theta \\ y &= r \cdot \sin\theta \\ z &= \sqrt{r^2 - r_0^2}\cdot \tan\eta + z_0 \end{aligned}\right\} \quad \ldots\ldots\ldots [2]$$

where

r, θ are parameters
r_0 = shortest distance between a_w and n
z_0 = "altitude" of r_0 over x,y plane
η = angle, which normal makes with x,y plane

(All these values are readily obtained by using the direction vectors of n as described by the authors.)

Now the point of intersection of the normal and the helicoid is given by equating z of Equations [1] and [2], thus

$$z_0 + \sqrt{r^2 - r_0^2}\cdot\tan\eta = \frac{L}{2\pi}\left\{\theta + \cos^{-1}\left(\frac{R_p + r_p}{r}\right)\right\} + \sqrt{r^2 - (R_p + r_p)^2}\cdot\cot\lambda$$

This equation has to be solved for r and θ by trial and error, as any equation in helical geometry. It will be more conveniently solved by rotating the x and y axes about the z axis until the y axis is perpendicular to r_0. Calling the new axes x_4, y_4, and z, the equation of n may be written as

$$\left.\begin{aligned} x_4 &= r_0 \\ y_4 &= (z - z_0)\cot\eta \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots\ldots [2a]$$

A similar transformation of Equation [1] to the x_4–y_4 system will then simplify the trial-and-error calculation.

Direct methods like this and the one described by the authors are certain to give the answer more quickly than the envelope method. They also have the advantage of enabling one to determine the exact point on the cutter for any desired point on the worm section.

The geometric relations described by the authors and by the writer are quite general and may be applied to tool design for machining of helical parts using end-milling cutters, grinding, and shaping processes.

Formed grinding wheels may be designed considering that a grinding wheel may be conceived of as a milling cutter with an infinite number of teeth, and the same principles as for milling cutters may be applied.

[7] "Konstruktion eines Fräsers, der eine Gegebene Schraubenfläche Erzeugt," by O. Baier, *Zeitschrift für angewandte Mathematik und Mechanik*, vol. 14, 1934, pp. 248–250.

[8] "On the Determination of Milling-Cutter Contour of Screwed Surface," by K. Okusima, Trans. Society of Mechanical Engineers of Japan vol. 3, 1937, pp. 268–272; English abstract, pp. S66-S67.

When using an end-mill process, two alternatives are possible:

1 The cutter axis may be fixed in a definite position with respect to the worm axis, e.g., in many cases perpendicular to, and intersecting the worm axis. Then there is only one correct cutter profile, which may be determined using the authors' method by rotating the worm surface with respect to the vertical end-mill axis, and finding the envelope surface of all worm-surface positions. Or Baier's method may be used by finding those normals of the worm surface which are also normals of the end-milling-cutter surface, i.e., those which intersect the end-mill axis. One single-end mill, however, cannot produce grooves with convex bottoms because of free-cutting limitations. It can produce flat-bottom grooves and concave grooves, such as twist-drill flutes.

2 The end-mill-cutter shape may be fixed as a conical, spherical, or any other shape cutter. Then the dependent variable is the path along which the tool has to move with respect to the worm surface. This path may be determined, bearing in mind that the cutter and worm surfaces always have to be tangential surfaces. From the exact tool path, and for a given tool-guiding mechanism, the exact cam shape may then be determined. This method has the advantages of simpler tool shapes (easier tool sharpening and replacement) and the possibility of milling convex groove bottoms and other complex helical parts. But it has the disadvantage of being a more involved operation because several cuts are necessary for a single groove. Also, the theoretically true worm surface can be obtained only by an infinite number of cuts. On the actual worm surface, although it may be well within the required tolerance, traces of the individual cuts will be visible.

Cams for the correct guidance of shaper tools for helical rotors may also be determined using the general principles that have been described.

All the foregoing applications of "analytic tool design," as this general type of work may be called, involve complex calculations, but, if tabulated calculating forms are used, the tool shape will be obtained much faster and cheaper than by shop trial-and-error methods.

Authors' Closure

The authors are grateful to Messrs. A. H. Candee and L. Pach for their valuable and interesting discussions. Their extensive references to the literature are welcome additions to the bibliography on the subject; apparently more has been done and written in this field than the authors had realized and they are glad to have their attention called to this work.

The authors agree with Mr. Candee that the problem is purely a geometrical one, however, they feel that the introduction of vectors, differentiation of vectors to obtain velocities, and other similar items needs no apology nowadays, since these tools are commonly taught in schools. These new frills merely bring "old-fashioned" solid geometry up to date, and enable one to simplify the derivations by using equations which approach more closely the geometric reality and bring out more readily the points of the proofs in a form which requires little memory work. What Mr. Candee calls "the theory of relativity" simply refers to the fact that to find out what a tool does to a piece of work, it is advisable to assume the point of view of that piece of work, watch the tool go by, and find the volume scooped out.

In addition to treating the specific problems discussed in the paper, it was the authors' intention to formulate general principles which will apply equally well to other similar problems; the criterion of deepest cutting, which was obtained in terms of the velocity of the cutting tool in its motion relative to the work, constitutes such a formulation. No apologies are needed for this point of view. The authors are grateful to both discussers for pointing out again that the problem reduces merely to finding the line of contact of two surfaces or the point of contact of two other surfaces.

The authors agree completely with Mr. Candee's criticism of the formula for the relation between φ_n and φ_c. It must be remembered, in this connection, that their primary intention was to obtain the exact shape either of the cutter or of the worm when the other is given. This shape may be specified by means of the deviation from any line. The particular line that was chosen was used merely because at least two nationally known tool vendors and our own gear plant were making regular use of this formula in calculating reference angles for checking cutters and worms. However, it was more with the idea of pointing out the inaccuracy of this formula rather than with any thought of recommending it that use was made of it. In footnote 4 of the paper, it was stated that results obtained from the formula were approximate. Had the authors been familiar with Mr. Candee's approximate formula which is both reasonably simple and accurate, they certainly would have used it in place of the one employed in the paper.

In Mr. Candee's discussion, reference is made to Wildhaber's formulas for calculating the radii of curvature of cutter, worm, and helical-gear profiles. When the authors first became concerned with cutter and hob shapes, an attempt was made to use these formulas to get more accurate cutters for two worm-gear jobs. Calculations carried out along this line gave profiles which were entirely unreasonable in the light of shop experience. The reason was not clear then; but it is clear now that the normal pressure angle of the worm φ_n and the cutter pressure angle φ_c are different, and hence radii of curvature are of no value in themselves unless the correct relation between those two angles can be established. Wildhaber gave no formula for the relation between these two angles except the following, which seems to imply that they are equal:

> "α = Thread profile angle in a normal section measured from the radius, and also the inclination of the cutter profile."

In reviewing other work on the same subject it is to be noted that the authors' methods make it possible to start with any general cutter, worm, gear, or hob profile and obtain the shape of the tool required or gear part produced. Other solutions have tended to treat only special cases, such as a straight-sided cutter or a straight-sided worm.

As pointed out by Mr. Candee, the envelope method may be laborious, especially where calculations have not been reduced to form-sheet routine, but it does have particular value of its own in determining root fillets, interference points, and scallops in the tooth surface. The alternative method of calculating directly for points on the final profile is often the quickest method of getting the shape of the working part of the tooth and should, therefore, be the method most often used.

The graphical method outlined by Mr. Pach is interesting. In general, the graphical constructions of the sine curves, corresponding to the projection of the helices of the worm on a particular axial plane, and their projections on a plane normal to the axis of the cutter, can only be carried out with a limited accuracy which is insufficient for the purpose at hand. For this reason, the analytical method is preferable. Yet the graphical method is valuable if for no other reason than it enables one to see the geometry of the problem more clearly.

While not agreeing completely with some of the criticisms, the authors feel that the points of view brought out by the discussions are valuable and will serve to clarify the subject and enhance the usefulness of the paper.

Deflection of Uniformly Loaded Circular Plates[1]

STEWART WAY.[2] This paper is of interest to anyone who has ever been concerned with the theory of circular plates bent to a surface of revolution.

The author introduces a parameter α which is related to the type of boundary support. As is pointed out, $\alpha = 1$ for a clamped plate and $\alpha = (1 + \nu)/(5 + \nu)$ for a simply supported plate. An elastic edge support also implies a particular value of α, depending upon the rigidity of the support. However, it should be observed that, in general, fixing the boundary conditions is not equivalent to specifying a value of α. Thus if the edge of the plate be clamped with any slope other than zero, α will depend not only upon the edge slope but also upon the load. Also, if the boundary condition consists of an applied edge moment M_{r1}, α will depend not alone upon M_{r1} but also upon q.

The writer has given some thought to what happens when α takes values outside the range

$$\frac{1 + \nu}{5 + \nu} < \alpha < 1$$

If we assume a rotationally elastic edge support of flexibility β, where β is the rotation of the support per unit of edge moment

$$\beta = \frac{1}{M_{r1}} \left(\frac{dw}{dx}\right)_1 \quad \text{.....[1]}$$

we can derive a relation between β and α, namely

$$\alpha = \frac{1 + \frac{D\beta}{a^2}(1 + \nu)}{1 + \frac{D\beta}{a^2}(5 + \nu)} \quad \text{.....[2]}$$

The maximum deflection, edge slope, and edge moment are related to α by

$$w_0 = \frac{qa^4}{64D\alpha} \quad \text{.....[3]}$$

$$\left(\frac{dw}{dx}\right)_1 = \frac{qa^4}{32D}\left(1 - \frac{1}{\alpha}\right) = 2w_0\alpha\left(1 - \frac{1}{\alpha}\right) \quad \text{.....[4]}$$

$$M_{r1} = -\frac{2Dw_0\alpha}{a^2}\left(5 + \nu - \frac{1 + \nu}{\alpha}\right) \quad \text{.....[5]}$$

The dependence of the foregoing quantities upon β is shown in Fig. 1 of this discussion.

The range of α values considered by the author is seen to correspond entirely to positive values of β. Negative values of β imply a negative flexibility of the edge support, a condition that is technically very unlikely to arise though it is certainly physically possible.

We observe from Fig. 1 that for β in the range

$$\frac{-a^2}{D(1 + \nu)} < \beta < 0$$

the plate, in the vicinity of the edge, is convex upward. The maximum deflection changes from positive to negative at

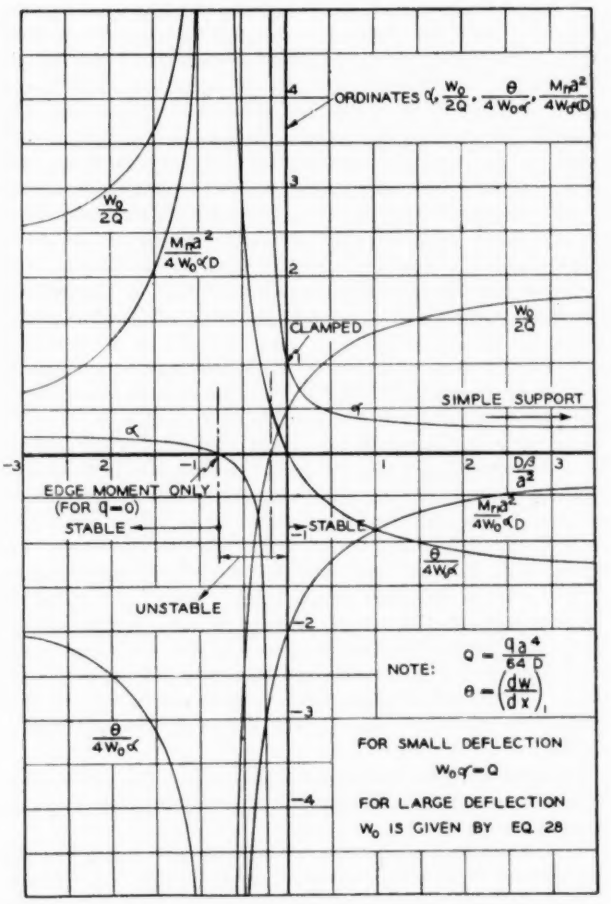

FIG. 1

$$\beta = -a^2/D(5 + \nu)$$

In this range of β values, the plate is in unstable equilibrium.

For values of β

$$\beta < \frac{-a^2}{D(1 + \nu)}$$

the plate is again convex downward, but is in stable equilibrium.

For the case

$$\beta = \frac{-a^2}{D(1 + \nu)}$$

the plate is in neutral equilibrium provided the load is zero. The applied edge moment arising from the rotation of the supports is just enough at all times to cause an equal rotation at the edge of the plate. The value of α is therefore the same as that for a plate loaded by edge couples only, namely, $\alpha = 0$.

If there should be plastic yielding of the edge support the author's Equation [3] would still be valid, but the value of α to be used would depend upon the load; so if α is to be experimentally determined in such a case, this should be done at the particular load for which one is interested in the stresses.

The contribution of the author to the large deflection theory is very commendable. It might be emphasized that, although the rotational flexibility of the supports is included in the theory, it is strictly assumed that there is no radial displacement at the edge. Most supporting structures occurring in practice which have rota-

[1] By F. C. W. Olson, published in the December, 1943, issue of the JOURNAL OF APPLIED MECHANICS, Trans. A.S.M.E., vol. 65, 1943, p. A-181.

[2] Mechanics Department, Research Laboratories, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. Jun. A.S.M.E.

tional flexibility would probably also have some translational flexibility.

For large deflections, the curves given in Fig. 1 of this discussion will also apply, except the curve for $w_0/2Q$. The question of the stability of the plate for negative β values and large deflection would need further investigation.

Author's Closure

Since the author is in complete agreement with the foregoing discussion, there remains only the pleasant task of thanking Stewart Way for his helpful and illuminating contribution.

Studies in Three-Dimensional Photoelasticity[1]

D. C. Drucker.[2] The "theory of laminar action" presented in this paper is not self-consistent and may lead to large error in many practical cases. In the problem of the transverse hole in a plate, or shaft, subjected to pure bending, it can be shown that this laminar action will exist except for a region of disturbance at the ends of the hole. The difficulty is that the dimensions of the disturbed region are of the order of magnitude of the diameter of the hole, and therefore will frequently cover the entire length. For example, the stress-concentration factor for a circular hole in a wide thin bent plate is approximately 1.8 and not 3 as for pure tension.

Fig. 1 of this discussion, which is the diagram of a lamina

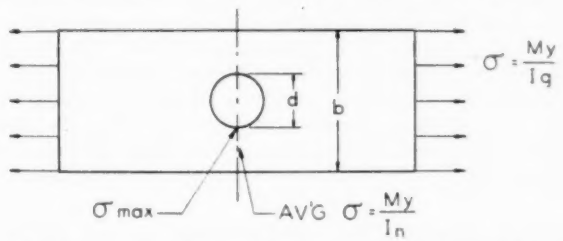

Fig. 1 Diagram of Lamina Perpendicular to Hole in Shaft

perpendicular to the hole in the shaft, shows the basic inconsistency. At some distance away from the hole the stress is given by $\frac{My}{I_g}$ where I_g is the moment of inertia of the solid cross section. At the line through the hole, the author reasonably assumes the average stress to be given by $\frac{My}{I_n}$, where I_n is the moment of inertia of the net section through the hole. He then finds the maximum stress by multiplying this average value by the two-dimensional concentration factor which varies from 3 to 2. It would, however, be equally possible to multiply the stress $\frac{My}{I_g}$ by its appropriate two-dimensional factor which varies from 3 to infinity. In the limiting case at the ends of the hole, the first procedure leads to a finite stress, the second to an infinite stress.

The reason is clearly that $\frac{My}{I_n} \times (b - d)$ is not in equilibrium with $\frac{My}{I_g} \times b$, i.e., the lamina has stresses acting on its top and bottom surfaces (in this case not even in equilibrium on each side of the hole), and thus is not independent of the rest of the shaft.

It therefore appears that the sharp decrease in stress at the ends of the hole may not actually occur, or at least no good theoretical evidence exists that it does. As a further point, the fairly high "edge" stresses produced in the freezing and slicing procedure make it difficult to determine boundary stresses.

Author's Closure

In the opinion of the author, Dr. Drucker failed to prove that the theory of laminar action, as presented in this paper, may lead to large error in practical cases. Consider the error: For $r/d = 0.07$, we have calculated and given in the paper two values of k_3, one based on laminar action and the other on the assumption that the maximum stress occurs at the end of the hole. The first is 2.18, and the second is 2.32, giving a possible error of roughly 6 per cent. This does not seem to us to be large. The curves in Fig. 17, show that the difference between the maximum stresses from laminar action and the extrapolated purely experimental results are small. The agreement of the results from laminar action with the experimental results by Peterson and Wahl proves that the errors must be small.

A factor of stress concentration is generally defined as the ratio of the maximum to the nominal stress at one and the same section. For the case under consideration this leads to the well-known range of 3 to 2. However, if k is defined as the ratio of the maximum stress at the net section to the nominal stress at another section where the stress is uniform, one arrives at Dr. Drucker's range from 3 to infinity. The introduction of such a definition seems to us to serve no useful purpose and to result in unnecessary complications. We prefer to adhere to the conventional definition. Infinity is not a number, and the factor of stress concentration, if it is to have meaning, should be a definite number. When a choice of definitions exists, we reject the one which leads to infinite factors.

The observation regarding a thin bent plate, in which the factor is 1.8, is irrelevant. We assume each lamina to be in pure tension or compression and not in bending.

The point regarding the existence of shear stresses in the extreme fibers of the beam and their influence on equilibrium is in the case of small holes, such as oil holes, of academic interest only and of no practical significance. Even in rigorous mathematical investigations, solutions are at times terminated with small disturbances in equilibrium. The presence of the shear

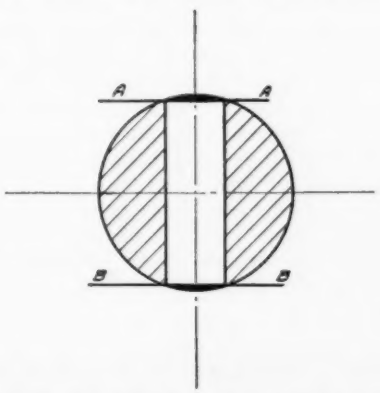

Fig. 2 Condition in Which Bending Stresses Above A–A and Below B–B Can Be Balanced by Shear Stress Only
(Solid areas show regions which cannot be represented by a continuous lamina. For practical cases these areas are small and approach 0 as the hole gets smaller.)

[1] By M. M. Frocht, published in the March, 1944, issue of the Journal of Applied Mechanics, Trans. A.S.M.E., vol. 66, p. A-10.

[2] Supervisor, Mechanics of Solids, Armour Research Foundation, Illinois Institute of Technology, Chicago 16, Ill.

stresses in the upper fibers is due not to any infinite factors of stress concentration but to the simple fact that the assumed laminar representation breaks down for plates of a width less than the diameter of the hole. We then have two disconnected plates, and not one continuous lamina with a central circular hole, and hence the bending stresses in the region of pure bending which are developed on the areas above line A–A and below B–B, Fig. 2 of this closure, can be balanced by shear stresses only.

If it is assumed, as we have done, that each lamina is in a state of two-dimensional stresses this would leave a small unbalanced force which is roughly proportional to the solid area above line A–A. It is apparent that this area, and therefore the unbalanced force acting upon it, approaches zero as the hole gets smaller, and for practical cases of oil holes this would always be a negligible quantity. For large holes, corrections would be necessary, since laminar representation would then be possible for a small part of the shaft only. Shafts with such large holes seem to us of little practical significance.

Dr. Drucker also states, "it can be shown (we presume mathematically) that laminar action will exist except for a region near the ends of the hole." In that case he supports our contention. We claim that the assumption of laminar action satisfactorily explains the experimental results, which clearly do not include the very extreme fibers. We do not dispute the statement that "the sharp decrease in the stress at the ends of the hole may not actually occur, or at least no good theoretical evidence exists that it does." No claim was advanced that such evidence does exist. We never even claimed the existence of conclusive experimental evidence on that particular point. It was clearly stated that further work on this matter is needed. The fracture, shown in Fig. 19 of the paper, fits in well with the idea of laminar action, in the extreme fibers, although as stated in the paper, it does not prove it conclusively.

We observe also that there is a vast difference between Dr. Drucker's initial assertion that laminar action can be shown not to hold in regions near the ends of the hole, and the closing statement, "no good theoretical evidence exists that it does." These statements are inconsistent.

The effect of time stresses has been amply discussed by the author in this and in another paper.[3] It is no doubt an undesirable characteristic of bakelite and affects somewhat the accuracy of the final results. In the problem under consideration, it was relatively easy to introduce corrections for them. It has also been shown that, with good technique, time stresses can be held to very low values. We have obtained frozen stress patterns of slices from shafts with transverse holes in tension, in which the boundary stresses were nearly as good as those found in freshly machined two-dimensional plates.[4]

In conclusion, we emphasize the essential fact that the theory of laminar action enables one to predict by a relatively simple calculation and good accuracy all the experimental values of k_3 available today from photoelasticity, strain gages, and fatigue tests from large shafts.

Stress Coefficients for Rotating Disks of Conical Profile[1]

E. O. Waters.[2] The author is to be complimented on having carried out a very painstaking analysis, with due attention to such mathematical details as convergence of series and degree of accuracy in incomplete series, details which the average engineer is apt to overlook or disregard as of minor importance. At the same time, the writer questions whether the type of problem shown in the illustrative example is worthy of such detailed and laborious computation. The accuracy of 5 parts in 2,000,000 claimed by the author for his tables would seem more appropriate for astronomical calculations than for a stress analysis where other factors such as yield strength, uniformity of material, and localized concentration of stress are, if the designer is fortunate, determinable with an accuracy of only 5 parts in 100.

The writer would suggest that reasonably accurate solutions for problems of this kind may be obtained by the method of least work, and that, by using this method, stresses in three dimensions may be found as easily as in two dimensions. This is an added element that should not be overlooked when dealing with solids of revolution whose length is of the same order of magnitude as the radius.

Stewart Way.[3] The author has made an admirable contribution in this paper to the theory of rotating disks. It is when we come to the application of the theory that perplexing problems arise. For a disk of regularly decreasing profile with increasing r, and for which the thickness is everywhere small compared to R, there is little doubt that the method of equivalent conical profiles would give good accuracy. When we have a disk of the form indicated in Fig. 2 of the paper, however, it is indeed questionable whether the theory of a rotating disk of conical profile can help us very much. The stress system produced by the overhanging guide vanes will be of an entirely different character from that considered in the author's theoretical treatment. The choice of this numerical example by the author was unfortunate.

For rotating structures of the type of Fig. 2, a satisfactory stress analysis can be obtained only if one goes into a considerably more exact theory which would take account of bending and fillet stresses, or else has recourse to an experimental method of stress analysis.

Author's Closure

The author is grateful for the stimulating comments of Professor Waters and Dr. Way. Professor Waters contends that the tables have been constructed with greater accuracy than is required by practical considerations. This situation exists because it was found necessary to construct better tables than those already published, in order to use the method of equivalent conical disks satisfactorily, since some of the arithmetical operations involved entail a loss of significant figures. Furthermore, some additional accuracy in the coefficients was obtainable with very little increase of labor by using the calculation methods described in the paper. It appeared desirable, therefore, to construct the best tables that could be computed economically for a sufficient number of entries, and at the same time consistent with the numerical methods available.

Professor Waters' proposal that the theory of least work be used for three-dimensional solutions of problems similar to the illustrative example suggests other methods rather than those described in the paper. Quite recently relaxation methods were recommended to the author in connection with solutions of like complex structures. These other methods have little or no relation to ordinary rotating-disk theory so that, strictly speaking, the results of thin-disk theory obtained in the paper have a limited range of applicability.

The question of applications is raised by Dr. Way whose ob-

[3] See author's paper, "Studies in Three-Dimensional Photoelasticity," *Journal of Applied Physics*, Jan., 1944, pp. 72–88.

[4] Ibid., Fig. 17.

[3] Mechanics Department, Research Laboratories, Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. Jun. A.S.M.E.

jections are recognized. This choice of example may have been unfortunate, however, it was the one available at the time for which an approximation to the stresses was required. It should not be overlooked that the various changes of profile in the example provide the designer with an excellent guide on how to proceed with the calculation in practically any situation to which the approximation is applicable. The question of applicability of the approximation can be settled only by comparison with an exact solution if available. The problem of estimating errors in a theoretical stress analysis of this nature is discouraging, but the author hopes to do some further work along the lines suggested in his reply to Professor Waters.

Book Reviews

On Growth and Form

ON GROWTH AND FORM. By Sir D'Arcy Wentworth Thompson. Revised and enlarged edition. University Press, Cambridge, England; The Macmillan Company, New York, N. Y., 1943. Cloth, $5^1/_2 \times 8^1/_2$ in., 1116 pp., 554 figs., $12.50.

REVIEWED BY M. HETÉNYI[1]

THE beauty and regularity of form in plants and animals have been agelong sources of fascination to mankind. Though it was always felt that the perfection of form is deeply connected with its purpose and usefulness, by far more scientific effort has been spent on the description and classification of these phenomena than on the investigation of the more fundamental question of their causation. The aim of the present book is to encourage investigations of this latter type and to indicate, at least, the profitable manner in which known physical and mathematical methods can be applied in the study of the complex problems of growth and form. As the author says in the introductory chapter: "The form of any portion of matter, whether it be living or dead, . . . may in all cases alike be described as due to the action of force. In short, the form of an object is a 'diagram of forces', in this sense at least, that we can judge of or deduce the forces that are acting or have acted upon it."

In this analytical spirit the author then proceeds to discuss, through the seventeen chapters of the book, an amazing array of examples of regularities in structure and development that can be found in living nature. The first two chapters are devoted to contemplations of fundamental nature, concerning matter, energy, and magnitude, and resulting in a number of gratifying conclusions obtained through dimensional considerations. The third chapter, on the rate of growth, is over 200 pages itself and comprises a wealth of statistical information which is likely to serve as basis for further meditation. Several chapters follow on the form and structure of cells and cell-aggregates. In this connection topics like the problem of minimum surfaces, states of equilibrium of membranes, the influence of surface tension, adsorption, etc., are extensively discussed. A separate chapter is devoted to the equiangular (logarithmic) spiral showing that this curve, by virtue of its continued similarity, is characteristic of such forms of living structures which grow by successive increments to one end (spiral shells, tusks, claws, etc.). The remarkable properties of this curve are known to have impressed James Bernoulli so much that he requested that it be engraved on his tombstone. Students of elasticity may be particularly interested in the pictures of chapter 13, showing the effect of torsion on the growth of horns. While horns of polygonal cross section exhibit conspicuously the anticlastic warping of the cross sections due to torsion, no such effect can be detected in horns with circular cross sections. There are two more chapters of structural character, one on the shape of eggs and other hollow structures, and the other on the relationship between form and mechanical efficiency bringing remarkable illustrations of stress trajectories in the structure of bones, precise three-dimensional lattice work in the vulture's wing bone, and many more of the like. The last chapter on the theory of transformations deals with the comparison of related forms on the basis of co-ordinate systems subjected to various types of distortion.

The mathematics employed throughout the book is of the simplest kind which can be understood and enjoyed by anyone without special preparation. The author does not fail to point out, however, that, while elementary means may bring instructive conclusions, the true and complete solution of most of these problems is yet unattained and is likely to require application of the most advanced methods available. Constant appeal is made therefore to the mathematical physicist pointing out a most worthy field for his labor, "a field which few have entered and no man explored."

The first edition of this book appeared over 25 years ago and has been out of print and scarce for quite some time. The present new and enlarged edition will therefore be doubly welcomed by the readers. The book is essentially the work of a grand amateur spellbound by the wonders of nature, but it is also likely to become a permanent source of inspiration for any specialist in the realm of physical sciences.

Mechanical Springs

MECHANICAL SPRINGS. By A. M. Wahl. Penton Publishing Co., Cleveland, Ohio, 1944. Cloth 6 × 9 in., xi and 439 pages, 228 figs., xlii tables, $6.

REVIEWED BY C. O. DOHRENWEND[2]

MECHANICAL springs and their uses have become quite important in the field of modern machine design and a rational approach to their design has become essential. The theory required to calculate the stresses and deflections and to make clear the fundamental underlying principles as well as the data necessary for design has been widely scattered in various textbooks and professional papers of engineering and scientific societies. This book on the subject brings together much pertinent data as well as the fundamental principles underlying all kinds of mechanical springs. The author has expressed in the foreword the hope that the book may contribute something toward the avoidance of unsatisfactory operation and mechanical failure of springs by helping to put the specifications for springs on a more rational basis. It is a certainty that the book will help to accomplish this end.

The material covered in the book is in good balance, even though a large portion (212 of the 439 pages) is devoted to the helical spring. The remaining portion covers coned disk,

[2] Chairman, Engineering Mechanics Research, Armour Research Foundation, Chicago, Ill.

flat disk, flat and leaf, helical torsion, spiral, ring, volute, and rubber springs, as well as information on spring materials and energy-storing capacities.

The part dealing with the helical spring includes detailed theoretical analysis with the proper emphasis on stresses, deflections, and the fatigue properties of the materials. Also included in this portion of the book is information on the effects of lateral loads, buckling, vibration, surging, and a chapter on static and fatigue tests on both helical springs and spring material. Three chapters devoted to practical selection, design considerations, and maximum space efficiency are of special interest to the mechanical engineer faced with selection and design problems. Included in these chapters are tables of allowable stresses, load-deflection data per turn for various wire and coil diameters, the effects of the end coils, eccentric loading, variation of the spring dimensions, and stress at solid compression. This material on the helical spring is not only complete but is written in a clear style with excellent illustrations, graphs, and tables. The special problems that arise in connection with the tension helical springs at the end coils are adequately treated in the chapter on tension springs. The uses of square and rectangular wire springs are described, and curves for the calculation of the stresses in the rectangular wire are given.

The material presented with respect to the interesting problem of coned disk and flat disk springs includes the theory for calculating stresses and deflections as well as information on practical designs.

The flat and leaf springs are treated briefly with only the development of the fundamental principles underlying calculations for the simpler shapes. However, the effect of large deflections is discussed as well as the stress-concentration effects due to holes, slots, notches, sharp bends, and clamped ends.

Two torsional types of spring are presented in two separate chapters. Stresses and deflections are calculated by curved beam theory for the helical type with circular cross section. The spiral type is considered for three kinds of spring: the first, many turns without coil contact; the second, few turns in the spring; and the third, large deflections with the coils in contact.

The equations for the ring-type spring are developed and comments on stresses, deflections, and design calculations are given in a short discussion.

The volute spring has recently had much attention, particularly in its military adaptations. The presentation includes comments on the characteristics of this type spring, and the development of the equations for stresses and deflections along with practical design methods for both the constant and variable helix angle.

Although rubber is not normally thought of as a spring material, recent applications have shown it important in this field. The author has included some discussion of these springs and has described the simple shear spring, the cylindrical shear and cylindrical tension springs with comments on the allowable stresses.

The last two chapters of the book deal with a comparison of the energy-storing capacities of the different types of springs and the properties and types of spring material available.

The mechanical engineer will find this book very useful, easy to read, and containing a wealth of data on mechanical springs and their uses, while the theoretical presentations will appeal to engineering teachers.

Flow-of-Metal Aspects of Shell-Forging

By M. D. STONE,[1] PITTSBURGH, PA.

WHEN the fears of a world-wide conflict were threatening to become a certainty, one of the problems confronting the Ordnance Department and industry in general was that of providing for the manufacture of high-explosive (H.E.) shells in large quantities as rapidly as possible, at the same time making the best use of available facilities and knowledge. It was soon realized that there were many things we would like to know, to help make the best decisions, which had to be left to experience, and little enough of that. Little work along such lines had been done in this country since the last war, and whatever experience was gained at that time was available in the minds of relatively few people presently active along similar lines. It was apparent, too, that greatly accelerated production and reduced mauufacturing costs were mandatory to keep such a production program as this, involving tens of millions of shells, reaching into the billions of dollars, within the bounds of practicability.

To help develop and co-ordinate the technical background in the manufacture of shell forgings, the Ordnance Department vitalized an A.S.M.E. Committee set up for this purpose somewhat prior to our actual entrance into the world conflict. The results obtained have been gratifying to everyone concerned, and it is the purpose of this paper to present and discuss generally those aspects of shell-forging having to do with metal flow and associated forces. Many problems immediately presented themselves which required detailed theoretical and experimental study to evaluate properly the various factors, and accordingly several studies of this type were undertaken, some of which are discussed in companion papers by Trinks, Sachs, and Nadai, all members of the Committee on Forging of Steel Shells.

In contemplating the most direct way of making shells, a first thought might well be—why not form it by deep-drawing a disk cut from a plate, similar to shell-case manufacture. A little investigation soon disposes of this query, from the economic point of view: The cost of steel in plate form, and the attendant scrap, are too great. Well, then, why not cast shells closely to shape, or perhaps, at least, cast slugs that require relatively little forging to obtain the final form. Again, the economics involved have dictated otherwise, at least, up to the present, with some additional mental reservations as to physical properties, as well.

Actually, the initial form of the semifinished steel that has crystallized out of a wealth of experience is the billet. The billet as conventionally used is cut to length from the longer billets or bars as rolled on a continuous mill, but in at least one case, the long, as-rolled billet is used. For very large shells, generally not discussed here, individually cast billets or ingots are used.

Methods of Shell-Making

In the earliest attempts to make shells, the natural procedure was to place the heated billet in a die to form the outside shape, and to pierce completely with a punch that conformed to the desired inside cavity. This obvious objective has never been commercially attained. And the pros and cons of this and similar considerations form the context of this paper.

The maximum economical temperature for forging rarely exceeds 2300 F. Even at these elevated temperatures, the piercing of, say, a 90-mm shell-forging, having an approximate length of 12 in. and an approximate wall thickness of $^1/_2$ in., to completion in one stroke, may involve pressures in excess of 80,000 psi referred to punch area. This pressure is influenced considerably by the shape of the punch tip, as well as the die shape, the quality of lubrication, the speed of penetration, the analysis of steel, etc. But such pressures as this, which mean a force on the end of the punch of

$$80{,}000 \times \frac{\pi}{4} (2^5/_8)^2 = 435{,}000 \text{ lb}$$

are more than can be tolerated from the point of view of punch bending, resulting in eccentric or crooked cavities. Then, too, the combination of such pressure with corresponding longer times of contact with hot steel resulted in deformation of the punch tip (mushrooming) causing further vitiation of the shell cavity, as well as short punch life.

It was apparent very early that complete piercing must be abandoned, and hence the problem of how properly to complete the forging presented itself. The almost universal solution up to the first world war was to push the pierced slug on a mandrel through a series of ring dies, called "drawing;" hence the development of the pierce-and-draw method. Even with a large part of the burden taken off the piercing punch, it was general practice during 1914–1918 to finish-machine the shell cavities, due to the multitude of difficulties that arose, and it was indeed a laborious and expensive procedure. Possibly the one major advance in shell-making made by the Army during the 1918–1941 interim period was the demonstration of the practicality of finish-forging shell cavities. This, of course, imposed a completely new set of conditions on the shell makers, and all past practice had to be modified to fit these requirements.

We shall concern ourselves with only those questions having to do with metal flow: How deep should the pierce be, and what is the proper division of work between the piercing and the drawing operations; what is the proper shape of piercing punch; what is the best speed of piercing; what are the required forging-press capacities; what is the best cross-sectional shape of the billet; should the billet be sized, and perhaps pointed; should the boattail be forged on the shell, etc.?

Piercing Operation

A fair average of the most recent practice of piercing is to pierce to about 70 per cent of completion on the smaller shells, such as the 75 mm, reducing the figure to about 50 per cent for the larger shells, such as the 155 mm. The reasons for this differentiation are well founded: An important consideration is the maximum permissible contact time between punch and hot billet compatible with reasonable punch life. For 155-mm shells, counting both in and out time, the duration may reach 4 to 5 sec, for penetrations of from 14 to 18 in. Because of the large punch diameters, around 5 in., and the greater wall thicknesses, around $1^1/_4$ in., and in view of the somewhat greater cavity tolerances, the greater punch lengths (corresponding to the greater piercing depths) are possible from the bending point of view and attendant eccentricity. For the smaller shells, involving smaller

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

punch diameters, the depth of penetration is limited mainly by considerations of cavity concentricity. Then, too, it is to be appreciated that the gain in reducing the piercing depth is two-fold, since a reduction in penetration depth necessarily means an increase in wall thickness of the pierced slug, since both the punch diameter and slug volume are constant. The effect of increasing the wall thickness is again to decrease the required piercing pressure. Other influences, tending to decrease piercing pressures, would be to increase the billet temperature, or to decrease the speed of piercing, but the relatively slight gains involved are more than offset by the reduced punch life, increased furnace costs, etc.

Another advantage gained by only partial piercing is that now the shape of the piercing-punch tip is no longer fixed, since the final cavity shape is thus determined by the draw mandrel. If for instance, the piercing punch could be flat-nosed, with possibly only the corners rounded, then the force could be reduced to its minimum. As the taper on the punch increases, the force to pierce increases considerably. This effect is evident in Fig. 1, which shows the results of piercing lead slugs with a variety of punch-tip shapes. A variation of more than 50 per cent is shown, the main action involved being that of friction along the

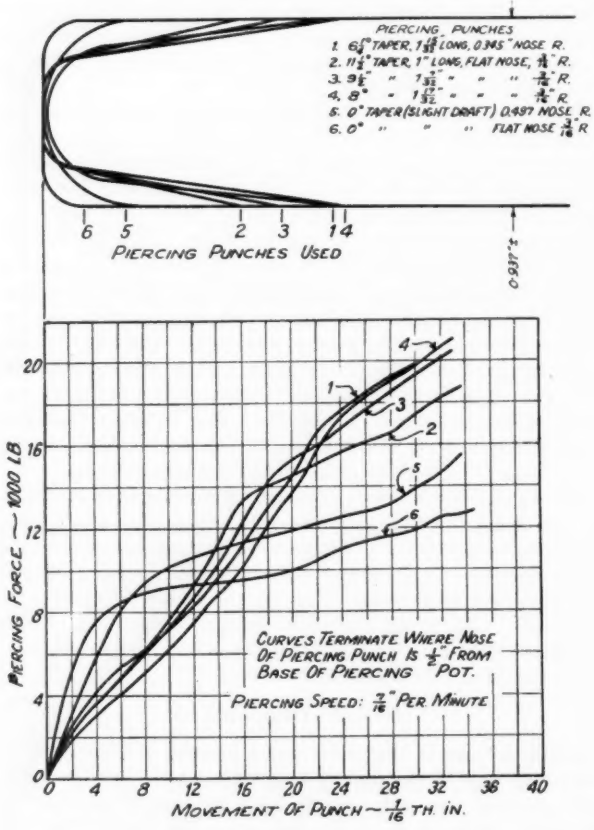

FIG. 1

tapered portion, as is developed in detail by Trinks in a companion paper. There are limits, however, on the arbitrariness of choice of the piercing-punch tip, i.e., it shall not have a taper less than that required by the final shell cavity (fixed by ballistic considerations), nor should it be too flat-nosed. This latter has to do with the nature of metal flow around the front end of the punch as it advances. In earlier times, it was observed that when the punch tip was flat it was possible to produce a loose "button" at the base of the shell cavity. This was a matter of considerable concern, until it was learned that its occurrence could be prevented by influencing properly the metal flow by using a sufficiently rounded punch tip.

FLOW OF METAL

Fig. 2 illustrates the nature of the metal flow, the existence of segregations or dirt in the steel bringing out the flow in the etched cross section. The illustrations show clearly the formation of a "false nose" (resembling the piling up of snow ahead of

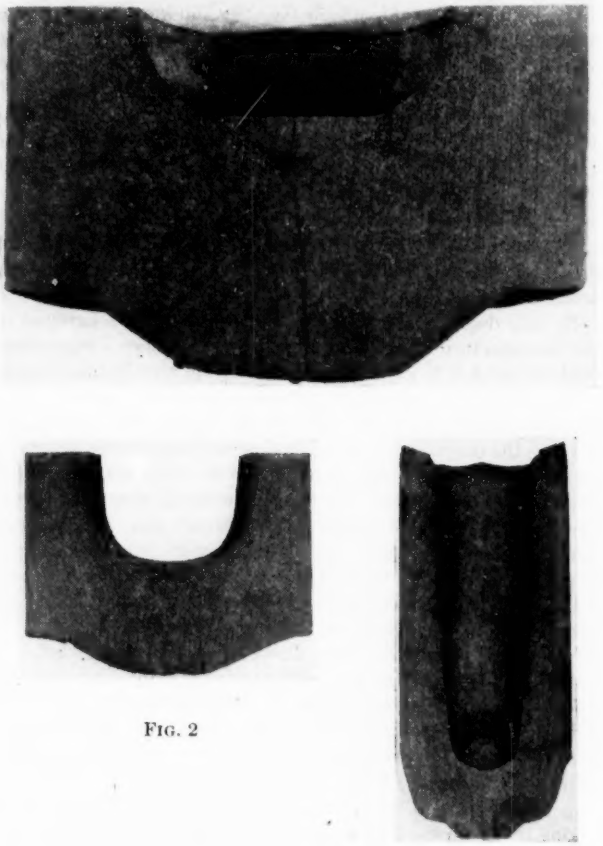

FIG. 2

a blunt-nosed snow plow), which, if the punch tip is sufficiently flat and, particularly, if the billet is pierced relatively cold, may actually result in metal failure. However, in a continuous search over a long period of time, not one case of a loose button has been encountered, and actual tensile tests from diametral specimens taken just below the point of deepest penetration have failed to show weaker metal, even though flow lines were visible (dirt).

The general flow of metal on the outside of the pierced billet is always such that tension strains exist. This is evident by examining the distance between flow lines at the base of the shells shown in Fig. 2. In Fig. 3, this is apparent again by observing the increase in distance between the diametral inserts along the outside surface. It emphasizes the necessity of shell-steel requirements that no seams, cracks, etc. shall be acceptable, since it is apparent that they would open up objectionably during piercing. This of course, is even more true in the subsequent drawing operations, where as much as 100 per cent elongations are sometimes taken.

The initial cross sectional shape of the shell billet is of considerable import, and the choice is influenced to some extent by whether the boat-tail is to be formed in the forging operation or not. It is obviously economically desirable to do this (rather

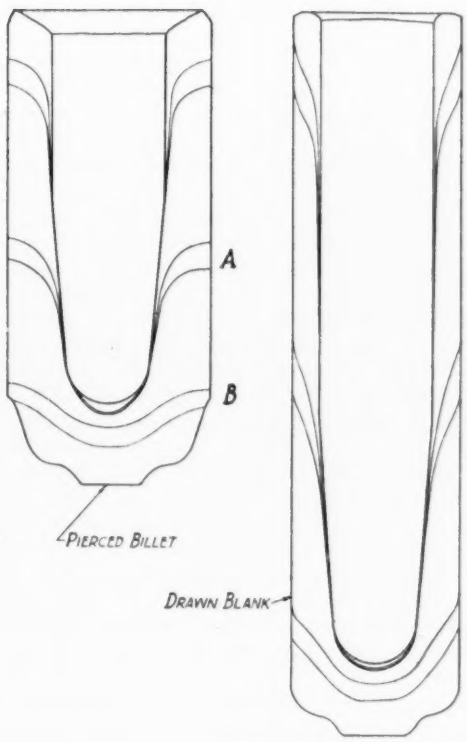

FIG. 3

than subsequently to machine it, with the attendant metal loss), all other considerations being equal. Most shell makers are now doing it. In designing the pattern of flow, it is desirable (see later) to reduce or eliminate what is called "extrusion" or backward flow of metal during the piercing operation, in order to maintain low piercing pressures. This means that the length of the original billet should be nearly the same as the length of the final pierced billet, aiming toward the ideal of straight radial flow, or "laying out" of the metal as it is sometimes called. While this ideal is unattainable, particularly near the base of the shell, we still cling to this concept, and, consequently, make the cross-sectional area of the original billet equal to the annular cross-sectional area of the pierced billet.

If the billet section being considered is a round (circular), then the problem presents itself of how to keep the slug central in the die prior to piercing. Actually, unless a preliminary "pointing" operation is provided, generally poor concentricity of piercing would follow even with the top of the shell guided. If now, the laying-out idea were abandoned, in order to favor concentricity, then a round billet closely fitting the die could be used, but with greatly increased piercing pressures, as shown in Fig. 4. However, in one plant where this practice is followed, a considerably reduced depth of pierce is used, counting heavily on a subsequent cross-rolling type of elongation. This method actually operates at low specific piercing pressures. Now, if a square section, or a round-cornered square is chosen, with metal area equal to the ultimate annular shell area, it is directly seen that the possibility exists of approaching the "laying-out" type of flow, while still retaining good concentricity by virtue of the diagonals of the square just fitting into the round shell dies. For square sections, the theoretical ratio of ID/OD should be 0.61. It is more than a coincidence that actual shell-forging diameter ratios (ID/OD) vary from 0.55 for the smaller shells to about 0.70 for the larger shells. This means that a slightly hollow square would be more suitable for the smaller shells, while appreciable corner radii are required for the larger ones.

It is possible to conceive that if the pierced slug is chosen to have too little piercing, that it would not properly fill out the die, particularly in the vicinity of the base. This is particularly true if the boat-tail is being forged on the shell and is always the case in attempting to get the sharp well-defined projection on the base that is required for subsequent machining purposes. If, by virtue of very thick walls, or a short depth of pierce, or both, or conceivably if lubrication were too good, piercing pressures as low as 15,000 to 20,000 psi only might be involved (referred to punch area), which would not be sufficient to cause the metal to flow into the far corners of the base, etc.

From what has been said, it can be appreciated how difficult or impossible it is to specify without qualification the capacity of a forging press to produce, say, 90-mm shells. Actual pres-

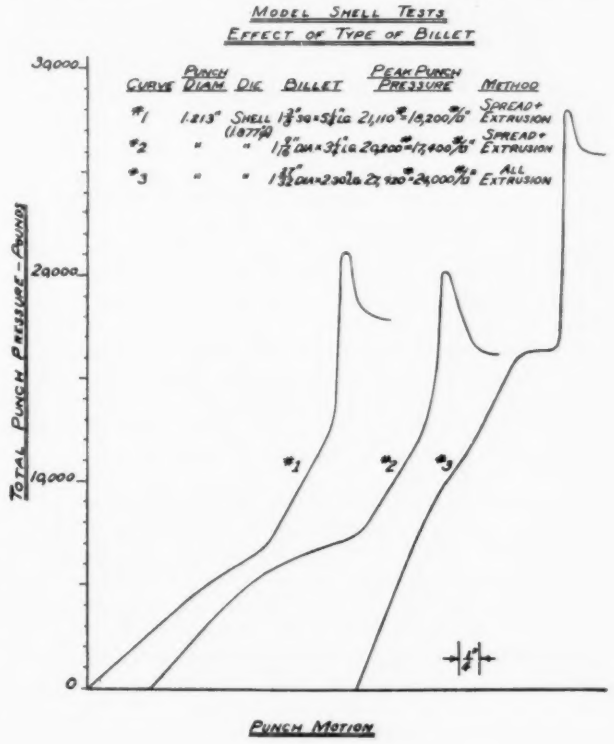

FIG. 4

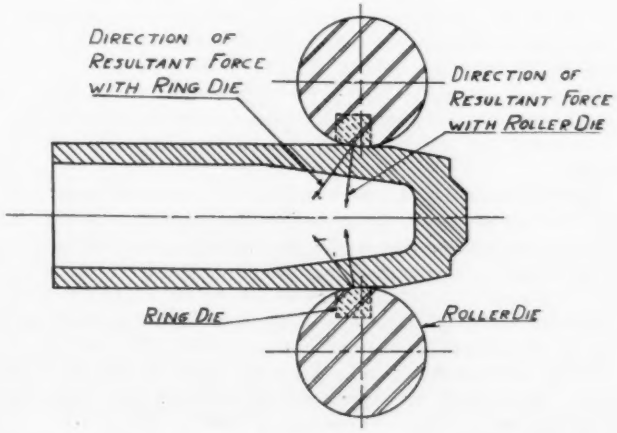

FIG. 5

sures as high as 80,000 psi and as low as 24,000 psi have been encountered in practice. Some cases are on record, where large forging billets, being pierced very slowly, required only 6000 psi, literally a "creep" stress. More usually, however, it might be safely said that optimum pressures for conventional practices seldom exceed 60,000 psi and are rarely lower than 30,000 psi. As has been said previously, the temperature of piercing, alone, can play an important role in fixing the required pressures, the resistance to deformation at 1800 F being approximately twice that at 2200 F. A fair approximation formula can be written as follows

$$P_t = P_{2200}\left(\frac{(2600 - t)}{400}\right)$$

when P_t = required pressure at temperature t (deg F), and $t \leq$ 2200 F. Therefore as a result of the multitude of uncertainties, many actual field tests have been carried out under a wide variety of conditions to evaluate quantitatively the requirements. These have covered piercing speeds from 2 ips to 25 ips (10 to 15 ips being usual), a variety of billet temperatures from 2400 F down to 1900 F, many types of lubricants, various billet shapes, several punch-tip designs, several ratios of ID/OD etc.

Drawing Operations

Until recently, practically all elongating after piercing has been accomplished by pushing the pierced shell (bottle, cup) through a series of ring dies by means of a mandrel whose shape conforms practically to the desired finished shell cavity. This operation is called "drawing." The simplified action in drawing involves a series of ring dies of successively smaller diameters, and the elongation is accompanied by a reduction in outside diameter, as well as in wall thickness. Installations have existed utilizing as many as 22 draw rings, and others with as few as 2, or even 1. Much work has been done to arrive at the optimum number of dies, as well as the most suitable reductions.

In the conventional pierce-and-draw process, as has been intimated earlier, elongations around 50 per cent are usual for the smaller 75-mm shells, increasing up to around 100 per cent for the larger 155-mm shells. Draw benches with from 3 to 5 sets of ring dies are frequent, the reduction per die ranging from 5 to 15 per cent and sometimes greater. There is an evident desire to reduce the number of dies as far as practicable, compatible with reasonable die life and keeping the mandrel forces low enough that bending or breaking of mandrels does not occur. This reduces the size (length) and expense of the draw press, as well as reduces floor-space requirements, since such machines are almost always horizontal affairs. In the case of the 155-mm bench, they may be as long as 40 ft. The matter of the required pressure to draw is obviously a function of the reduction taken, the die shape, type of lubricant, to some extent the speed, and yet more to complicate matters, it is influenced by the thickness of the base, shape of boat-tail if any, etc. For these and several allied reasons, an extensive series of investigations was undertaken and is discussed in a companion paper by Sachs.

Let it be mentioned, however, that the maximum reduction per die must necessarily be limited by the possibility of punching through the base, or even pulling the shell in two by wall failure. Base strength is the determining strength factor, however. Precautions against such failure are usually taken by maintaining the radius and shape of the nose of the pierce-and-draw mandrels the same, and not permitting too thin a base. The practice of forming boat-tails results in further reduction of the peak drawing force. Since shells are drawn directly after piercing, without reheating, an average temperature of 2000 to 2100 F is to be expected. At these temperatures, pressures of around 25,000 psi, referred to the area of displaced metal, are normally encountered.

By the use of forged boat-tails, not only may the maximum drawing force be reduced, but also the pressure of the punch tip tending to perforate the base. In fact, unless proper precautions are observed, this pressure may be reduced to zero, and the base of the shell may actually "run ahead" of the mandrel, paradoxical as this may seem. This phenomenon of running ahead or "ballooning" is still a matter of concern to many operators. The initial statement in this paragraph is not to be construed to mean that the existence of a boat-tail is the cause of ballooning, in fact, quite the reverse is true. The result, of course, is a scrapped shell, due to faulty cavity.

An understanding of this phenomenon in flow of metals is important, mainly to prevent its occurrence. The question of where the shell material in the region of die contact flows to is a matter of least resistance. Not only is it conceivable, but demonstrable, that if the friction between the punch shank and shell is too little (too well lubricated), and if the contact point between die and cup is too close to the base, and particularly if too much gas pressure is built up due to combustion of the lubricant, then ballooning is a certainty.

In earlier years, this gas-pressure formation was so serious that mandrels were drilled with a central hole to permit the backward escape of gases, although a needle of metal was usually formed by the metal's being forced into the same hole and had to be subsequently "spaded" off, or peened over. This imperfect method of reducing gas pressure has been more recently replaced by the device of always making the piercing punch slightly larger than the draw mandrel, thus permitting the gases to escape as the shell passes through the first draw ring, and before it has been forced down to mandrel dimensions. Even now, if a careless operator lubricates the mandrel too liberally, enough gas pressure can be built up to propell the shell off the end of the mandrel at dangerous speeds, as it emerges from the last draw ring.

Some mitigation of the running-ahead tendency may be obtained by placing the draw rings close enough together so that the shell is entering the next ring die before it quite leaves the preceding one. This expedient also reduces the over-all length of the draw press, but the increase in draw force involved usually discourages operators from adopting this practice. In some plants, where this difficulty has been only imperfectly overcome, the shell is allowed to be pushed against an end stop, after it has left the last die ring, thus re-establishing the cavity form again.

Roller-Type Dies Adopted

The first serious effort to reduce draw-mandrel pressures once the optimum design of ring die was reached was to resort to roller-type dies. In this construction, a nest of 2, or 3, or even 4 rollers, is designed to form a circular roll pass, capable of taking considerable reduction. The decrease in required pressures and the prolonged die life have proved the value of this modification. However, even with roll sets staggered with respect to each other, each consecutive set "ironing out" any fins or overfills left by the preceding one, it is still necessary to retain a final ring die which serves to smooth down the surface and more accurately size the outside of the shell. A preferred expedient to minimize fins, etc. is to machine a flat, or even a peripheral projection at the bottom of the concave-roll contour that will just offset the tendency of the metal to flow into the spaces between rolls.

A great deal of difficulty was encountered when roller dies were first installed, due to an increased tendency to run ahead, and several operators abandoned the construction because of it.

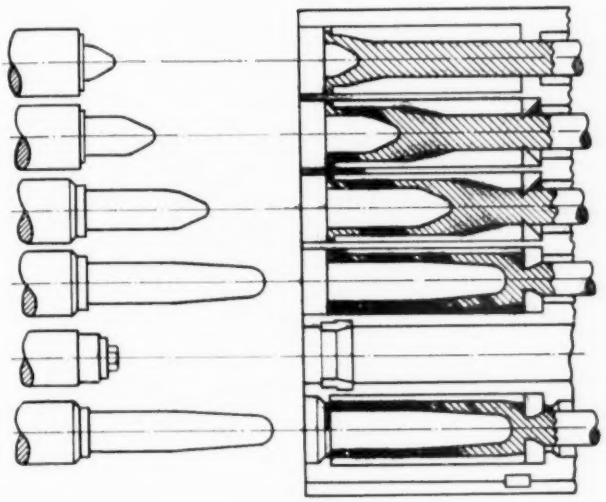

FIG. 6

However, after gaining a proper and detailed understanding of the determining influences, it has developed that all sizes of shells may be drawn through roller draw benches, and preferably so. The important difference between the actions of the ring die and roller die in running ahead of the shell is illustrated in Fig. 5, in which it is seen that, due to the decreased friction of the roller die, the component of the draw force tending to keep the cup on the mandrel is considerably less. The remedy has been so to modify the taper of the boat-tail that the first contact point between shell and die is well behind the internal contact point between mandrel tip and shell.

Another very recent method of elongating pierced shells, introduced essentially at the beginning of this war, has been to cross-roll the cup between 3 driven shape rolls, inclined at an angle to each other, while being mounted on a mandrel, which also assists in the forward motion through the mill. An additional aim of this machine is to reduce cavity eccentricity, the idea being that for equal roll pressures (and they will tend to be essentially so), more metal will be reduced where the absolute thickness of metal is greater. Thus a bottle having a $^{3}/_{4}$-in-thick wall on one side and $^{5}/_{8}$ in. thickness on the opposite side might well reduce to $^{3}/_{8}$ in. and $^{5}/_{16}$ in., say, after an over-all 100 per cent elongation, thus reducing the difference in wall thickness by substantially one half. However, there can be no correction of this sort on the boat-tail, which may be an important shortcoming, particularly for long boat-tail shells. There is sufficient merit in this method, however, for it to be well worth further study. In the draw bench, the tendency is more to concentrate the load on the thinner side (particularly if the shell is only in one die at a time) thus making it even thinner, and causing bending (banana shell) and increased eccentricity.

The principle of operation of this mill merits a separate paper in itself. Suffice it to say that the formed rolls rotate so that they tend to feed slightly at the same time they tend to rotate the shell rapidly. The action of the mandrel, however, is to aid in feeding the mill, so that a helix angle of metal flow is obtained. This angle must be such that it has a tangent greater than 1.8, to avoid premature metal rupture along a flow line, in a longitudinal tension test. Most of the work of reducing is done by the "hump" on the rolls, and while considerable difficulty was experienced in its early days of development, and while the method still requires personnel familiar with the intricacies of shape-rolling, it definitely constitutes a contribution to the art of shell elongation. Cross-rolling alone, however, does not produce a finished shell, and it is finally pushed through one or two ring dies to take out any rolling marks, to push the shell back

FIG. 7

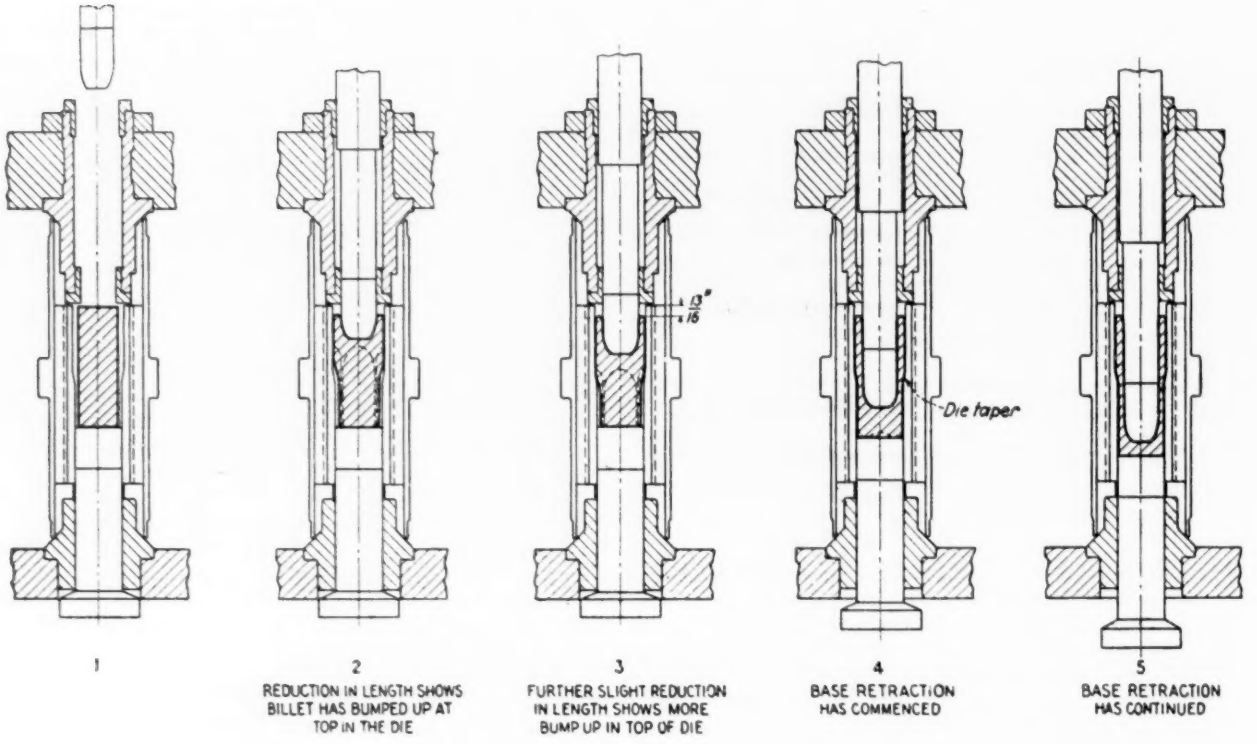

FIG. 8

onto the mandrel if the circumferential component of rolling has expanded it too much, and finally to size it.

There have been many and varied attempts to simplify the shell-forming process, primarily along the lines of reducing the amount of elongation, or eliminating it entirely. A generally successful sequence has been to double-pierce and then draw through a single ring. In this scheme, during the first piercing operation, the billet is upset (flattened or cabbaged) and only slightly indented, thus serving to center the billet in the die firmly and accurately. With this preliminary piercing accomplished, it is then possible to pierce practically to completion (using a punch shape that defines the finished cavity). The last operation is to withdraw the punch, now with the billet on it, and slip into place a die ring (at the same time rotating the piercing die out of position), and then a second operation of the punch sizes the shell. The well-designed machine has both punch mandrels in the same head, which are indexed in and out of position, with the final finished shell being drawn vertically downward.

"Upsetter" Method of Shell-Forging

Another and very successful attempt to eliminate drawing has been the development of the "upsetter" method of shell-forging, which comprises a series of progressive piercings from billet to final forging. The chief advantage offered by this method, from the flow-of-metal point of view, is the freedom of choice permitted in the punch-and-die design, up to the last set, which must conform to the outside and inside shapes prescribed pretty much by the finish-machined contours. The design of the production machine, based on the multiple-pierce idea, has been to use split dies, all dies being parts of a single die block and therefore opened and closed together. The machine is mechanically operated, both as to the operation of the dies, through toggles, and for the operation of the punch block. In the early tool designs, excessive pressures and die wear were encountered and led to the adoption of "forging with a collar," as shown in Fig. 6. A study of the flow of metal shows great ingenuity and thought in the matter of tool design. In the first pass, the conical-shaped punch forces the metal sideways to fill up the die (and thus centers the forging), as well as forms the collar (shown in black). The pointed punch is retained in the next two steps, with the metal being practically wedged apart, in an effort to obtain the ideal "laying-out" action described earlier; all the time the metal is in slight tension, pulling against the collar formed during the first pass. The 4th pass finds the punch assuming a form closely resembling the final shape in the 5th piercing pass (actually the 6th, since a collar-shearing operation is carried out in between).

The conception that the process causes the metal to flow only radially without any extrusion, is not borne out by an examination of split shells, with inserts imbedded therein, to reveal flow patterns. In Fig. 7, it is seen that the inserts do not remain radial, but are inclined both to the surface of the punch and of the die, showing relative-motion drag in each case. Due to the fact that wall thicknesses in this method are thin (final) in each pass, and also that a more pointed punch is used than is usual in piercing punches, piercing pressures, as measured by calibrated strain gages, mounted on the upsetter-machine tie rods, and also on the pitmans of the machine, are on the high side of the figures mentioned earlier in the paper, ranging from 55,000 to 60,000 psi maximum. Due to these pressures, if the die-closing toggles are not rigid enough or if any wear has taken place, the dies tend to open up slightly, resulting in both eccentricity and ovality of the forged cavity. Due to the fact that the machine is of the mechanical-crank type, watchfulness is maintained that oversize billets are not put into the machine, as abnormally high forces could be developed which might result in breakage. Because multiple punches and dies are employed, and can be

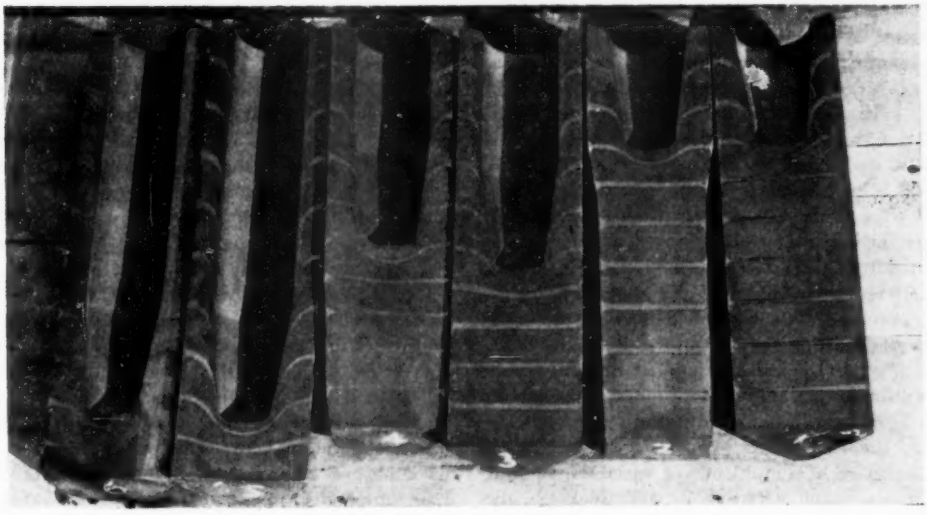

FIG. 9

plentifully cooled between passes, long tool life is obtained. For the smaller sizes of shells, this method has proved outstanding.

FORGING SHELLS BY "ONE-SHOT" PROCESS

The ultimate in simplicity in shell-forging, as has been said earlier, would involve piercing to completion in one stroke. As early as the last war, attempts along such lines reached commercial proportions. The difficulties presented by attempting to produce a shell in "one shot" are (1) thin walls, (2) long pressure stroke, resulting in greater tendency of punch to bend and punch tip to fail, and (3) long taper of punch tip, since the punch must conform to the final finished cavity. The consequences of (1) and (3) are to increase greatly the required piercing pressures, which when coupled with (2), which means greater tendency for lubrication failure and longer time in contact with hot metal, tend to decrease tool life disastrously, not to mention worse eccentricities and rough cavities.

The point of attack in approaching this problem in 1914–1918 was to decrease the required piercing pressures by eliminating as much as possible the movement of metal relative to the die walls. The idea was sound. The tremendous role of friction in metal flow, such as necessarily takes place in shell-forging, is appreciated when it is realized that free, unrestrained compression of shell steels at temperatures around 2200 F requires only about 4000 psi. The idea adopted was to build the shell die in two parts, the cylindrical wall and the base. The base was held fixed, but the wall die was left free to float, the idea being that as the metal moved axially either upward or downward, the floating die would move freely with it, reducing wall-friction effects. The method was developed to a satisfactory commercial degree.

However, when the same method was resurrected at the beginning of the present war, it failed because of the increased stringency of requirements, mainly as to forged-finish cavities and closer tolerances. Another possible objection was that since the metal-flow velocities are not all equal along the wall, there still is bound to remain some degree of frictional resistance, even in a floating die. The problem was solved by now holding the wall die fixed, allowing the base to retract, as a function of pressure build-up, and most importantly, carrying out the operation very rapidly (as compared with the early practice). Fig. 8 shows the various stages in the formation of a British shell as made by this method in Canada and is self-explanatory. Pressures involved vary from 45,000 psi to 55,000 psi maximum, referred to the punch area. We would expect about the same pressures for United States H.E. shells, since although British shells require a blunter punch, they have thinner walls and are specified to be forged at lower temperatures. Excellent concentricity of shell cavities, with smooth satinlike internal finishes, are obtained. The problem of tool materials for the deep penetrations involved is solved by the use of cast iron for both punch and die alike, following practice in similar situations in the hot-rolling of steel. The comparatively short punch life of from 50 to 75 shells before redressing is just about compensated for by the lower cost of cast iron compared to tool steel. The question of why such good concentricity is retained in spite of the relatively high pressures mentioned earlier must be answered by the fact that in this process only about 30 per cent of the total pressure is permitted to come on the base. The remaining resistance must therefore be distributed along the punch body, resulting in less tendency to bend, etc.

This method, popular in Canada, is practiced with variations in one American forge, although less perfectly since a separate base-setting operation is required. Both practices require that the billet be gripped tightly near the open end (a collar being forged on in one case) so that metal pressure against the die walls is decreased, tending further to reduce frictional effects. The primary reason why this method has attained success has been a clever attack on the problem of metal flow, see Fig. 9.

While much could be said of other methods and variations in shell-forging, notably the French extrusion method, their lack of widespread use at the present time will constitute a limit on this discussion, as well.

For the H.E. type of shell, it has never been possible to forge completely the ultimate shape of the shell. In all cases, the shell forging must be subsequently formed to give the projectile the proper shape along the ogive. In earlier days, and particularly in Europe, shell forgings were frequently made with the nose integral (instead of the base, as now). However, the weakness of the screwed or assembled base interfered with the proper fragmentation of the shell, and so the present general practice was adopted, requiring a separate forging operation called "nosing."

"NOSING" OPERATION

Nosing, as it is generally practiced, is accomplished by forcing a contoured die over the open end of the shell. While similar

results could be obtained by spinning, swaging, or hammering, the required contours, metal thickness, etc. do not require anything more elaborate than the simple operation mentioned. Even this simple operation, however, requires a great deal of intelligent study.

At the beginning of the war, and particularly earlier, it was deemed essential that shell forgings be heated, even to a forging temperature of 2200 F in some cases, in order to carry out the operation. It was soon realized that when the die was forced down (usually) over the shell, the compression stresses built up, varying from practically zero at the open end, increasing to a point where circumferential buckling of the shell took place, attended by equally objectionable wall thickening. It was thus obvious that differential heating of the shell was necessary, and, accordingly, it is now general practice to heat only slightly more than that which is ultimately required in forming the nose. In addition to the matter of distribution of initial temperature, it was evident, and still is, that the nature of metal flow from initial shape to final is a function of a multitude of variables, such as friction, machine finish, initial variation in wall thickness, die temperature, speed of nosing, etc. Accordingly, a theoretical and experimental investigation was sponsored, and is reported in a companion paper by Nadai and Carlson, to attempt to correlate fundamental concepts with actual experience.

In order to obtain circumferential uniformity in heating for nosing, particularly for the older furnaces, it is necessary to rotate the shells as they project into the heating zones. Uniformity of heating in one case is obtained by use of a salt bath, but unsatisfactory axial variation in temperature results. More recently, heating by high-frequency (1000 to 3000 cycles per sec) induction has been introduced. Because of the thinness of the shell walls, heating times are not long even for the older furnaces, varying from 5 to 15 min, and, consequently, scale formation is not the serious problem it is in forging. For the induction method, the time is reduced even to a matter of seconds, and by judicious spacing of the induction coils, ideal temperature distribution may be obtained.

The importance of the speed of nosing was muffed badly by several operators early in the war. In an attempt to use old, slow nosing presses, ram speeds as low as 1 ips were encountered. Even though the actual flow resistance is less at slower speeds the long time of contact with the cold dies cooled off the shells so rapidly (sometimes dropping 800 to 1100 F) that the presses would "stall' before completion of the operation. This situation was aided considerably by heating the dies to say 600 F(at which temperature they would tend to maintain themselves in production). Nosing speeds were increased, as well, and many hydraulic presses operate as high as 30 ips, dropping down to say, 5 to 10 ips for the last $^1/_8$ in. of the operation. For the same temperature, an increase of speed from 1 ips to 10 ips would only increase the nosing pressure by about 25 per cent whereas a drop in temperature only 400 F would increase the pressure 100 per cent.

The matter of lubrication in nosing is of great importance. For instance, a good lubricant will result in the shell actually increasing in length as a result of the nosing operation, whereas a poor lubricant will result in its shortening. A poor lubricant, say, by virtue of its being burned out before the operation is completed, may so increase the pressure required that the shell may buckle, the press stall, and the shell stick in the die long enough to result in a cracked die, and hence a pro luction delay. A well-maintained lubricating film also reduces the cooling off of the shell, to a degree.

Cold Nosing

It can be understood therefore because of the problems involved in hot-nosing, such as heating costs, matters of scale formation, possibilities of buckling, nonuniformity of nosing (unless lubrication, temperature distribution, speed, etc. are watched closely), that attention was diverted toward the possibilities of cold-nosing. At the present time, it is universal practice to cold-nose 75-mm and 90-mm shells, and about 75 per cent of the 105-mm shells are cold-nosed. The 155-mm shells are, however, all hot-nosed, and it is interesting to examine the factors involved.

At the outset, we must recognize that the specific compressive resistance cold is about 4 to 5 times that of the hot steel at the temperature it has at the completion of the nosing operation, say 1500 to 1600 F. However, our ability to lubricate better the cold operation than the hot, going from friction coefficients as high as 0.6 to 0.8 down to values of the order of 0.2 to 0.3, results in the total required pressures being only of the order of twice that conventional for hot practice. This is borne out, for instance, for the 105-mm shells, where hot-nosing is satisfactorily accomplished at pressures of from 100 to 175 tons (dependent upon temperature, etc.), while cold-nosing conventionally requires 300 to 350-ton presses. Cold-nosing of 75-mm shells requires 100- to 150-ton presses.

As has been said, 155-mm shells cannot be cold-nosed successfully. This does not mean that they cannot actually be nosed. As is known, all shells being considered in this paper take the same booster and fuse, so that the larger the shell the larger the ratio of shell diameter to nose diameter. For the 75-mm shell, this ratio is about $1^1/_4$; for the 105-mm $1^3/_4$; and for the 155-mm about $2^1/_4$. The metal flow in the latter case is so severe when done cold that the high residual stresses set up during nosing, inevitably result in cracking and fracture, the nose gradually opening up like a flower. If it were practical, this probably could be avoided by a strain anneal, but this additional operation would more than offset the advantages of the cold operation.

Control of the flow of metal in the nosing operation is one of the most important and one of the most complex aspects of the operation. What is the proper initial shape of shell, as to internal shape, or external shape, and wall thickness, to permit the most expeditious forming of the nose. In some cases, the outside of the shells are left perfectly cylindrical (just as they come from the draw benches), and the inside cavity is varied by shaping

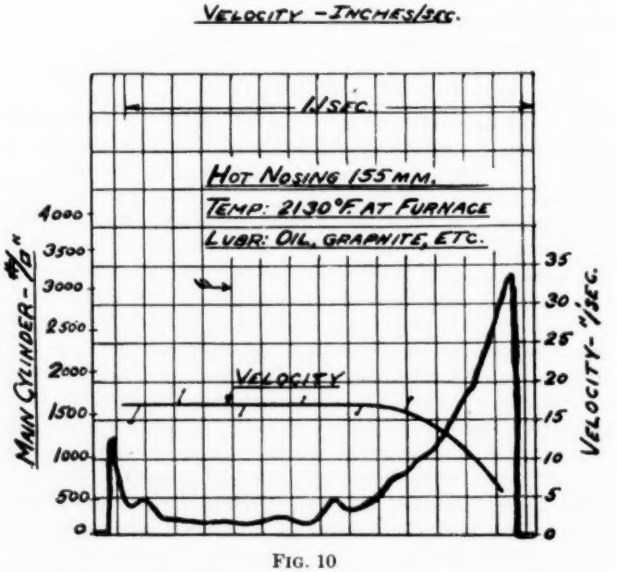

Fig. 10

the draw mandrel. This is obviously an ideal method since it minimizes machining costs and conserves metal. More often, however, the cavities are left cylindrical, and the outside is machined to a template. At best, however, certain empirical procedures must be relied on—sometimes the machine finish may so influence the efficacy of lubrication (too smooth a finish does not hold the oil in place, for instance, etc.) that a shell will shorten one time, and lengthen the next.

From an examination of the type of resistance met in the nosing operation, Fig. 10, it may be in order to observe how naturally a crank-type press fits the requirements. Crank-type or mechanical presses usually are less expensive than hydraulic presses (when a special hydraulic system is to be included), but suffer from the objections that they develop their force only near the end of the stroke, and being positive stroke machines, may develop forces sufficient to break the machine if workpieces too large for space allowed are inadvertently used. The shell, being nosed, moreover, is a workpiece that if accidentally too long, may relatively easily take up the extra length without developing abnormal pressures.

Forces Acting in the Piercing of Cylinders

By W. TRINKS,[1] PITTSBURGH, PA.

THE present paper refers to the forging of a hollow cylinder (with a solid base) which is an intermediate product in the making of munitions as well as of seamless tubes. In the making of goods of both kinds, a cylindrical (or almost cylindrical) body of circular cross section is incompletely pierced by a punch. The bottom or base remains solid and is not pierced. As a rule, the cross section is a round-cornered square at the beginning of the piercing process, but it changes to round at the time when the force which is required for piercing reaches its maximum value. The "slug" (so-called before piercing) becomes a "cup," or a "bottle," or an "intermediate blank" after piercing.

The force which is required for piercing is of importance to the mechanical engineer because it is he who has to build and guarantee the machines which do the piercing. Several experimenters have determined the piercing force, and theories have been proposed for determining this force analytically. A good bibliography on this subject is given by Dr. G. Sachs.[2]

This paper is an attempt to consider the effect of a number of variables and to predict, at least in a general way, the influence of each of these variables upon the force which is required for piercing.

Punches are either cylindrical, with a flat end, or else tapered as shown in Fig. 1. The latter, being the more general case, is considered here. In Fig. 1 an axial element dx is shown with a generatrix length $dx/\cos\alpha$ where α is one half of the total cone angle. The variable radial pressure is p, and the pressure on the cone element is $p\cos\alpha$. The frictional unit pressure along the cone element is $p\cos\alpha\tan f$, where f is the friction angle.

The pressure against the die is difficult to estimate. For infinitely thin blanks, it equals the pressure against the punch. For very thick blanks, the pressure against the die is almost zero because tangential stresses in the pierced material carry the load in almost the same manner in which the walls of a gun carry the force of the explosion. The assumption is here made that the pressure against the die is 40 per cent of the pressure between plastic material and punch. Evidently this assumption is too low for thin-walled shells and too high for thick-walled shells. In the final answer, this assumption, if wrong, can easily be corrected. Observation of die wear confirms the correctness of the assumption.

Then as the punch is forced into the plastic material, increase of axial force on the punch between points (1) and (2) is

$$dP = 2\pi r(dx)p(\tan\alpha + \tan f)$$

where P, r, x, and p are variable and where f, the friction angle, may also be variable. A relation between the variables is furnished by the following equation (see Fig. 2): Axial component of friction force equals difference of force on two sides of annular area between die and punch. Algebraically, the equation is

$$2\pi r(dx)p(\tan\alpha + \tan f) + 2\pi R(dx)0.4p\tan f = 0.7(dp)\pi(R^2 - r^2)$$

The factor 0.7 indicates that part of the increase in pressure is due to 1 p (against the punch) and part of it due to 0.4 p (against the die). Substituting the relation

$$r = r_0 - x\tan\alpha$$

we obtain

$$2(r_0 - x\tan\alpha)p(\tan\alpha + \tan f)dx + 0.8Rp\tan f(dx) = 0.7[R^2 - (r_0 - x\tan\alpha)^2]dp$$

The integration can be performed if α and f are constant. If they are not constant, then they can be considered constant for short lengths x, and the integration can be performed in steps. Separating the variables and expanding furnish

$$\frac{dp}{p} = \frac{2r_0(\tan\alpha + \tan f) + 0.8R\tan f - 2x\tan\alpha(\tan\alpha + \tan f)}{0.7(R^2 - r_0^2) + 2\times 0.7r_0 x\tan\alpha - 0.7\tan^2\alpha x^2}dx$$

The right-hand differential is of the form

$$\frac{(m + nx)dx}{a + 2bx + cx^2}$$

the integral of which is (for the case in question)

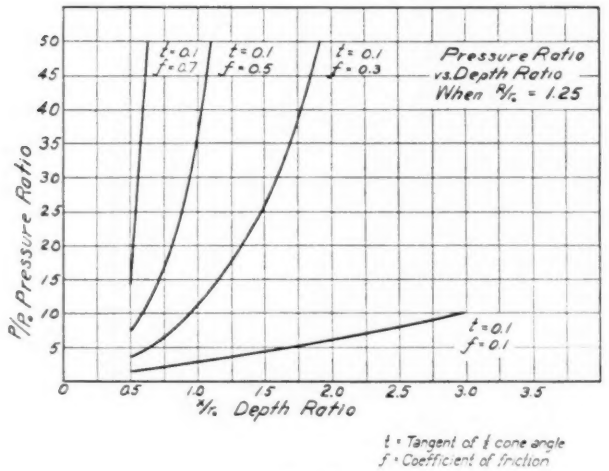

FIG. 3

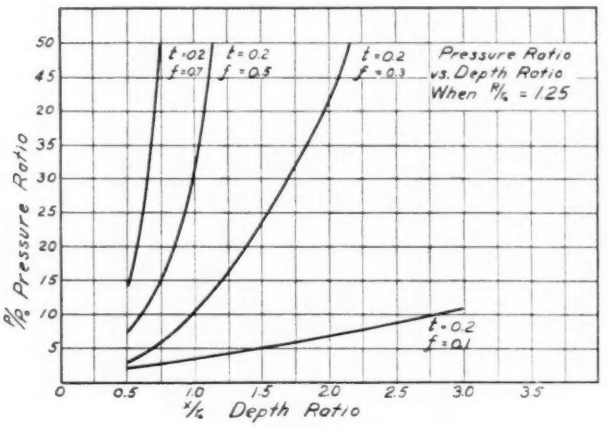

FIG. 4

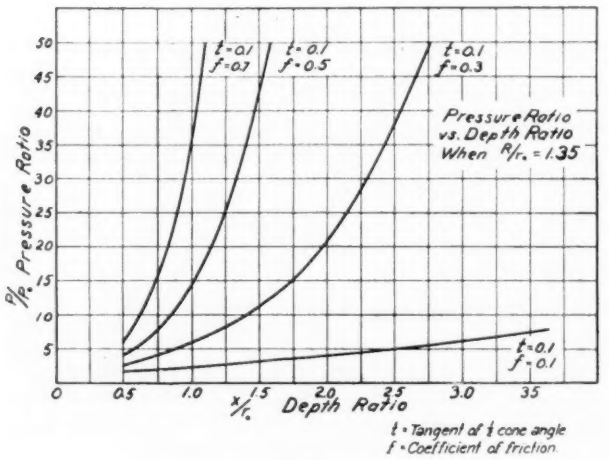

FIG. 5

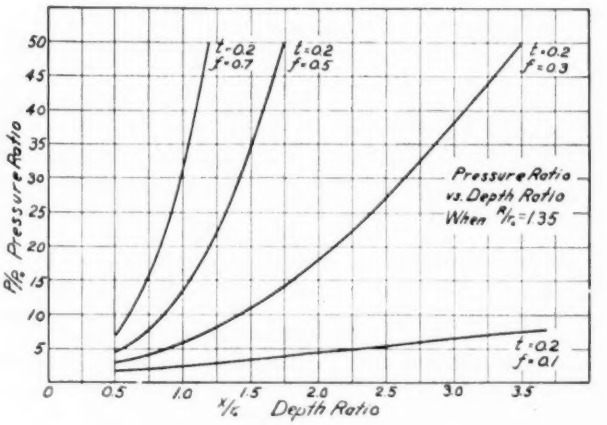

FIG. 6

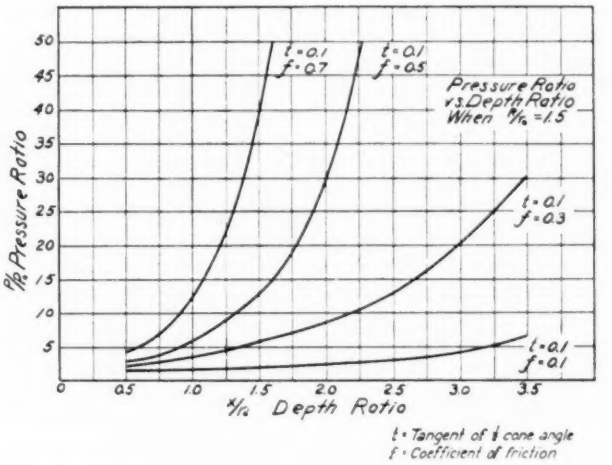

FIG. 7

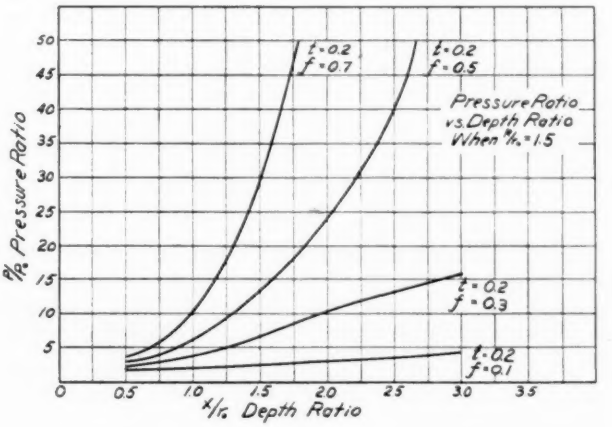

FIG. 8

$$\frac{n}{2c}\log_e(a + 2cx + cx^2) + \frac{mc - nb}{c}\frac{1}{2\sqrt{b^2 - ac}}\log_e\frac{\sqrt{b^2 - ac} - b - cx}{\sqrt{b^2 - ac} + b + cx} + C$$

The next step is to substitute in this integral the corresponding quantities for m, n, a, b, and c. The work is shortened if t is written for tan α and f for tan f. Then

$$\begin{aligned} m &= 2r_0(t + f) + 0.8Rf \\ n &= -2(t^2 + tf) \\ a &= 0.7(R^2 - r_0^2) \\ b &= 0.7r_0t \\ c &= -0.7t^2 \end{aligned}$$

The integral is of the form

$$\log_e p = A \log_e f_1(x) + B \log_e f_2(x) + C$$

where $f_1(x)$ and $f_2(x)$ are two different functions of x. Calling p_0 the radial pressure against the punch at the top of the cone where it merges into the cylindrical position of the punch, integration between limits furnishes

$$\frac{p}{p_0} = [f_1(x)]^A + [f_2(x)]^B$$

The substitutions are not difficult, but long and tedious; they are therefore omitted. The final equation is

$$\frac{p}{p_0} = \left[\frac{\left(\frac{R}{r_0}\right)^2 - \left(1 - \frac{xt}{r_0}\right)^2}{\left(\frac{R}{r_0}\right)^2 - 1}\right]^{\frac{t+f}{0.7t}} \left[\frac{\left(\frac{R}{r_0} - 1 + \frac{xt}{r_0}\right)\left(\frac{R}{r_0} + 1\right)}{\left(\frac{R}{r_0} + 1 - \frac{x}{r_0}t\right)\left(\frac{R}{r_0} - 1\right)}\right]^{\frac{0.8f}{1.4t}}$$

In this equation t stands for tan α and f stands for tan f.

A change in the assumption that the pressure against the die is 40 per cent of the punch pressure changes only the exponents. If, for instance, the pressure against the die equals 0.6 p, then the first exponent becomes $\frac{t + f}{0.8\,t}$ and the second one $\frac{1.2\,f}{1.6\,t}$. It should be noted that the friction coefficient does not appear in the base but only in the exponents where it appears in the ratio, $\frac{\tan f}{\tan \alpha} = \frac{f}{t}$.

In order to gain a sense of values with regard to the numerical influence of the different variables, the pressure ratios $\frac{p}{p_0}$ were plotted against the depth ratios $\frac{x}{r_0}$ where x equals the axial distance from the largest diameter of the cone and r_0 is the largest radius of the cone at the point where it merges into the cylindrical section of the punch. The curves were plotted for two cone angles, 5.72 deg (tan α = 0.1) and 11.31 deg (tan α = 0.2). For each cone angle, four coefficients of friction were selected. They are 0.1, 0.3, 0.5, and 0.7. Another variable had to be taken care of, namely R/r_0, which expresses the thickness ratio after piercing. Three values for R/r_0 were selected; they are 1.25, 1.35, and 1.50. The six graphs thus obtained are shown in Figs. 3 to 8.

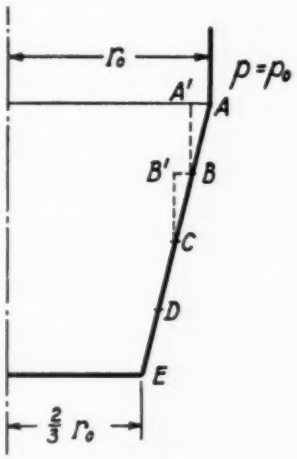

FIG. 9

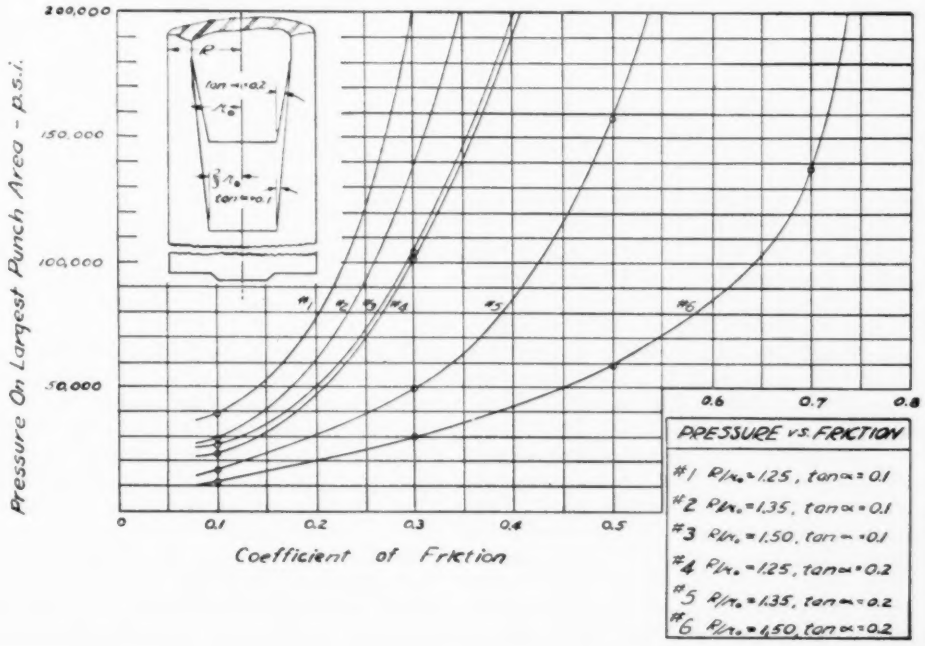

FIG. 10

These curves are not the goal; they are an intermediate step toward a second integration by means of which the axial force (which resists penetration by the punch) can be computed. It is possible to write a differential equation for this force by making use of the exponential equation for the pressure ratio. It may, however, not be possible to integrate that equation. For that reason the following step-by-step method of summation was used:

A cone with flat bottom, the latter having a diameter equal to two thirds of the maximum diameter, was selected (see Fig. 9). Its length was divided into four equal parts, and the average pressure for each section was computed. The pressure ratios were taken from the curves (Figs. 3 to 8) for points B, C, D, and E. The calculation was carried out for two values of α and for three values of R/r_0. The average pressure between A and B was taken to act on annulus $A'A$; the average pressure between B and C was taken to act on annulus $B'B$, and so on.

Some doubt exists about the manner in which the radial pressure at E affects the axial pressure against the bottom of the cone. For want of a complete theory, the axial pressure acting on the bottom area was taken to be 20 per cent higher than the radial pressure at point E. The value of 20 per cent was selected by judgment to account for the frictional resistance of the plastic material while flowing radially outward along the bottom. The friction factor is affected by the distance between bottom of punch and bottom of die. The influence is almost negligible, except during the last very small fraction of the piercing stroke. The effect of this distance was not taken into account.

All calculations were made for $p_0 = 1$. The summation was then multiplied by the natural flow resistance which was taken to be 5000 psi. This value may be considered typical for 2200 F steel temperature and for average speed of penetration.

The final result of these calculations was plotted in the curves of Fig. 10. It is evident that coefficient of friction, cone angle (tan α = 0.1 and 0.2), and the ratio of diameters of die bushing and punch (1.5, 1.35, 1.25) exert great influence on the piercing force.

The combination of a long, slender taper (tan α = 0.1) with a thin wall of shell (R/r_0 = 1.25) causes enormously high punch forces even with a low coefficient of friction, whereas a short stubby taper (tan α = 0.2) combined with a thick-walled forging (R/r_0 = 1.5) causes low punch loads, even for fairly high coefficients of friction.

Punch Pressures

In practice, punch pressures between 25,000 and 60,000 psi are on record. In general, they follow the trend indicated by the curves of Fig. 10, in so far as cone angle and wall thickness are concerned. Unfortunately, no numerical check between theory and practice is possible because, up to the present time, no method exists for measuring the coefficient of friction between punch and slug.

For some combinations of wall-thickness ratio and cone angle, the theoretical punch pressures assume exceedingly high values, much higher than those recorded in practice. The difference between theory and practice is probably caused by slip friction changing to nonslip friction when the coefficient of friction and the pressure assume high values. By that statement is meant that in such a case the hot metal does not slide along the tool but sticks to it, deformation taking place in the hot metal. This method of deformation is well known from the flow around the bottom of a punch as illustrated in Fig. 11. The metal in the section-lined portion sticks to the punch, and flow occurs in the metal along the dotted line. The actual flow boundary is best observed in dirty steel. Fig. 11 was traced from a sectionalized cup or bottle made from steel with segregation lines.

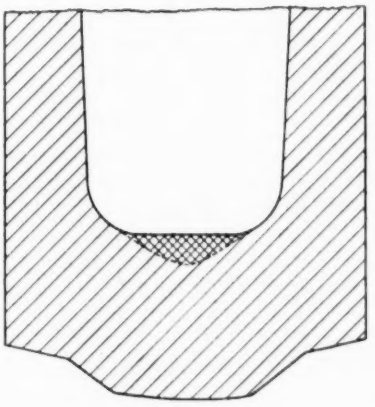

Fig. 11

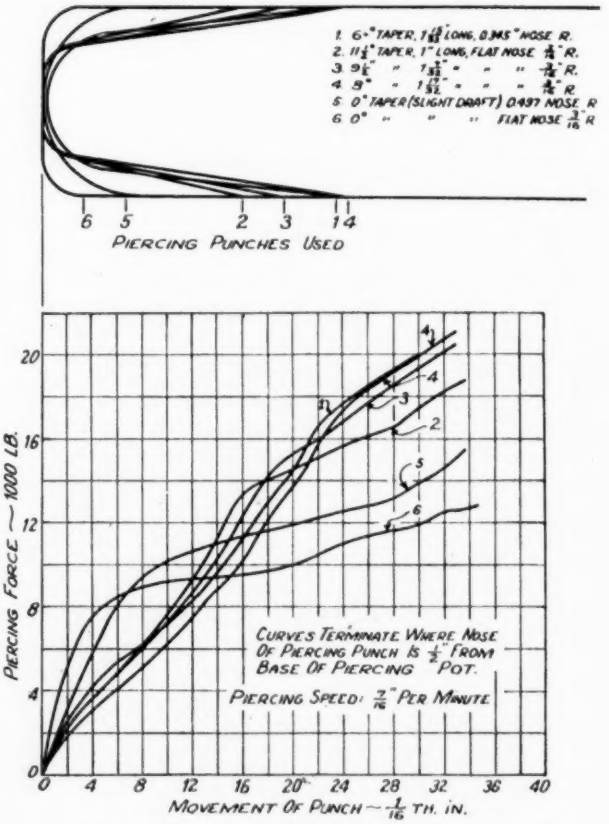

Fig. 12

The correctness of the theory developed in this paper is confirmed by tests which were made at Case School of Applied Science, Cleveland, Ohio, under direction of Prof. G. Sachs. These tests were made by piercing lead slugs of $1^{15}/_{16}$ in. diam with punches a little less than 1 in. diam. The results of these tests afford a comparison of the effects which different shapes of piercing points exert upon the force which is required for piercing. In Fig. 12 (which was plotted from the test data), it is observed that the pointed punches (No. 1 and No. 4) penetrate easily (local deformation) but build up a great resistance at deep penetration, whereas the flat punches (No. 5 and No. 6) offer a more nearly constant resistance because they reach constant conditions of flow earlier in the stroke.

Experimental Study of Shell Drawing

By GEORGE SACHS[1] AND G. B. KASIK,[2] CLEVELAND, OHIO

1 INTRODUCTION AND OBJECT

THE "forging" of high-explosive steel shells presents a difficult problem in hot-working steel because of the severe deformation accomplished from billet to finished forging. The problem is further complicated by the necessity of maintaining close tolerances as dictated by the shortage of material, labor, and equipment, especially in the early stages of production.

To meet this problem, several methods and/or combination of methods have been employed for shell manufacture. The five most important methods may be classified as follows, it being understood that variations in many details occur which modify this strict classification.

In all modern methods the forging is made to a finished cavity, or the finish-machining restricted to the outside of the shell. The entire forming cycle of the shell consists in the "forging" of the finished cavity of the shell and its "nosing" after machining. Only the forging phase is discussed in this report.

1 *The Pierce-and-Draw Method.* Nearly 50 per cent of all high-explosive shells are fabricated by this method. The shells are processed in either hydraulic or mechanically operated presses in two stages. In the first stage, a piercing press is employed to forge a cavity in a solid round or square-shaped slug in one or two operations. Then, in the second stage, the pierced slug is transferred to a drawbench, which carries the pierced slug, "cup," or "bottle," over a mandrel having the shape of the finished cavity, through a series of dies, thereby reducing the diameter and wall thickness, and elongating the shell. Ring dies or roller dies may be used, and up to 22 dies in tandem have been installed on a drawbench; however, 4 to 6 is the usual number of passes required to accomplish the reduction from the pierced to the finished forging. In some mechanical forging machines the piercing and drawing are accomplished by the same machine.

A recent modification of the pierce and draw method known as "progressive pierce and draw" has been developed. By this method the slug is progressively pierced in solid dies by two or more operations to nearly the dimensions of the final forging. This pierced slug is then engaged over a draw mandrel, conforming to the dimensions of the finished cavity, and drawn through one or two sizing rings. The transfer of the forging from station to station may be manual or automatic.

2 *The Upset Method.* By this method a single forging machine progressively pierces the solid billet, generally in five stages, to form a finish-forged shell. The upsetter utilizes five punches or mandrels, and correspondingly five split dies which comprise the various stations. The tools work horizontally and are arranged vertically. The billet progresses from the top station, where it is upset and a centering depression made by a short punch, to the bottom station where a relatively long punch, conforming to the shape of the finished cavity, sizes the diameter of the finished forging and brings the base to the proper thickness.

3 *The Pierce and Cross-Roll Method.* By this method a billet is first pierced either by a press or drop hammer which furnishes the bottle for the shell-rolling mill. Three contoured rolls are used of such design and so aligned as to force the cup over a mandrel having the shape of the finished cavity. Following the rolling operation, the forging, with the mandrel still in it, is pushed through a sizing ring to iron out the slight grooves and irregularities left by the rolling operation.

4 *The Extrusion Method.* Considerable controversy exists as to the optimum division of work between the initial piercing operation and the secondary drawing, or sizing, operation. The extrusion method accomplishes most of the deformation in the first operation by extruding the hot solid billet, held in a short die, over a punch having nearly the dimensions of the final cavity. The tip of the punch is positioned only a short distance into the opening of the die or container holding the billet. The metal extrudes out along the punch but is unrestrained along the outside surface. During the operation, the die bottom and billet move against the die and punch, such that the billet is pushed out of the stationary die over the stationary punch. The method has the advantage of a minimum friction between the billet and tools, since high friction is present only at the die mouth where the metal is forced through the orifice between die and punch. Practically no friction exists along the undeformed billet and die wall except for a small amount created by the slight upsetting of the billet in the die.

5 *The One-Shot Method.* In the "one-shot" forging method, the punch enters the solid billet held in a split piercing die and moves relative to the die. It differs in this respect from the extrusion method in which the punch position relative to the die is fixed. In order to minimize backward extrusion along die and punch, the bottom of the die is allowed to recede against a predetermined pressure as piercing progresses. Thus, only the part of the billet which is unworked at a given point of the operation, and which offers little frictional resistance along the die wall, is moved. Essentially this method is forward extrusion; and since the pierced section is restrained between punch and die, it can be held to close limits. The forged shell is obtained in one operation, the piercing punch having the dimensions of a finish-forged cavity.

The need for correlating desirable information as to the best practice for forging shells by the various previously discussed methods, and making it available to forging plants, has prompted The American Society of Mechanical Engineers, authorized by contract with the Ordnance Department, to undertake a survey of present practice. Because conditions encountered in the field are not entirely suited to accurate investigation of some of the fundamental variables, the department of metallurgy at Case School of Applied Science accepted an offer to amplify the A.S.M.E. Shell Forging Research Committee's report by laboratory-controlled tests covering numerous variables encountered in the drawing phase of the pierce-and-draw method. The choice of this field of investigation rested on the premise that the pierce-and-draw method was most important by virtue of the fact that more shells are made, at present, by this method than by any other.

Originally, the work was scheduled to cover only the hot-drawing of model steel shells, but adverse conditions during the beginning of the investigation delayed procurement of the experimental equipment. Therefore work was started using lead for the test metal, since the necessary equipment for drawing this

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

material was on hand. Lead was chosen also because of its amenability to experimental work in that it could be readily handled, and important variables, such as friction, could be closely controlled; further, lead can be hot-worked at room temperature to simulate hot-working of steel at high temperatures.

The important variables encountered in the drawing operation which have been investigated include the following:

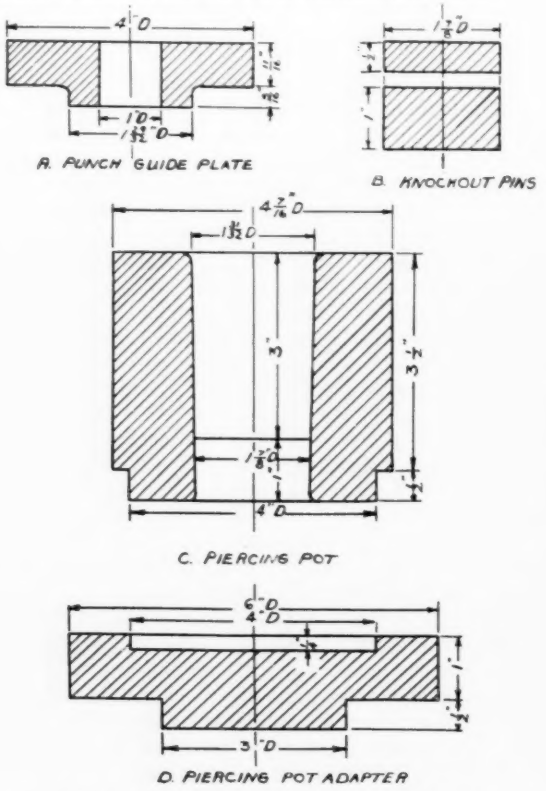
1 Effect of reduction of area in a single pass through ring dies
2 Effect of boat-tail
3 Effect of die angle
4 Effect of cavity shape
5 Effect of punch shape
6 Effect of wall thickness
7 Effect of base thickness
8 Effect of lubrication
9 Effect of speed.

In order to correlate the results on steel with those of lead, tests were run covering the effect of a given variable on both materials. Most of the variables were investigated in this manner.

In addition some observations were made on the piercing of lead slugs.

2 MATERIAL AND PROCEDURE

The material and procedure for this investigation can be divided into two more or less distinct parts, namely, the work with lead specimens, and the work with steel specimens.



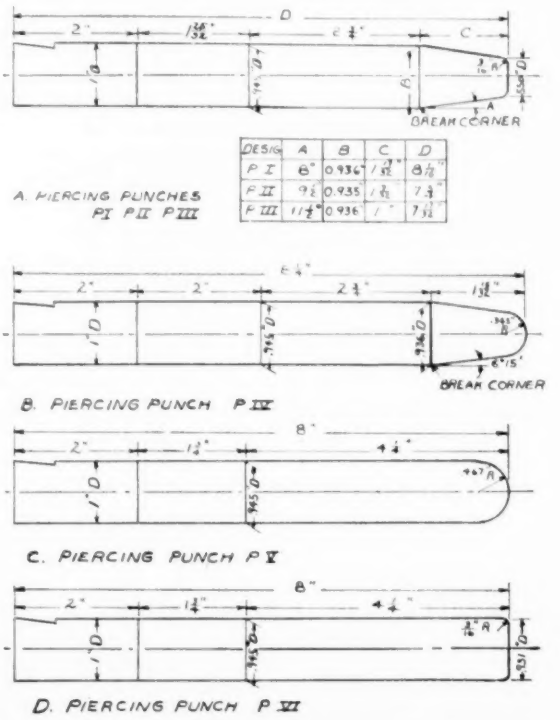


FIG. 1 TOOLS REQUIRED FOR PIERCING LEAD

WORK WITH LEAD SPECIMENS

Commercially pure lead having the following chemical analysis was used in this part of the work: 0 per cent Sn, 0.002 per cent Sb, 0.15 per cent Cu, trace of Zn, remainder Pb.

Small slugs were individually cast in the die pot used for piercing. The piped section was removed by sawing and the slugs cleaned preparatory to the piercing operation.

Piercing was done with a 10,000/60,000-lb Tinius Olsen testing machine. Dimensioned sketches of the piercing tools are

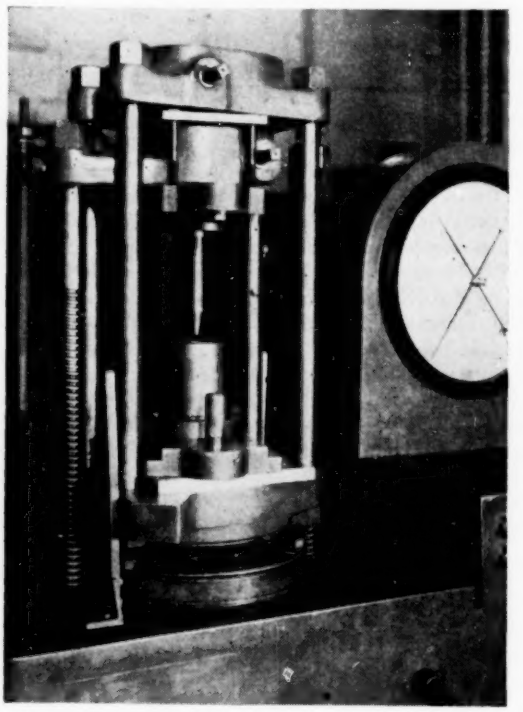

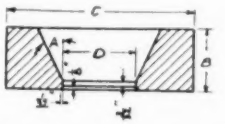

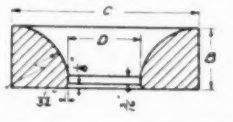

FIG. 3 TOOL ASSEMBLY AND TESTING MACHINE FOR PIERCING LEAD

shown in Figs. 1 and 2. The testing machine and piercing assembly are illustrated in Fig. 3. Piercing was performed at a speed of 0.5 to 1 ipm. Representative force-stroke curves were taken for each of the six piercing punches used. In general, the depth of pierce was $2^1/_2$ in., or such as to permit the base of the pierced slug to be faced in a lathe to $^1/_2$ in., which was the standard base thickness used in these tests.

B. RADIUSED DIES

FIG. 4 DIMENSIONED SKETCHES OF DRAW DIES

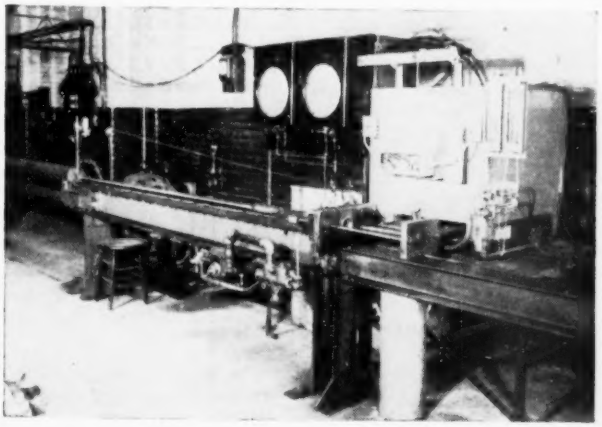

FIG. 6 DRAW BENCH AND AUXILIARY EQUIPMENT FOR DRAWING LEAD AND STEEL CYLINDERS

For the early tests S.A.E 20 machine oil and castor oil were tried as lubricants; for later tests, concentrated oil dag (a suspension of colloidal graphite in petroleum oil having a solids content of 10 per cent by weight) was used with more satisfactory results. The lubricant was swabbed on die, punch, and slug.

Following the piercing operation, all pierced lead slugs were annealed in an oil bath for 45 min at 300 F. This reatment fully annealed and homogenized the structure.

The bottles were machined to the desired dimensions prior to the drawing operation. This consisted essentially in turning the specimens on a mandrel held in a lathe to various outside diameters and shapes. The standard specimen, pierced with piercing punch IV, was turned to the following dimensions:

Outside diameter	1.525 in.
Wall thickness	0.292 in.
Base thickness	0.5 in.
Length: Lot 1	$2\ ^{23}/_{32}$ in.
Lot 2	$3\ ^1/_4$ in.
Lot 3	$3\ ^1/_2$ in.

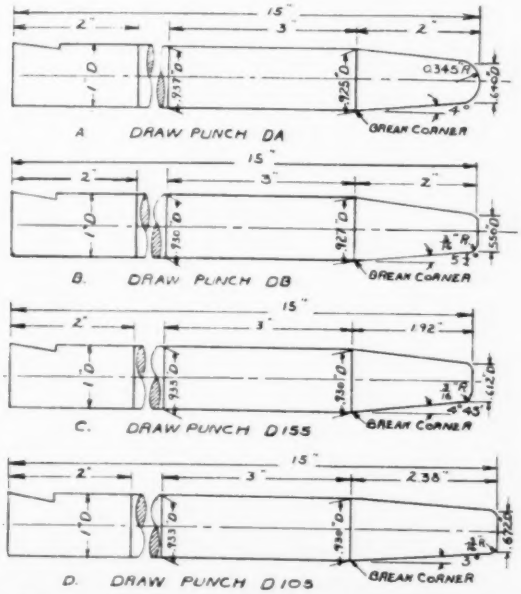

FIG. 5 DIMENSIONED SKETCHES OF DRAW MANDRELS

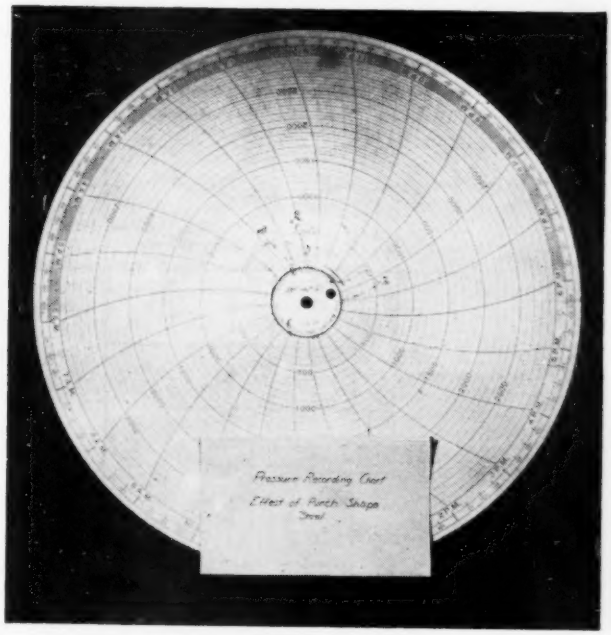

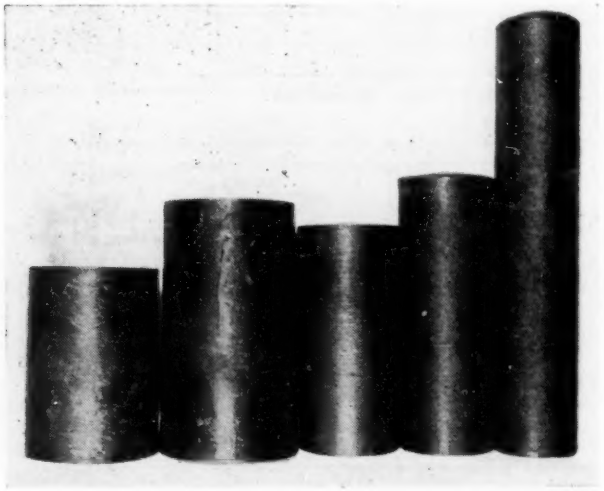

FIG. 7 PRESSURE-RECORDING CHART FOR RECORDING FORCES OF DRAW DIE; $\times^1/_3$

Variations from the standard dimensions were obtained by turning to various outside diameters, turning boat-tails (outside tapers at the base), facing the base to different thicknesses, or by piercing with different piercing punches.

Regarding the drawing operation, the tools used, i.e., dies and draw mandrels, are shown in the dimensioned sketches, Figs. 4 and 5. Four different mandrels were used, and 13 dies of various nominal diameters and contours.

Most of the drawing was performed on an experimental hydraulic drawbench, Fig. 6, loaned to Case School by the Wolverine Tube Company, Detroit, Mich. The bench was converted from a drawbench to a push bench by the use of a yoke arrangement which carried the draw mandrel. The bench was equipped with a Hanna hydraulic cylinder having a 4-in. bore, $1^1/_2$-in. piston rod, and a 7-ft stroke. It was originally equipped with a vane-type pump capable of delivering 5 gpm of oil at a maximum pressure of 1000 psi. With this system, the speed of drawing could be varied from approximately 0 to about 9 fpm. For the most part, 27 ipm was the draw speed used for the lead draws.

(a, Cast and cropped slug; b, pierced slug; c, machined bottle; d, drawn bottle; e, redrawn bottle.)

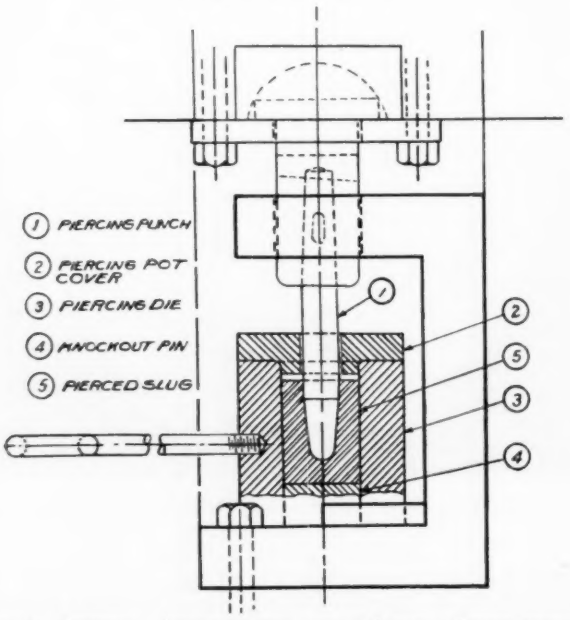

FIG. 9 GENERAL ARRANGEMENT FOR MAKING EXPERIMENTAL SHELL FORGINGS

In order to speed up the drawbench, a 40-gpm gear pump and larger valves were installed, which permitted a maximum free draw speed of about 80 fpm.

In order to record the forces involved in the drawing operation, the drawbench was equipped with a modified Emery cell which transmitted pressure variations on the die to a recording pen. The recording pen traced these pressure variations on a calibrated chart driven by a synchronous motor, Fig. 7. By knowing the speed of rotation of the chart, a force-stroke curve was readily constructed. The assumption was made that the speed variation of the drawbench under load was negligible, although at high pressures this was not strictly true. Furthermore, at high draw speeds, the first impact peak was not registered by this system, the time interval being of too short duration to allow the recording system to reach equilibrium. To obtain the force-stroke curves for the high-speed tests, a steam-engine indicator was employed, which will be described later.

For a lubricant in the lead-drawing operations, Ironsides AF-11 diluted 2 parts of water to 1 part of lubricant, by weight, was employed. This was found to give most satisfactory and consistent results, after having tried castor oil and mineral oils.

The drawn shells were readily stripped and then measured for changes in dimensions. In representative cases, the shells were split longitudinally to facilitate checking the changes in contour.

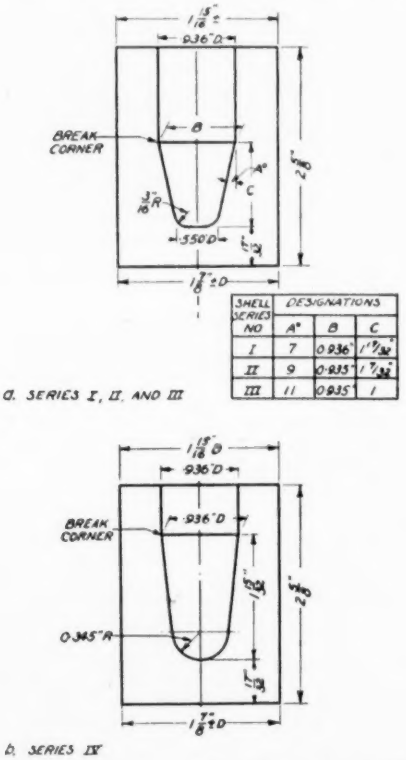

FIG. 10 DIMENSIONS OF PIERCED STEEL BOTTLES

In Fig. 8 are shown the several steps for the sequence of operations with lead, namely, (*a*) the cast and cropped slug, (*b*) the pierced slug, (*c*) the pierced slug after machining, (*d*) the drawn bottle, and (*e*) the redrawn shell.

WORK WITH STEEL SPECIMENS

The material for this part of the investigation was cut from rod stock having the following analysis: 0.34 per cent C, 0.87 per cent Mn, 0.028 per cent P, 0.016 per cent S, 0.20 per cent Si.

The pierced steel slugs were supplied for this investigation by the Shell Forging Research Committee and were pierced in a C-press, a sketch of which is shown in Fig. 9; no piercing of steel was carried out at Case School. The dimensions of the pierced cylinders are shown in Fig. 10. Unfortunately, however, the actual pierced slugs varied considerably in some respects from the drawings shown. This was particularly true with respect to the shape of the bottom of the cavity which, in many cases, was ballooned badly.

These as-received bottles were then machined to the desired dimensions; the standard-machined bottle, pierced with P IV piercing punch, had the following dimensions:

Outside diameter	1.400 in. (or such as to permit 20 per cent reduction in a single pass)
Length	$2^{5}/_{8}$ in.
Base thickness	$^{1}/_{2}$ in.

Because of the power limitation at the draw bench (11,000 to 12,000 lb maximum force on the mandrel) a 1.328-in. nominal diameter die was used for most of the drawing, which required a bottle outside diameter of 1.400 in. to obtain 20 per cent reduction. As in the case of lead, some bottles were turned with boat-tails (3 to 10 deg taper from a 1.220-in. base diameter) and/or various outside diameters.

Prior to the drawing operations, the machined specimens were raised to forging temperature, 2200 deg F, in a high-temperature Hevi-Duty electric furnace equipped with Smith alloy heating elements. A controlled atmosphere was produced and maintained by an Electric Furnace gas generator. Generally, an atmosphere consisting of a 7:1 air-gas ratio, at 250 cfh at the generator and 1.0 in water pressure at the furnace was used. The gas was dried by passing it through Electrodriers which reduced the dew point to —60 deg F. No CO_2 removal was attempted. The cold pierced forgings were placed in the furnace and held 30 to 45 min before drawing.

All steel drawing was performed on the hydraulic drawbench, previously described under lead drawing, Fig. 6. In the case of

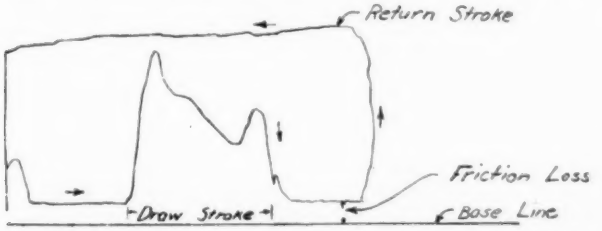

FIG. 11 PRESSURE-DISPLACEMENT CURVE REGISTERED BY ENGINE INDICATOR; ×1

steel, however, only a few preliminary tests were carried out at slow speed (8 fpm), since cooling of the specimen took place to such an extent before completion of the operation that the draw force required was more than the bench could develop. Consequently, the greatest number of steel draws were run at about 40 fpm; even so, sufficient cooling was encountered as to raise the draw force appreciably toward the end of the draw. The time required to remove each specimen from the furnace and complete the draw was about 10 sec; thus, the base temperature would drop 100 deg F, and the wall temperature 200 deg F, by the time the bottle hit the die. The wall temperature would drop as much as 400 deg F, by the time the draw had been completed.

Because the pressure-recording system, which was used for the lead draws at slow speeds, failed to register the peaks in the force-stroke curve at high speeds, a Maihak steam-engine indicator was employed in the steel draws. This indicator was connected in the hydraulic oil line on the pressure side of the cylinder. The indicator drum was actuated by the drawbench piston through a reducing mechanism. Thus a fairly accurate pressure-displacement curve, Fig. 11, was obtained which was readily converted to a force-stroke curve. The actual draw force on the mandrel at any time was taken as the product of the measured oil pressure in the pressure side of the cylinder during the draw (minus the friction loss at no load) and the effective piston area. The stroke was computed by adding to the length of the drawn shell, the contact length along the die, plus any bending or piercing of the bottom of the shell during drawing.

During the preliminary draws in steel, severe scoring of die and mandrel occurred which materially decreased the drawability and increased the draw forces. In these runs, light machine oil and flake graphite were swabbed on die and mandrel before each draw. Mixtures of colloidal graphite in light machine oil at various concentrations were also tried without success. A few special light-oil-vehicle lubricants, containing graphite particles of various macro sizes, in addition to colloidal graphite, also proved unsatisfactory.

Finally, a lubricant composed of heavy mineral oil (near grease), with graphite of colloidal and macro size (Fiske's No. 514-A hot die lubricant) was adopted which proved most satisfactory.[3]

Both the draw mandrel and die were swabbed with lubricant prior to each run.

The practice of "graphoiding" the surface of the tools was employed. This consisted in thoroughly degreasing the tools after which they were preheated to 300 to 350 F. They were then dipped while hot in a dilute solution of aqua dag[4] two or three times, allowing the solution to dry on the tools between each immersion.

It was found that Meehanite dies, heat-treated for high strength, resisted scoring and pickup much better than steel dies; the flake graphite in the cast iron apparently acts as a lubricant in itself. It was noted in this investigation that the first pieces drawn through a die caused severe pickup which then tended to smooth out with successive draws. Also, a heavy reduction caused less scoring of the land or bearing than did a light pass.

[3] We are indebted to Mr. J. R. McKee, representative for Fiske Brothers Refining Company, Toledo, Ohio, for his co-operation in furnishing this lubricant.

[4] One part concentrated aqua dag, 20 parts distilled water. This formula and the concentrated aqua dag were furnished through the courtesy of G. F. Willson, representative of Acheson Colloids Corporation.

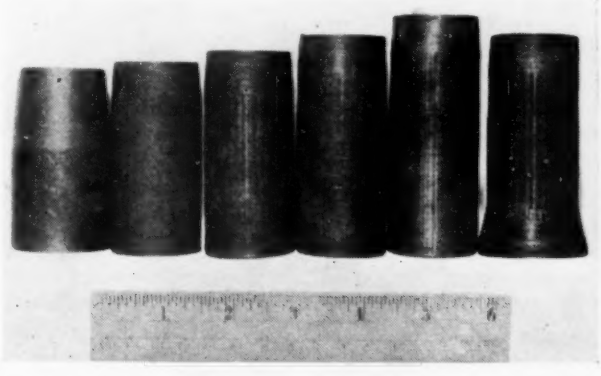

FIG. 12 SERIES OF DRAWN STEEL SHELLS SHOWING THE AS-TURNED BOTTLE, 9, 20, 30, $40^{1}/_{2}$, AND AN ATTEMPTED 44 PER CENT REDUCTION

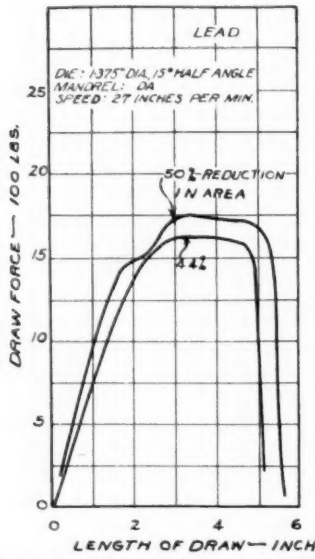

FIG. 13 FORCE-STROKE CURVES FOR VARIOUS REDUCTIONS WITH BOAT-TAIL

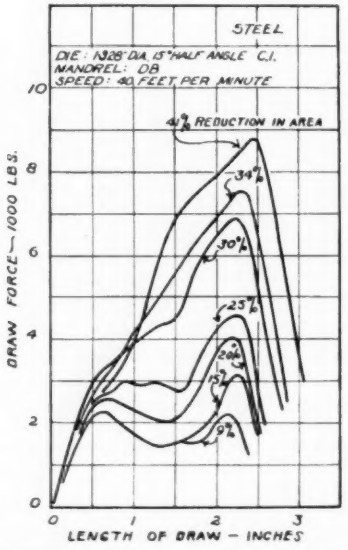

FIG. 14 FORCE-STROKE CURVES FOR VARIOUS REDUCTIONS WITH BOAT-TAIL

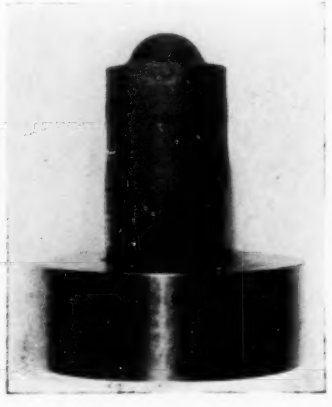

FIG. 15 AN ATTEMPTED STEEL DRAW OF 44 PER CENT REDUCTION IN AREA WHICH STALLED THE DRAW BENCH; ×1/2

Before a run was made, the draw die was preheated to about 600 F. Between each draw, the mandrel was removed and water-quenched to 100 F.

3 RESULTS OF TESTS

REDUCTIONS PERFORMABLE IN DRAWING A SHELL

When a pierced slug or "bottle" is pushed through a draw die, it is generally observed that the mandrel punches or pierces through the bottom if a reduction in diameter and wall thickness above a certain limit is attempted. The wall of the bottle does not participate in this operation; and it will be shown later that the same failure occurs if an attempt is made to push or "extrude" a circular blank through the die. Consequently, in order to eliminate this failure, or to increase the limit of reduction of the wall thickness, the diameter of the base can be reduced. This is

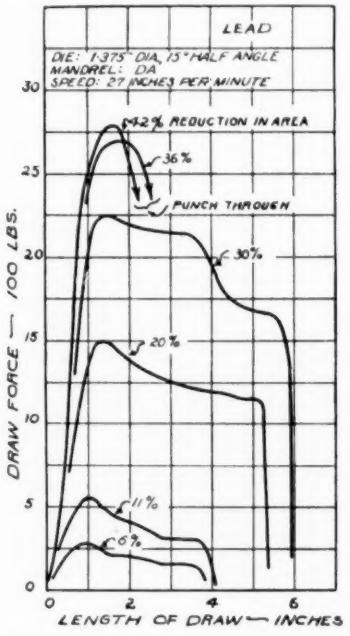

FIG. 16 FORCE-STROKE CURVES FOR VARIOUS REDUCTIONS WITHOUT BOAT-TAIL

a common commercial procedure, resulting in a bottom with a tapered base, or boat-tail.

Attempts were made to determine the possible wall reduction by using model bottles in lead and steel with a sufficiently extensive boat-tail, Fig. 12. With such bottles,[5] base failures are eliminated, and rupturing in the wall should occur if the attempted reduction exceeds the limits of forming. However, in the tests on both lead, Fig. 13, and steel, Fig. 14, this limit could not be reached because it required test conditions beyond the limits of equipment. With lead, the available dies and mandrels permitted reductions of the cross-sectional area of the cylindrical portion of the bottle up to 50 per cent, and no failure occurred at that reduction. Therefore the limit of reduction or "drawability" of lead tubing, drawn over a moving mandrel, or "rod" (as opposed to a stationary mandrel, "plug," or "pin") exceeds 50 per cent. With steel, a reduction of 44 per cent could not be achieved because of the high load which stalled the drawbench, Fig. 15, while a bottle was drawn successfully with 40½ per cent reduction in wall area. The observed possible high re-

[5] In this series with varying reductions, the variation was only in the outside diameter of the bottle, while the other dimensions were kept constant.

ductions agree both with theoretical conceptions,[6,7] and with experimentation on cold-drawing of other metal products, particularly of cartridge cases.[8] According to the theoretical conceptions, a maximum (average) reduction of over 60 per cent should be achievable, provided that the frictional coefficient be-

[6] "A Theory of Tube Drawing," by G. Sachs, *Modern Industrial Press*, June, 1942, p. 26.

[7] "A Theory of Tube Drawing With a Rod," by G. Sachs, D. Tracy, and J. D. Lubahn, unpublished.

[8] "Cold Working of Cartridge Brass," by F. J. Lerro, *Modern Industrial Press*, Feb., 1940, pp. 8–14.

tween die and bottle is equal to that between bottle and mandrel; and such high reductions can be actually performed.

On the contrary, a square-nosed bottle will draw only up to a certain reduction in diameter of the base; to be discussed later. The common measure of reduction, that of the cross-sectional area of the cylindrical wall, has no influence on the strength of the bottom and, consequently, should vary widely with the geometrical relations of the bottle. Thus in a representative series on lead, Fig. 16, bottles were drawn successfully to a reduction in wall area of 30 per cent; while in other series, maximum wall reductions anywhere between 25 and 38 per cent were encountered, see later. In representative series on steel, Figs. 17 and 18, a reduction of over 22 per cent was achieved while another series yielded a maximum wall reduction as low as 16 per cent. These variations were observed in tests on slightly different shapes of bottle and tools, but optimum frictional conditions.

On the contrary, in a preliminary series in which excessive friction and pickup occurred, the bottom of a steel bottle was pierced at a wall reduction of only 6 per cent, Fig. 19. This result shows that the frictional conditions between bottle and die are another factor of paramount influence regarding the reduction of the bottom of the bottle.

In order to prove the validity of these conceptions, (1) a series of circular lead blanks of increasing diameter were pushed through a die, Figs. 20 and 21, and (2) a series of bottles without boat-tail but with a cylindrical wall were drawn with the same die and cylindrical mandrel (flat-nosed, $^3/_{16}$ in. tip radius). The results, Fig. 22, show (*a*) that the force at which the bottom fails is practically identical in both series, and (*b*) that the force is slightly higher for a bottle than for a disk, the reduction being the same. The actual limit for the disk could not be determined because of

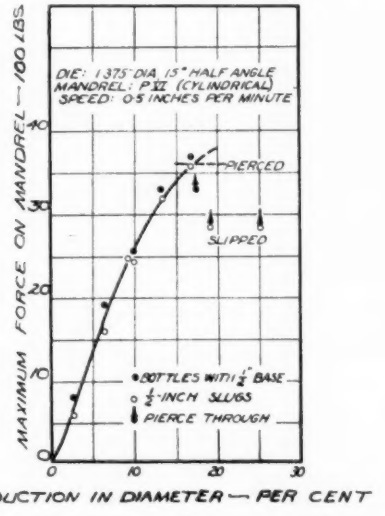

FIG. 23 EFFECT OF REDUCTION IN DIAMETER ON MAXIMUM FORCE FOR LEAD CYLINDERS AND CORRESPONDING CIRCULAR DISKS

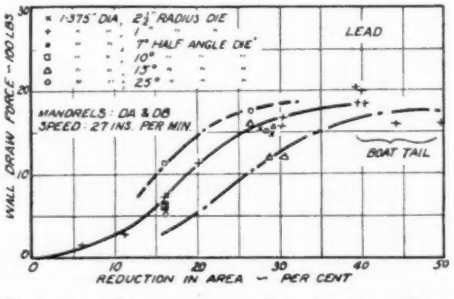

FIG. 24 EFFECT OF REDUCTION AND DIE ANGLE ON WALL DRAW FORCE

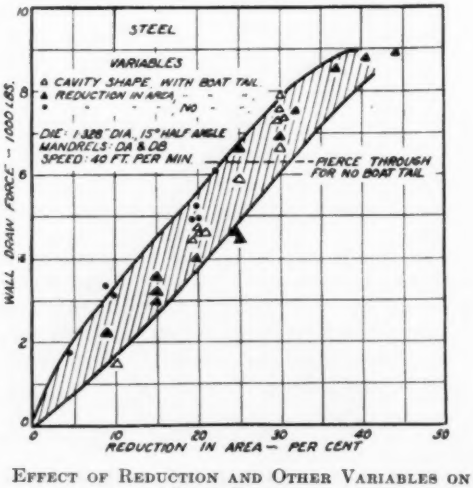

FIG. 25 EFFECT OF REDUCTION AND OTHER VARIABLES ON WALL DRAW FORCE

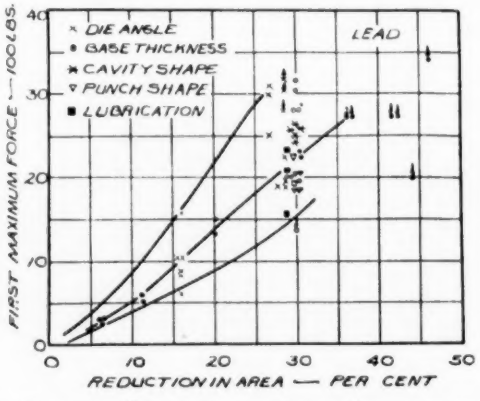

FIG. 26 EFFECT OF REDUCTION AND OTHER VARIABLES ON MAXIMUM DRAW FORCE

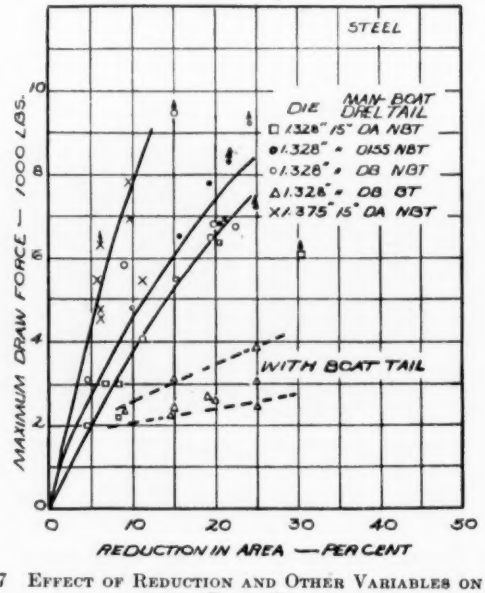

FIG. 27 EFFECT OF REDUCTION AND OTHER VARIABLES ON MAXIMUM DRAW FORCE

slippage, but the piercing force determined by common punching of a disk limits the possible reduction of the disk diameter to practically the same value as that of the bottle diameter, Fig. 23.

Force Requirements in Drawing a Shell

The force-stroke curve for the drawing of a bottle usually possesses a complex shape, which in addition varies widely with the processing condition.

Fig. 28 Bottom Failure (Pierce-Through) for Tapered Mandrel and Predraw Cavity With Lead

Fig. 29 Bottom Failure (Punch-Out) for Cylindrical Mandrel and Predraw Cavity With Lead

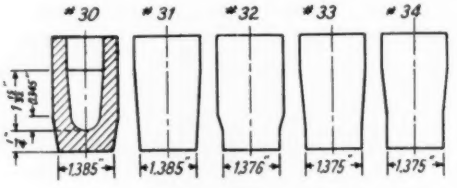
However, if a bottle with a square nose (i.e., no boat-tail) and a cylindrical wall is drawn by means of a cylindrical mandrel, the force-stroke curve, Fig. 22, becomes rather elementary and can be analyzed readily. Such a force-stroke curve generally consists of a "first maximum" superimposed to a practically constant force for the remainder of the stroke.

The first portion of a force-stroke curve is again determined by the diameter and thickness of the base, but in addition, by the reduction of the relatively thick wall close to the base of a commercial bottle.

The experimentation with disks clearly reveals that the force in the region of the first maximum, i.e., from the start of the draw to a certain distance beyond the first maximum, results for the most part from the extrusion of the base (disk) through the die. The slight difference is explained by the fact that a short length of the wall adjacent to the base is reduced simultaneously with the base when it has entered a certain depth into the die.

Fig. 30 Example of Bottom Deformation: Bending, at High Reductions With Lead; $\times 1/2$

The following horizontal portion of the force-stroke curve represents entirely the reduction of the wall, such as occurs in regular drawing of tubing.



The more complex appearance of the force-stroke curves for drawing a bottle with a tapered cavity and by means of a tapered mandrel, Fig. 14, is explained by the fact that both the wall thickness and the reduction in cross-sectional area vary during the stroke. They are governed by the contours of the bottle both before and after the draw; the wall thickness and reduction changing sharply at any change of taper. As the force is roughly proportional to either of these two factors, other conditions being constant, the force may fluctuate irregularly within wide limits. Therefore as the wall thickness of the bottle decreases with increasing distance from the base, any peak in the force-stroke curve (with the exception of the first maximum) also indicates a high localized reduction. These relations, i.e., the change of cross section and reduction during the stroke, can be revealed only by a detailed theoretical and/or experimental analysis of the geometrical relations during the draw.

Superimposed on these variations in force is the increase in the force because of progressive cooling during the draw. As this factor does not occur in the tests on lead, their force-stroke curves usually possess a horizontal portion at the end, where the wall thickness both before and after the draw is constant. On the contrary, the decreasing temperature always causes the force-stroke curves for steel to rise toward the end of the draw.

The force-stroke curves for square-nosed specimens generally exhibit a first maximum, which is larger and extends over a longer stroke, the smaller is the diameter of the cavity at the base. Its shape also determines the subsequent changes in wall thickness, which in turn determine the draw force. The variations in these conditions explain the widely varying appearance of the first portion of the force-stroke curve.

If the base diameter is reduced by a boat-tail, the first maximum correspondingly decreases, and with a sufficiently extended boat-tail, the first maximum disappears, see Figs. 12 and 13.

Other factors being identical both the first maximum (if present) and the draw force increase with the reduction in outside diameter. By convention, the reduction of the cross-sectional area at the mouth is used as the measure for the reduction. Therefore, the force at the end of the draw can be used as representative of the forces required to reduce the wall thickness.

VARIOUS BOAT-TAIL SHAPES INVESTIGATED

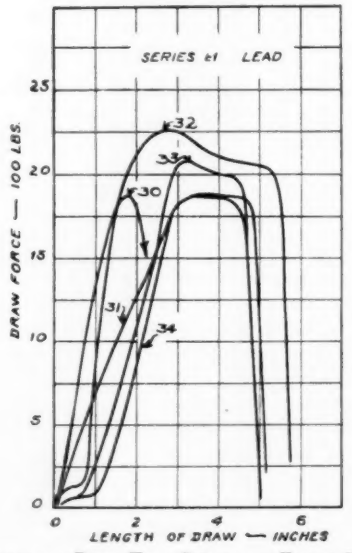


FIG. 31 EFFECT OF BOAT-TAIL SHAPE ON FORCE-STROKE CURVES

Figs. 24 and 25 illustrate the increase in the first maximum, and Figs. 26 and 27, in the final wall draw force, with increasing reduction, for both lead and steel, under widely varying conditions.

It is interesting to note the types of failures which occur when too great reduction is attempted. For specimens without boat-tail, at too-high reductions, a tapered mandrel may pierce through, carrying a small cap of metal just sufficient to cover the mandrel tip ahead of it, Fig. 28; under such circumstances, no fracture occurs at the wall, even though the wall area may be partially drawn. For a cylindrical mandrel, the punched-out cap is larger, having a diameter the same as the die opening, and the fracture occurs at the base of the wall in a typical tensile fracture for hot-working, Fig. 29. For intermediate reductions, where piercing-through does not occur, the bottom may be deformed either by bending and/or by piercing a slight amount; the term "bending" being applied to a deformation of the base without loss of base thickness, Fig. 30.

For steel, piercing through the square-nosed specimens takes place in a fashion similar to that for lead. However, it was noted that in some instances, for comparatively great reductions, the wall of the steel shell showed tendencies to neck down locally about one-half way up the mandrel taper. Apparently, the thick wall in the lower part of the bottle remains hotter and has lower tensile strength than the wall near the mouth which subsequently requires high forces for its reduction.

EFFECTS OF VARIABLES

The numerous variables encountered in drawing a pierced steel bottle, listed previously, could not be followed up systematically, but only by means of spot tests in this investigation. The effects of eight variables each were investigated in this manner for lead and for steel. In order to evaluate clearly the effects of each variable, an excessive number of tests would be required. However, the time and funds allotted for this investigation were limited, which explains why no definite conclusions can be drawn regarding the quantitative influence of each individual factor. Nevertheless, the results of the various series agree with general conceptions and outline a number of qualitative relations. In order to present this material without excessive repetition, it has been decided, therefore, to assemble the results of representative

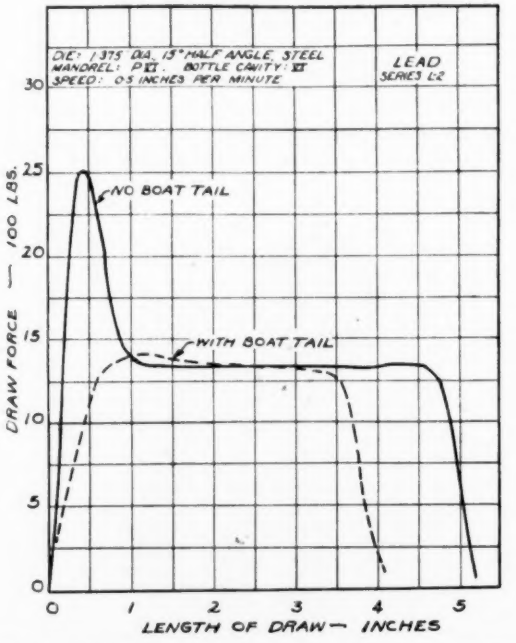

FIG. 32 EFFECT OF BOAT-TAIL SHAPE ON FORCE-STROKE CURVES FOR DRAWING LEAD BOTTLES WITH CYLINDRICAL CAVITIES

series, L-1 to L-9 for lead and S-1 to S-4 for steel, by short individual discussions, supplemented in most instances by graphical representations which summarize the conditions and observations. In addition, general relations and conclusions will be discussed in some detail.

Effects of Boat-Tail Shape, Series L-1 and L-2, Figs. 31, 32:

Lead Bottles:

2 $^{25}/_{32}$ in. long, IV cavity, 1.608 in. OD, $^{1}/_{4}$ in. base thickness, 0.333 in. wall thickness, various boat-tails.

Drawn:

Die.....No. 10, 1.375 in. diam, 1 in. radius, steel
Mandrel.....DA

Lubricant.....Ironsides AF-11, as received
Speed.....27 in. per min
Reduction.....40 per cent

Remarks. The representative series L-1 on lead, Fig. 31, illustrates that the shape and size of the boat-tail has a decided effect on the first maximum force and, consequently, the maximum reduction in wall area. The first maximum may be eliminated entirely by a suitable boat-tail. In the case of such bottles with tapered cavities, it was found that the boat-tail shape also had a slight effect on the draw force required for the reduction of the wall. No explanation can be given for this phenomenon, that the wall-drawing force increased with increasing first maximum.

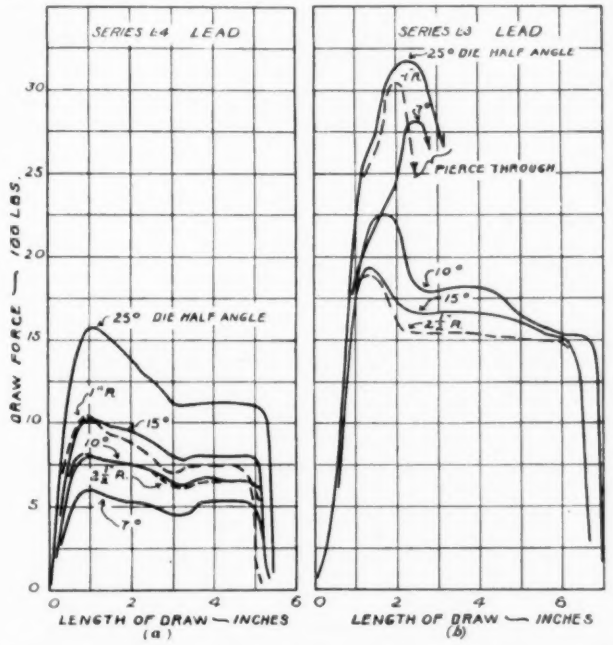

FIG. 33 FORCE-STROKE CURVES WITH VARIOUS DIE ANGLES AND CONTOURS FOR TWO REDUCTIONS

FIG. 34 LEAD SHELLS REDUCED IN AREA 30 PER CENT IN A SINGLE PASS THROUGH 7 DEG, 15 DEG, AND 25 DEG HALF-ANGLE DIES, RESPECTIVELY

In another series, L-2, Fig. 32, with bottles having a cylindrical cavity, it was found that the shape of boat-tail in no way influenced the part of the force-stroke curve representing the drawing of the wall. These tests similated a second draw wherein the punch tightly fitted the bottle cavity before the draw.

Several additional series on steel and lead confirmed the general effects of the boat-tail on the shape of the force-stroke curve and the magnitude of the possible reduction.

This experimentation was not sufficient to establish an optimum contour and length of the boat-tail. Its dimensions should be adjusted to the cavity and mandrel contours, in order to keep the reduction of the wall at the base small. However, the reduction should not be so small as to cause "sinking" of the bottle, i.e., drawing without decrease in wall thickness, which leaves an air pocket between mandrel and bottle, and which may cause a "balloon nose" or "running ahead" of the drawn shell.

Effect of Die Angle and Contour, Series L-3 and L-4, Figs. 33, 34:

Lead Bottles:

2 $^{23}/_{32}$ in. long, IV cavity, 1.454 in. and 1.510 in. OD, $^1/_2$ in. base thickness, 0.256 in. and 0.292 in. wall thickness, no boat-tail

Drawn:

Dies.....
No. 1, 1.375 in. diam, 7 deg half-angle, steel
No. 2, 1.375 in. diam, 10 deg half-angle, steel
No. 3, 1.375 in. diam, 15 deg half-angle, steel
No. 4, 1.375 in. diam, 25 deg half-angle, steel
No. 10, 1.375 in. diam, 1 in. radius, steel
No. 13, 1.375 in. diam, 2$^1/_2$ in. radius, steel
Mandrel.....DB
Lubricant.....Ironsides AF-11, as received
Speed.....27 in. per min
Reduction.....16 and 29 per cent

Remarks. For a relatively large reduction of 29 per cent, Fig. 33 (*b*), series L-3, the optimum die half-angle appears to be about 15 deg, when the first maximum and wall draw force are a minimum. For lower reductions the optimum die half-angle decreases slightly, series L-4, Fig. 33 (*a*).

A small angle die (7-deg half-angle) yields as high a maximum force as does a large (25-deg) half-angle die, but the first maximum portion of the curve is wider and extends over more of the stroke in the latter case, i.e., a considerably greater amount of work is required for a given reduction through a wide-angle die than by smaller angles. This is explained by the fact that, although the friction decreases, the shear or nonuniform deformation increases with increasing die angle, the net result being a greater total drawing stress. For very small die angles, the theoretical draw force is less, due to a wedge action, but friction increases greatly to yield high drawing forces.

If bell-shaped dies of different radii are used, the relation of die radius to draw force, etc. is very similar to that of the die half-angle in the case of straight-angled dies; the important factor in the former case being the chord angle, or "effective angle" of the die, Fig. 33.

With a 7-deg die, the end of the mouth of the drawn shell was nearly perpendicular to the mandrel, but with increasing die angle the mouth sloped in toward the base at an angle of 60 deg with the shell axis, indicating a condition of nonuniform strain during drawing. Fig. 34 indicates the variation in deformation of the base when drawing pierced lead shells through 7 deg, 15 deg, and 25-deg half-angled dies, respectively.

Effect of Cavity Shape Without Boat-Tail, Series L-5, Fig. 35:

Lead Bottles:

3$^1/_4$ in. long, 1.529 in. OD, $^1/_2$ in. base thickness, 0.295 in. wall thickness, no boat-tail

Cavities: I:..... 8 deg, 1$^{17}/_{32}$ in. taper, 0.550 in. diam, flat base
II:..... 9$^1/_2$ deg, 1$^{17}/_{32}$ in. taper, 0.550 in. diam, flat base

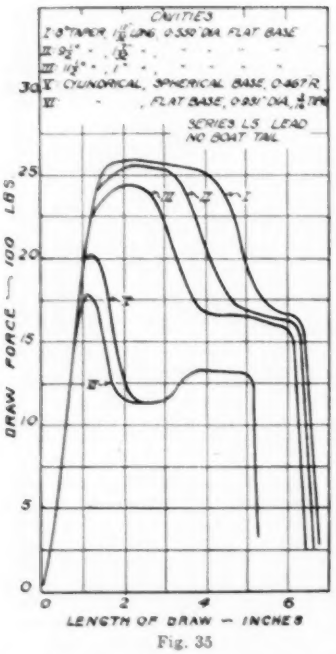

Fig. 35

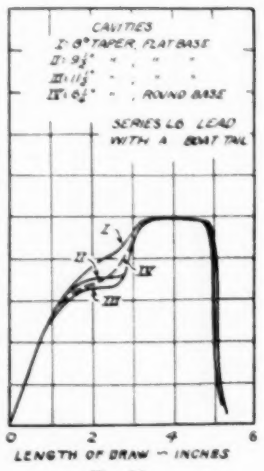

Fig. 36

FIG. 35 FORCE-STROKE CURVES FOR VARIOUS CAVITIES WITHOUT BOAT-TAIL

FIG. 36 FORCE-STROKE CURVES FOR VARIOUS CAVITIES WITH BOAT-TAIL

III:..... 11½ deg, 1 in. taper, 0.550 in. diam, flat base
IV:..... 6¼ deg, 1 13/32 in. taper, 0.345 in. radius, round base
V:..... cylindrical 0.467 in. radius, round base
VI:..... cylindrical 0.931 in. diam, flat base

Drawn:

Die..... No. 10, 1.375 in. diam, 1 in. radius, steel
Mandrel..... DA
Lubricant..... Ironsides AF-11, diluted 2:1 by weight with water
Speed..... 27 in. per min
Reduction..... 30 per cent

Remarks. In Fig. 35 are illustrated the force-stroke curves for this series which show that the first maximum decreases with an increase in cavity size. This is expected since a large cavity (shorter taper) results in a thinner wall near the base, requiring less force for wall reduction in the second stage of the draw operation. Drawing a pierced slug having a cylindrical cavity with tapered mandrel results in a pronounced minimum, indicating pure sinking of the represented portion of the wall.

The cavity shape has a negligible effect on the draw force for the cylindrical portion of the shell wall.

Effect of Cavity Shape With Boat-Tail, Series L-6, Fig. 36:

Lead Bottles:

3¼ in. long, 1.526 in. OD, ½ in. base thickness, 0.292 in. wall thickness, boat-tail (1.375 in. base OD to 1.525 in. in 2 in.—2 deg 11 in. taper), cavities I, II, III, IV

Drawn:

Die..... No. 3, 1.375 in. diam, 15 deg half-angle, steel
Mandrel..... DB
Lubricant..... Ironsides AF-11, diluted 2:1 by weight with water
Speed..... 27 in. per min.
Reduction..... 29 per cent

Remarks. At the given reduction of 29 per cent, the slight variation in cavity shape had little effect on the first part of the force-stroke curves, and no effect, as expected, on the part representing the drawing of the cylindrical wall, Fig. 36.

Specifically, the larger the angle of the cavity taper, or the shorter the taper, the lower is the first part of the force-stroke curve. This is in agreement with results on boat-tail and mandrel shape, since any factor which reduces the reduction at the bottom decreases the first maximum; for in boat-tailing, metal is removed from the outside to reduce the reduction, while with a larger cavity near the base (large cavity taper), or small mandrel taper, there is less metal inside and more clearance, respectively, each of which permits more sinking than ironing of the wall during the draw. Actually for the given reduction with boat-tail, only sinking at various points along the draw-mandrel taper was noted.

Effect of Cavity Shape With Boat-Tail, Series S-1, Fig. 37:

Steel Bottles:

2⅜ in. long, 1.400 in. and 1.460 in. OD, ⅛ in. base thickness, 0.237 in. and 0.268 in. wall thickness, boat-tail (5 deg from 1.220 in. base diam), cavities: I, II, III, and IV

Drawn:

Die..... No. 7, 1.328 in. diam, 15 deg half-angle, Meehanite
Mandrel..... DB
Lubricant..... Fiske's No. 514-A hot-die lubricant, as received

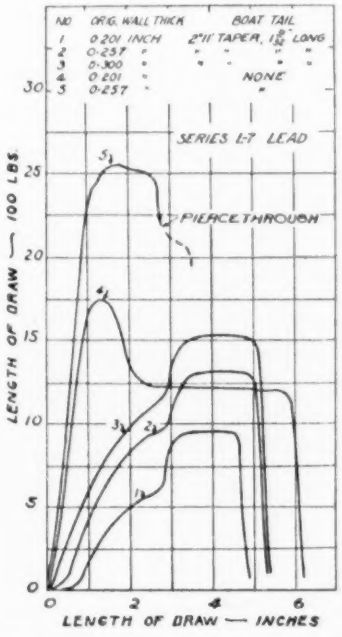

Fig. 39 Effect of Wall Thickness on Force-Stroke Curves

Effect of Punch Shape, Series S-2, Fig. 38:

Steel Bottles:

$2^5/_8$ in. long, IV cavity, 1.400 in. OD, 1/2 in. base thickness, 0.235 in. wall thickness, no boat-tail

Drawn:

Die	No. 7, 1.328 in. diam, 15 deg half-angle, Meehanite
Mandrels	D105: 3 deg taper 2.38 in. long, 0.672 in. diam, flat nose
	D155: $4^3/_4$ deg taper 1.92 in. long, 0.612 in. diam, flat nose
	DB: $5^1/_2$ deg taper 2 in. long, 0.550 in. diam, flat nose
	DA: 4 deg taper 2 in. long, 0.345 in. radius, round nose
Lubricant	Fiske's No. 514-A hot-die lubricant, as received
Speed	40 fpm
Reduction	20 per cent

Remarks. In Fig. 38 are shown the results of drawing with various mandrel shapes accomplishing a given reduction in wall cross section. The following table indicates that the larger the mandrel-nose diameter (equivalent to a smaller cavity at the base) the higher is the first maximum. Drawability is increased by increasing the mandrel-tip diameter, since in so doing more support is offered the base during the first and critical stage of the draw operation.

Draw mandrel	First maximum, lb	Tip diameter, in.	Wall force, lb
D105	7600	0.67	4700
D155	7550	0.61	4800
DB	6850	0.55	5250
DA	6450	0.35 R (round nose)—	

Effect of Wall Thickness, Series L-7, Fig. 39:

Lead Bottles:

$3^1/_4$ in. long, IV cavity, various outside diameters, 1/2 in. base thickness, various wall thicknesses, with and without boat-tail

Lubricant	Ironsides AF-11, diluted 2:1 by weight with water
Speed	27 in. per min
Reduction	27 per cent

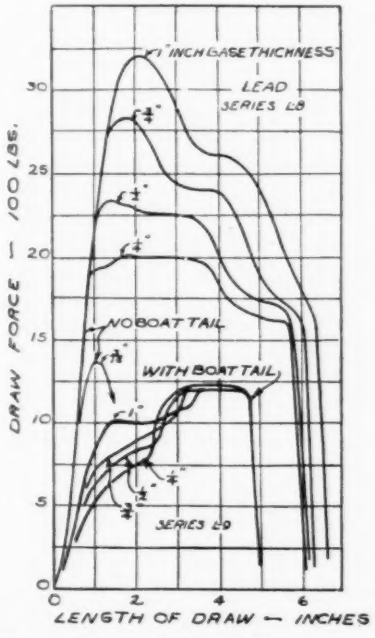

Fig. 40 Effect of Base Thickness Without Boat-Tail and With Boat-Tail

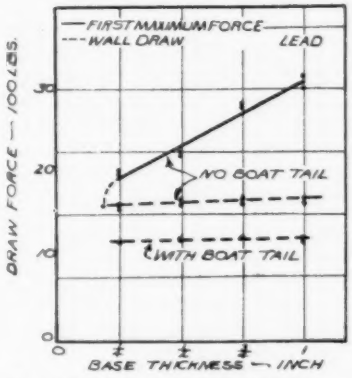

Fig. 41 Effect of Base Thickness

Remarks. The wall thicknesses of the bottles in this seriss ranged from 0.176 in. to 0.309 in. It has been observed in these

tests that as the wall thickness increases, with the base thickness unchanged, the first maximum becomes less pronounced; thus, for a 0.176-in. wall thickness, the first maximum is 100 per cent greater than the wall draw force, whereas for a 0.309-in. wall the maximum force is only 20 per cent greater, Fig. 39. Further, as the wall thickness increases, the first maximum peak changes from sharp to a rounded and wider shape.

The tests also indicate that the unit wall drawing force, i.e., the force related to the unit cross section of cylindrical wall before drawing, increases with increasing wall thickness at a low reduction of 16 per cent, without boat-tail. However, at higher reduction, with boat-tail, there is no effect from thickness over the range investigated.

Fig. 39 again shows that a boat-tail not only decreases the first maximum, but also the wall drawing force.

In general, increasing the wall thickness, while keeping the reduction and base thickness constant, resulted in the same phenomena as did decreasing the mandrel-tip diameter. Thus, unless the mandrel-tip diameter increases relatively with the shell diameter, the tendency to pierce appears. Specifically, while a wall thickness of approximately 0.26 in. pierced at an attempted reduction of 27 per cent, a thinner wall of 0.20 in. could be drawn successfully at this reduction.

Apparently piercing-through does not occur in lead until the compressive stress on the base is about 10,000 psi, as computed from the projected area of the tip of the flat-nosed mandrels. For the round-nose mandrel, DA, the piercing stress is reached at 7000 psi.

Effect of Base Thickness Without Boat-Tail, Series L-8, Figs. 40 and 41:

Lead Bottles:

$2^{23}/_{32}$ in. long, IV cavity, 1.529 in. OD, 0.295 in. wall thickness, 1 in., $^3/_4$ in., $^1/_2$ in., $^1/_4$ in., $^3/_{16}$ in. base thicknesses, respectively, no boat-tail

Drawn:

Die	No. 10, 1.375 in. diam, 1 in. radius, steel
Mandrel	DA
Lubricant	Ironsides AF-11, as received
Speed	27 in. per min
Reduction	$30^1/_2$ per cent

Remarks. A series of pierced lead slugs with base thicknesses of 1 in., $^3/_4$ in., $^1/_2$ in., and $^1/_4$ in. were drawn successfully at $30^1/_2$ per cent reduction, while a $^3/_{16}$-in-base specimen pierced through at this reduction, series L-8, Fig. 40. The first maximum increases linearly with the base thickness but there is no change in wall draw force, Fig. 41. By shifting the respective force-stroke curves a distance equivalent to the base thickness, it was found all peaks occur at the same abscissa value.

The slight difference in length of draw, as shown in Fig. 40, is due, not to a difference in length of drawn shell, but rather to the slowing of the draw bench at the higher loads.

Effect of Base Thickness With Boat-Tail, Series L-9, Figs. 40 and 41:

Lead Bottles:

$3^1/_4$ in. long, IV cavity, 1.525 in. OD, 1 in., $^3/_4$ in., $^1/_2$ in., $^1/_4$ in. base thickness, 0.292 in. wall thickness, boat-tail: 1.375 in. base OD to 1.525 in. OD in 2 in. (2 deg 11′ taper)

Drawn:

Die	No. 3, 1.375 in. diam, 15 deg half-angle, steel
Mandrel	DB
Lubricant	Ironsides AF-11, diluted 2:1 by weight with water
Speed	27 in. per min
Reduction	29 per cent

Remarks. By putting sufficient boat-tail on a specimen, the wall drawing force may be decreased by some 25 per cent, while any increase in base thickness has no effect on this value, but displaces the stroke a distance equivalent to the change in the base thickness.

The first part of the force-stroke curve is affected but slightly by changing the base thickness, and the length of the draw is not altered, Fig. 40.

Effect of Temperature, Series S-3, Figs. 42 and 43:

Steel Bottles:

$2^5/_8$ in. long, IV cavity, 1.400 in. OD, $^1/_2$ in. base thickness, 0.235 in. wall thickness, boat-tail (5 deg from 1.220 in. base diam)

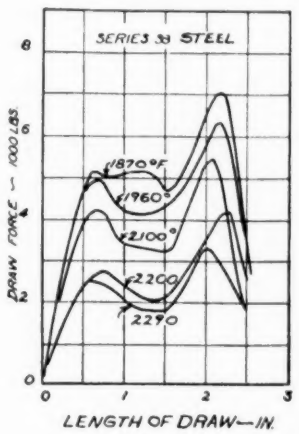

Fig. 42

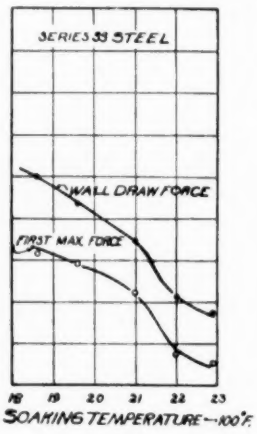

Fig. 43

FIG. 42 FORCE-STROKE CURVES FOR VARIOUS TEMPERATURES

FIG. 43 EFFECT OF TEMPERATURE ON DRAW FORCES

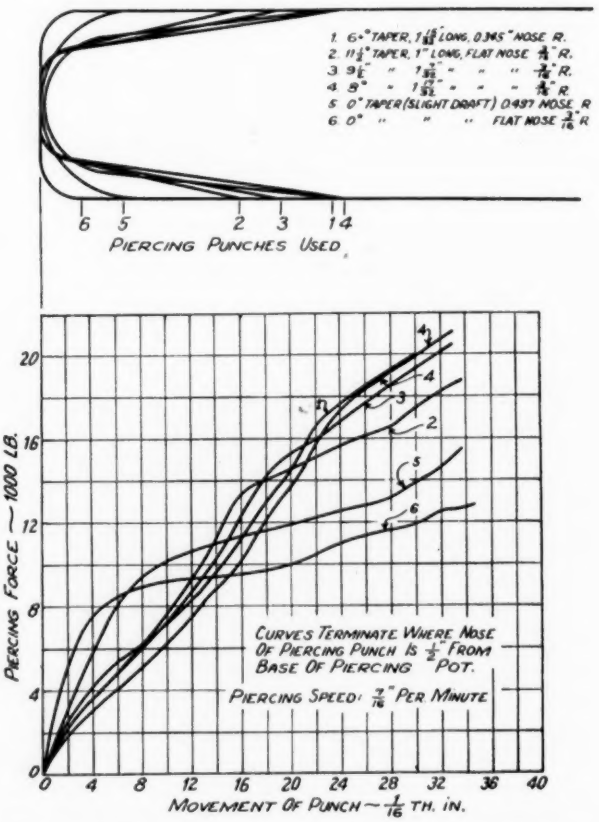

FIG. 44 FORCE-STROKE CURVES FOR PIERCING WITH VARIOUS PUNCHES

Drawn:

Die	No. 7, 1.328 in. diam, 15 deg half-angle, steel
Mandrel	DB
Lubricant	Fiske's No. 514-A hot-die lubricant, as received
Speed	40 fpm
Reduction	19 per cent

Remarks. The following table shows the representative values obtained for a series designed to indicate the effect of temperature:

Furnace temperature, deg F	Wall draw force, lb	Stress on remaining section, psi
1850	7000	9950
2000	5500	7850
2300	3700	5300

Fig. 42 indicates how the force-stroke curve varies with temperature, and, in Fig. 43, is shown the forces plotted versus the soaking temperature. It is to be noted that the temperature indicated on the abscissa scale is the soaking temperature (furnace temperature) and the actual drawing temperature may be 100 to 300 deg F lower depending upon the handling time, drawing speed, etc.

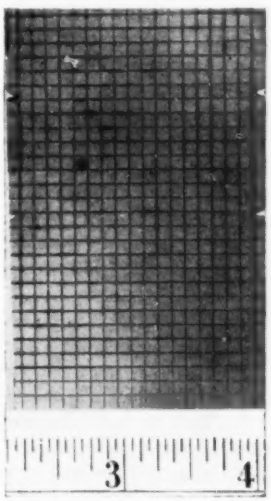

FIG. 45 SPLIT LEAD SLUG WITH SCRIBED GRATING, BEFORE PIERCING

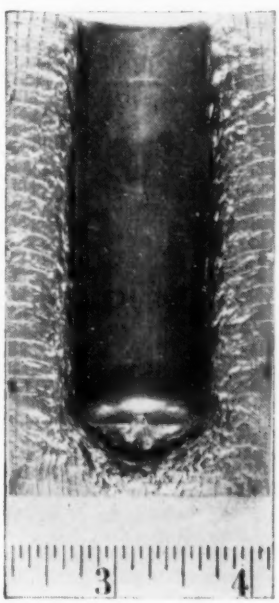

FIG. 46 SPLIT LEAD PIERCED SLUG, SHOWING DEFORMATIONS OF GRATING AFTER PIERCING

The shells, series S-3, drawn at low temperature show practically no difference in drawn dimensions from the high-temperature draws.

Effect of Speed, Series S-4:

Steel Bottles:

$2^5/_8$ in. long, IV cavity, 1.400 in. OD, $^1/_2$ in. base thickness, 0.237 in. wall thickness, boat-tail (5 deg from 1.220 in. base diam)

Drawn:

Die	No. 7, 1.328 in. diam, 15 deg half-angle, Meehanite
Mandrel	DB
Lubricant	Fiske's No. 514-A hot-die lubricant, as received
Speed	40, 50, and 65 fpm
Reduction	19 per cent

Remarks. A few tests on draw speed have been performed, but the effect of this variable alone is obscured by other factors, principally temperature.

The range of draw speeds investigated showed a slight trend toward increasing power requirement, with increasing speed from 40 to 65 fpm.

Trial	Speed, fpm	First maximum, lb	Wall draw force, lb
1	40	3300	4950
2	50	3950	5050
3	65	(3250)	5150

PIERCING OF LEAD SLUGS

A few observations on the piercing of lead slugs has shown that a blunt-nosed piercing punch requires less force for deep piercing than tapered punches. Thus a cylindrical punch with a flat nose and small tip radius required less force to pierce a given depth than any of the tapered punches or the round-nosed cylindrical punch used, Fig. 44. A small punch taper apparently results in a wedging action which creates high frictional resistance.

An attempt to analyze the piercing operation was undertaken in which a cast-lead billet was split and a grating scribed on one parting face, Fig. 45. The halves were then clamped together and the specially prepared billet pierced. The resulting deformation of the billet and grating is illustrated in Fig. 46. Unfortunately no time was available for analysis of this interesting problem.

4 DISCUSSION AND CONCLUSIONS

Experimentation on model shells in lead and steel was conducted in order to obtain a perspective of the effect of the numerous variables involved in the drawing phase of the pierce-and-draw method of fabricating high-explosive shells.

Because of difficulties involved in building special equipment, the effects of most variables were investigated in a detailed manner with lead at room temperature. At this temperature, lead possesses properties similar to a high-melting metal at hot-working temperatures.

High-temperature tests introduce, as additional factors or complications, variations in friction, in temperature, and in temperature distribution. A number of tests were conducted with steel in order to confirm conclusions drawn from the tests with lead and to determine differences introduced by the additional factors, if present.

The efficiency of a shell-drawing operation is measured commonly by the "reduction" in cross-sectional area of the tubular section at the mouth of the pierced bottle. Experimentation in

which the only variable was the outside diameter of the bottle showed that the maximum possible reduction or "drawability" varied widely with the other variable factors.

A lead bottle with a square nose, i.e., without a "boat-tail," can be given a maximum reduction of approximately 35 per cent in a single pass through a ring die of proper contour. The drawability of steel under similar conditions is only 20 to 25 per cent.

These values of drawability are much lower than those attainable for tubular specimens. This is explained by the fact that the maximum reduction is not determined by a tension failure of the wall, but by a shear failure or piercing through the base.

The intricate shape of the force-stroke curves is explained by the following relations: The force-stroke curve is composed of two superimposed parts, the forces for extruding the bottom, and the forces for drawing the wall. Because of variations in the wall thicknesses of the bottle and the subsequent drawpiece, and the resulting fluctuations in reduction, the wall draw force also fluctuates within wide limits. In addition, the variations and changes in the temperature of steel cause a gradual increase of the draw force as the stroke progresses.

The force-stroke curve for a bottle with a square or blunt base generally exhibits a high "first maximum" which is explained, for the most part, by the reduction of the base. The reduction of the adjacent wall also contributes to this first maximum.

Both the first maximum and the wall drawing forces increase with increasing reduction. Failure by piercing through the bottom occurs when the first maximum reaches a certain value, which is independent of the variations in the upper shell wall thickness.

Consequently, any factor which reduces the first maximum (for a given thickness of the bottom) also increases the possible maximum reduction. Such expedients used to relieve the excessive bottom deformation are: (1) Boat-tailing, or tapering the outside of the shell toward the base; (2) selecting a die having an optimum die angle; and (3) employing a pierced slug having a large cavity which provides a thin wall and a large clearance for the mandrel tip.

A suitable boat-tail eliminates the first maximum, since the reduction of the base diameter then becomes very small, or may be eliminated completely.

The optimum die half-angle for lead was found to be 15 deg.[9] Only a slight difference in forces was detected between curved dies and straight-angle dies with the same effective half-angles. The effect of die angle is explained by the phenomena (*a*) that the force to push a slug through an opening should decrease with decreasing angle because of a wedge action, but (*b*) that the frictional resistance increases with decreasing angle.

[9] "An Investigation of Hot Drawing on the Mandrel," by E. Schneider, *Journal of the Iron and Steel Institute*, vol. 104, 1921, pp. 191–227.

For a given mandrel shape, the greater the clearance between mandrel tip and bottle cavity, the lower is the first maximum and the higher the drawability, because of the correspondingly decreasing wall thickness and reduction at the base of the shell.

For a given cavity shape piercing through the base during the drawing operation may be inhibited to some extent by use of a draw mandrel having a large nose tip diameter (or nose radius, in the case of round-nosed mandrels). It is the diameter of the mandrel tip which determines the sheared area, and, consequently, the strength of the base, while the taper of the front end of the mandrel determines the reduction and the force required for the draw. Consequently, the drawability is increased with increasing tip diameter and decreasing taper of the mandrel, other factors remaining constant.

Thin-walled shells can be given greater successful reductions than thick-walled shells, other factors remaining constant. For a given cavity shape and mandrel shape, the thicker the wall the smaller is the mandrel-tip diameter relative to shell outside diameter and the lower is the drawability.

It has been found that base thickness has little effect on the drawability, for the strength of the base against piercing-through increases in the same proportion as the force required to push the base through the die. Only a very thin base will cause early piercing-through.

Proper lubrication and tool material were found to be very important factors determining the maximum reduction for steel. A lubricant of colloidal graphite in heavy petroleum oil used in combination with a heat-treated Meehanite die and steel mandrels was found to reduce the friction to a minimum, and thereby to yield a minimum draw force. A filmed wax-and-soap-base lubricant gave good performance for lead.

The temperature of steel bottles had little effect on the drawability. The lower the temperature, the greater is the shear resistance, but also the higher are the draw forces required.

The effect of speed was not clearly revealed in this investigation because of the limited number of draws which were performed.

Acknowledgments

The authors wish to express their gratitude to Prof. K. H. Donaldson, head, department of metallurgical engineering, Case School of Applied Science, and Dr. M. D. Stone, manager of development, United Engineering and Foundry Company, Pittsburgh, Pa., and chairman of The American Society of Mechanical Engineers Shell Forging Research Committee, for their co-operation in securing the necessary equipment and material for this investigation.

Plastic States of Stress in Curved Shells: The Forces Required for Forging of the Nose of High-Explosive Shells

By A. NADAI,[1] EAST PITTSBURGH, PA.

Problem of Nosing a Shell

THE forging of artillery shells and of air bombs requires a high degree of skill of the shops. Considerable practical development work and costly experiments were performed in the steel mills of this country when war broke out and the necessity suddenly developed for the manufacture of large quantities of hollow bodies for the artillery and aircraft. This report deals with a mechanical analysis of the forces required for forming the noses of shells. The present practice is to compress the open end of a cylindrical shell forging after it has been preheated in the radial direction by forcing it into a suitably shaped die. Small shells are cold-nosed. In this report, hot-nosing primarily will be considered, although the development outlined may well be extended to the cold-nosing process.

At the beginning of this war very little practical information was available concerning the capacities of the heavy hydraulic presses used for forging shell noses. Considerable difficulties arose from this fact alone since capacities of presses were either under or over-rated due to the complete lack of information concerning the nosing forces. The nature of the radial plastic flow accompanying the formation of similar shapes has not been studied, although the process of making blunt ends in hollow containers has many additional practical applications. In many plants costly large-scale shop experiments had to be performed until the precise shapes of the profiles of shells were determined which were needed in the original cylindrical forgings to produce the prescribed shapes of shells in their finished condition. Other important factors which had to be studied were the distribution of the temperature along the cylinder requiring a drop in temperature from the tip at the open end toward the rear portion of the shell, the effects of lubricants suitable for cold- or for hot-nosing preventing excessive die wear, speeds of pressing, etc.

In the fall of 1942, the A.S.M.E. Special Research Committee on Forging of Steel Shells (Dr. M. Stone, Chairman, and Prof. W. Trinks, Projects Director) arranged on behalf of the Army Ordnance, Washington, the details of an investigation with the Westinghouse Research Laboratories to be carried out on the mechanical problem of the plastic forming of the nose of a shell. In this first partial report, a theoretical analysis is given of the equilibrium systems of the internal stresses in the plastic state during the formation of a curved shell with rotational symmetry, from which an expression is derived for the axial resultant "nosing force." This is the resultant at the bottom of the curved portion of the nose which determines the total nosing resistance, or the capacity of the forging machine or hydraulic press used for forging the nose.

Friction forces between the die and the shell must be considered. They were assumed to be proportional to the specific pressure in the contact surface. Friction forces act in the direction opposite to the sliding motion of the material relative to the die. From the distributions of the axial and circumferential stresses predicted by the theory, several important conclusions can be drawn concerning certain limiting conditions which must be satisfied during nosing of a shell to avoid local thickening at the bottom of the nose and concerning limiting magnitudes of the friction.

Expressions for the plastic strains are quoted which give an idea of the amounts of the compressional distortion of the material. These geometric relations should well serve to predict the original shape of the shell required to produce a finished shell with prescribed wall thicknesses.

General Equations for Plastic States of Stress in a Thin Curved Shell Whose Middle Surface Is a Surface of Revolution

When a ductile metal is permanently deformed, it is known that stresses in the strain-hardening range, i.e., at sufficiently low temperatures, depend solely upon the permanent strains, and that at sufficiently high (forging) temperatures they are independent of the strains but increase with the plastic rates of deformation. Although it appears possible to treat mathematically certain special cases of plastic flow by assuming that, "in the strain-hardening range," stresses depend upon the plastic strains in a given manner, or that, on the other hand, "at forging temperatures," they are known functions of the rates of strain, it seemed more desirable to develop such cases of plastic flow under further simplified assumptions, particularly for the case of hot-nosing.

It is known that the distributions of the stresses in a curved shell of given dimensions, whose wall thickness is comparatively small, is determined solely by the three static conditions which express the equilibrium of the small elements of the shell in the general case, provided that the lateral pressure carried on the surface of the shell is given. When a shell is deformed by a distributed pressure exerted through a die, the foregoing statement regarding the lateral pressure does not hold. The contact pressure between the die and the shell is one of the unknown quantities which must be determined. In addition to the three static equations in the general case one new condition is therefore needed if the shell material is deformed in the plastic state. For this fourth equation, the condition of plasticity can and will be here introduced. This briefly explains the plan upon which the computations of this paper were based.

When the nose of a shell is forged at 1800 F, or at a near-by temperature, a certain length of the originally cylindrical shell in Fig. 1 (*a*) near the open end *e* is preheated and this hot portion is forced to enter the die *d*. The remaining portion of the shell below the plane *cc* shown in Fig. 1 (*b*) is left cold and should not be

[1] Consulting Mechanical Engineer, Research Laboratories, Westinghouse Electric & Manufacturing Co. Member, A.S.M.E. Special Research Committee on Forging of Steel Shells. Mem. A.S.M.E.

Contributed by Special Research Committee on Forging of Steel Shells and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

deformed. An element of material situated above the plane *cc* is essentially compressed permanently in the circumferential directions of the circular cross sections of the shell which are perpendicular to its axis. The theory predicts and observations prove that the major principal compression stress during the forging of the nose of a shell is this circumferential stress. In addition, the metal is also under the action of considerable axial compression stresses (more precisely of normal stresses in the directions parallel to the tangents of the middle or meridian curve in the axial-plane sections of the shell). Since the elements of the nose must glide under heavy pressure along the inner working surface of the die, considerable frictional forces must also be produced in the contact surface resisting this gliding motion. In spite of these complications in the actual flow the metal is essentially compressed in the circumferential directions and must therefore expand both in the radial and axial directions when the nose of a shell is forged.

A point P in the undeformed shell (Fig. 1) will be found after

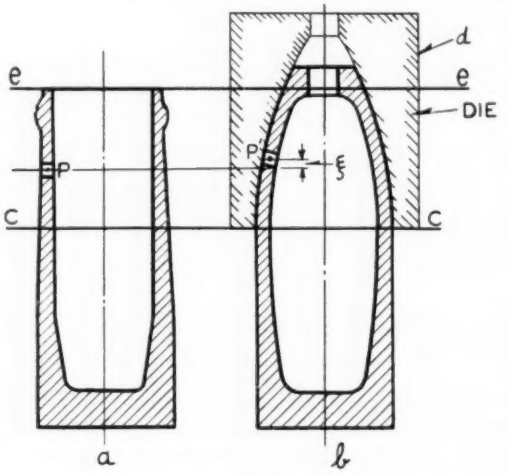

FIG. 1 NOSING A SHELL

nosing in a position P', in which P' has been displaced by a certain amount ξ in the axial direction. We shall not attempt to describe in a more complete way the fate of an element of material during its radial motion although some good means could be used for this purpose which are available through the recently improved theories of plastic flow. Expressions for the finite plastic strains, however, will be established. The true distribution of the plastic strains becomes somewhat more involved near the tip of the nose, and it should be noted that the permanent strains near the tip are of comparatively large magnitude for the more slender shapes of shells, where the reduction of length in a peripheral direction may reach compression values amounting to 50 per cent or even much more.

Near the bottom of the nose (the plane *cc* in Fig. 1) the strains remain quite small. When describing the mode of distortion in the nose of a shell, it should be noted furthermore that the straight lines perpendicular to the cylinder surface in the original state of the shell will be slightly distorted, but essentially they will be tilted during the forging process and remain straight lines perpendicular to the curved middle surface of the finished shell.[2] Such a motion in a shell, having a comparatively large wall thickness, should lead to bending strains and stresses. We will neglect these and the distortion within the shell walls resulting from the presence of the shearing stresses which transmit the friction forces in the contact area, because the bending strains are much smaller than the strains due to compression. A further remark must refer to the conditions at the bottom of the nose. In the computations to be given the elastic portions of the strains are entirely neglected for the same reasons and because they are only small fractions of the total strains. Consequently, it will not be possible to satisfy boundary conditions also at the bottom of the shell (in the plane *cc* Fig. 1) where the plastic portion borders the portion of the shell which remains cylindrical. Since these two portions are in integral connection, maintenance of "the continuity" of material should require that certain systems of forces and bending moments should act. These latter must deform slightly elastically both the curved and also the cylindrical portion of the shell. These stresses belong to the category of secondary stresses which are neglected.

[2] The axial-plane sections of actual shells which were investigated in other parts of this report by R. K. Carlson demonstrate this statement conclusively. Pins which were inserted in the shell before the nosing remained essentially straight after the forging.

NOMENCLATURE

The following nomenclature will be used:

- σ_t = normal stress in circumferential direction ("tangential" or "hoop" stress)
- σ_a = normal stress along meridian of shell ("meridian" stress)
- σ_r = radial stress
- p = pressure between die and shell, psi
- σ_0 = yield stress of metal for tension
- r = radial co-ordinate
- x = co-ordinate parallel to axis of shell
- h = wall thickness
- α' = angle of inclination of tangent to meridian curve of shell
- $\alpha = \frac{\pi}{2} + \alpha'$
- ds = arc element along meridian curve
- μ = coefficient of friction
- β = friction angle defined by $\mu = \tan \beta$
- r_t = radius of curvature in normal section of shell in perpendicular plane to plane of meridian
- r_a = radius of curvature in meridian plane containing axis of shell

For the middle surface of the curved portion of the shell, a surface of revolution is assumed. The external forces and the internal stresses and strains are assumed to act rotationally symmetrically around the axis AA of the shell, Fig. 2. A small element of a shell in two enlarged views is represented in Fig. 2. On this element six forces act. One pair of these forces consists of the resultant forces of the normal stresses σ_a acting along the

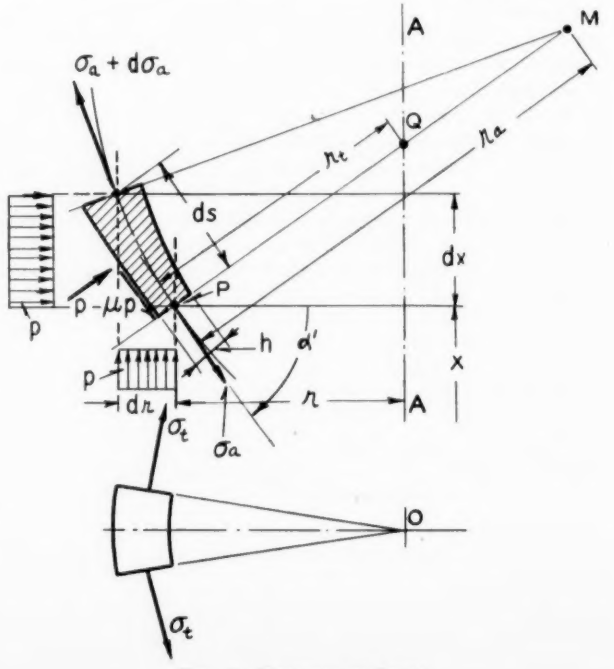

FIG. 2 ELEMENT OF SHELL

meridian curve and the other pair of the resultants in the circumferential directions of the hoop stresses σ_t. The forces in each pair are slightly inclined to each other due to the curvature of the middle surface of the shell nose. Furthermore, on the outer surface of the shell, act the distributed contact pressures p and the friction forces. These latter will be assumed to be equal to μp per unit of area. Assuming that the shell element, shown in Fig. 2, is moving in the upward direction relative to the die, these friction forces on the small shell element must act downward, as is indicated in the figure.

In the theory of thin shells[3] whose middle surface is a surface of revolution, two static equations are developed. The first one expresses the condition of equilibrium of the components of the forces in the direction of the axis of rotation and can usually be written in finite form. The second expresses the equilibrium of the components of the forces in the normal direction to the tangent plane for a small shell element, such as the one which was represented by Fig. 2.

Since in our present problem the normal pressure p of the shell is an unknown quantity, it will be well at this point to derive the first condition. Consider a ring of material which is obtained by rotating the shaded meridian section, represented in the front view of Fig. 2, around the axis AA. Neglecting first the friction forces, the following three components of forces in the axial direction of the shell must be considered in equilibrium

$$2\pi(\sigma_a + d\sigma_a)(h + dh)(r + dr) \sin(\alpha' + d\alpha') - 2\pi\sigma_a hr \sin\alpha' + \pi[(r + dr)^2 - r^2]p = 0 \quad [1]$$

The first term in this equation represents the resultant of the normal stresses σ_a in the axial direction in the upper ring section and the second term in the lower section of the ring. In the third term, the pressure p is multiplied by the projected area of the ring on a plane perpendicular to the axis of rotation. From Equation [1] therefore it follows that

$$pr + \frac{d}{dr}(\sigma_a hr \sin\alpha') = 0 \quad [2]$$

In this equation, we now wish to include the friction forces. For this purpose a term

$$-2\pi\mu pr \sin\alpha' ds$$

has to be added on the left side of Equation [1]. Since the projections of the arc element ds in the radial and axial directions are

$$dr = \cos\alpha' \cdot ds, \qquad dx = \sin\alpha' \cdot ds \quad [3]$$

and $dx/dr = \tan\alpha'$ we see that, in Equation [2], we have to add the term

$$-\mu pr \tan\alpha'$$

The first condition of the equilibrium of the components of the forces in the axial direction is therefore expressed by

$$\frac{d}{dr}(\sigma_a hr \sin\alpha') + pr(1 - \mu\tan\alpha') = 0 \quad [4]$$

if the friction forces are also to be included.

The second condition required for expressing the equilibrium of the forces in the normal direction to the tangent plane is furnished by the theory of thin curved shells

$$\frac{\sigma_a}{r_a} + \frac{\sigma_t}{r_t} = -\frac{p}{h} \quad [5]$$

[3] "Statik und Dynamik der Schalen," by W. Flügge," Berlin, J. Springer, 1934, p. 21.

In it r_a and r_t designate the radii of curvature PM and PQ of the curved middle surface of the shell, Fig. 2, in the meridian plane and in a plane perpendicular to the latter. Point Q is the point at which the normal at point P to the curved middle surface intersects the shell axis AA.

For determination of the three unknowns, σ_a, σ_t, and the contact pressure p, a third equation is required. This is the "condition of plasticity" of the flowing metal, according to which the octahedral shearing stress must be constant. If σ_1, σ_2, σ_3 are the principal stresses and σ_0 the yield stress in tension, it is expressed by

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 2\sigma_0^2$$

In the case of a plastic shell which carries along its outer surface a distributed normal pressure p and whose inner surface is free, we can take

$$\sigma_1 = \sigma_t, \quad \sigma_2 = \sigma_a, \quad \sigma_3 = -\frac{p}{2}$$

The plasticity condition therefore is expressed by

$$\left(\sigma_t + \frac{p}{2}\right)^2 - \left(\sigma_t + \frac{p}{2}\right)\left(\sigma_a + \frac{p}{2}\right) + \left(\sigma_a + \frac{p}{2}\right)^2 = \sigma_0^2 \quad [6]$$

The three Equations [4], [5], and [6] are sufficient for determining the three unknown functions σ_a, σ_t, and p and solve the general problem of the plastic equilibrium of thin shells of rotational symmetry.

Although the profiles of actual artillery shells have a constant radius of curvature along their outer machined surface, and must not necessarily have a constant value of r_a along the middle surface if the wall thickness h tapers down, probably for most artillery shells one can assume that r_a = const. It is sufficient to discuss the case of shells whose mean meridian curve is obtained by rotating a circular arc around an axis. From a mechanical viewpoint, they are essentially special cases of the type of surface of revolution known as "torus," whose most common example is the inner tube of an automobile tire.

Two special cases of surfaces of revolution will be discussed in this paper. For the first, we select the cone. The exact solution for a perfectly plastic conical shell with uniform thickness is derived, which allows useful conclusions. The second case is the torus shell whose mean meridian curve is an arc of a circle. An exact solution for this case can also be obtained after a simplification is introduced in the plasticity condition by assuming that, in a plastic shell, essentially the circumferential stress remains constant or that in the shell $\sigma_t = -\sigma_0 = \text{const}$.

We note finally that, as soon as expressions for the pressures p and the stresses σ_a and σ_t have been found satisfying the equations mentioned, the total force P which is required for maintaining equilibrium with the internal stresses during nosing can easily be computed. All that is required for obtaining the total nosing resistance P is to compute the axial component of the resultant of the meridian stresses σ_a at the base of the nose. If $(\sigma_a)_{r_2}$ is the meridian stress, at the base of the nose, and if r_2 and h_2, respectively, are the radii and wall thickness at that point, then P is given by

$$P = 2\pi r_2 h_2 (\sigma_a)_{r = r_2} \quad [7]$$

assuming that the meridian curve of the profile of the shell has a vertical tangent for $r = r_2$ in the plane cc of Fig. 1.

A simplified theory of plastic shells, which are comparatively narrow bands of a thin body of revolution (conical, cylindrical shells, torus), can be based upon the following three equations

$$\frac{d}{dr}(hr \sin\alpha' \cdot \sigma_a) + (1 - \mu\tan\alpha')rp = 0 \quad [4a]$$

$$\frac{\sigma_a}{r_a} + \frac{\sigma_t}{r_t} = -\frac{p}{h} \quad \ldots\ldots [5a]$$

$$\sigma_a^2 - \sigma_a\sigma_t + \sigma_t^2 = \sigma_0^2 \quad \ldots\ldots [6a]$$

if the pressure p is neglected in the "plasticity condition," Equation [6]. In many applications, it is permissible to express this last condition of flow in the even simpler form

$$\sigma_t = -\sigma_0 = \text{const} \quad \ldots\ldots [6b]$$

Use of these equations is made in subsequent sections.

Conical Shells of Uniform Thickness in Plastic State

With reference to Fig. 3, introducing the angle of inclination of

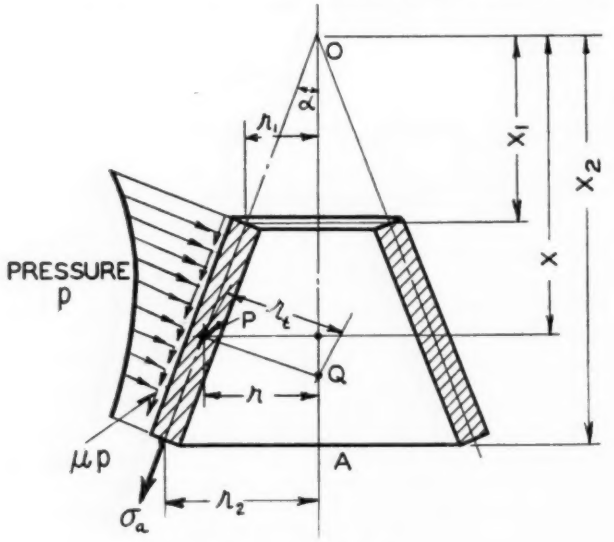

Fig. 3 Conical Shell

the cone α = angle POA we must take for the angle $\alpha' = \frac{\pi}{2} + \alpha$ in Equation [4]. The angle α is a constant in Equation [4]. This becomes

$$\frac{d}{dr}(\sigma_a hr \cos\alpha) + pr(1 + \mu \operatorname{cotan}\alpha) = 0$$

In this equation, we also take h = const, and replace the variable radius $r = x \tan\alpha$ by the independent variable x which measures the distance of a point P of the cone from the apex O. After solving for p we obtain for the pressure p the expression

$$p = -\frac{\cos\alpha}{(\mu + \tan\alpha)} \cdot \frac{h}{x} \cdot \frac{d}{dx}(x\sigma_a) \quad \ldots\ldots [8]$$

In the second equilibrium condition Equation [5], the first term vanishes since the radius of curvature of a straight meridian is $r_a = \infty$. The second radius of curvature for a conical shell is

$$r_t = \frac{r}{\cos\alpha} = \frac{\sin\alpha}{\cos^2\alpha} x$$

Equation [6] therefore condenses down to

$$p = -\frac{\cos^2\alpha}{\sin\alpha} \cdot \frac{h}{x} \cdot \sigma_t \quad \ldots\ldots [9]$$

furnishing a second independent expression for the pressure p.

In the plasticity condition Equation [6], we introduce a further simplification by neglecting the pressure p in it as is usually done in similar cases.[4] The third condition appears therefore in the form

$$\sigma_t^2 - \sigma_t\sigma_a + \sigma_a^2 = \sigma_0^2 \quad \ldots\ldots [10]$$

According to Equation [10], the hoop stresses σ_t in function of the meridian stresses σ_a satisfy an ellipse. Orientation of this "plasticity ellipse" is shown in Fig. 4. It passes through the

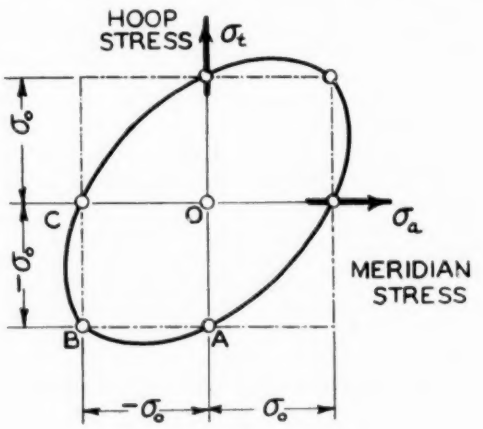

Fig. 4 Plasticity Ellipse

points 0, $\pm\sigma_0$; $\pm\sigma_0$, 0; $\sigma_t = \sigma_a = \pm\sigma_0$; the semiaxes of the ellipse are

$$\sqrt{2}\,\sigma_0, \quad \sqrt{\frac{2}{3}}\,\sigma_0$$

In the case of "drawing" of a shell, portions of the ellipse muse be considered in which at least the meridian stress σ_a is a tensilt stress and positive. With reference to our present application to the nosing of artillery shells, on the other hand, the shell is compressed by the heavy lateral pressures p and we need to consider the lower arc of this ellipse ABC, Fig. 4. In this quadrant of the σ_a, σ_t plane we will encounter both principal stresses σ_a and σ_t as negative quantities, i.e., as compression stresses.

After eliminating p from Equations [8] and [9] and after introducing for $\mu = \tan\beta$ and the abbreviation for a constant k

$$k = \frac{\tan\alpha}{\mu + \tan\alpha} = \frac{\tan\alpha}{\tan\beta + \tan\alpha} \quad \ldots\ldots [11]$$

we find that the two unknown stresses σ_a and σ_t must satisfy the following two equations in a plastic cone

$$k \cdot \frac{d}{dx}(x\sigma_a) - \sigma_t = 0 \quad \ldots\ldots [12]$$

$$\sigma_t^2 - \sigma_t\sigma_a + \sigma_a^2 = \sigma_0^2 \quad \ldots\ldots [13]$$

After eliminating from these equations, for example, σ_t, Equations [12] and [13] define a first-order differential equation for the stress σ_a. The solution can therefore contain only one integration constant and only one boundary condition can be satisfied. The conditions during nosing require that the stress $\sigma_a = 0$ at the tip of the nose. This is therefore the boundary condition which is to be satisfied. We note that the metal at the tip of the nose of a shell is merely compressed in the circumferential direc-

[4] The solution could be worked out also without the omission of p in Equation [8], but it seems unnecessary to go to these complications.

tion and must therefore expand in all perpendicular directions by equal amounts.

The set of Equations [12] and [13] is of a type which has previously been discussed by the author. Their solution is obtained by changing the independent variable x and after introducing a new dependent variable φ. We take for

$$u = \log_e \frac{x}{x_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots [14]$$

and assume that the stresses σ_a and σ_t can be expressed in the form

$$\sigma_a = -\frac{2\sigma_0}{\sqrt{3}} \sin(\varphi + \varphi_0) \quad \ldots\ldots\ldots\ldots [15]$$

$$\sigma_t = \frac{2\sigma_0}{\sqrt{3}} \sin\left(\varphi + \varphi_0 + \frac{2\pi}{3}\right) \quad \ldots\ldots\ldots [16]$$

Making use of these two new variables u and φ, we note that Equation [13] is identically satisfied and that, after the expressions for the stresses σ_a and σ_t are substituted in Equation [12], a differential equation for φ is obtained

$$\frac{d\varphi}{du} = \frac{c_0 \sin\varphi}{k \cos(\varphi + \varphi_0)} \quad \ldots\ldots\ldots\ldots\ldots [17]$$

which can be integrated. The solution is

$$\cos\varphi_0 \cdot \log \sin\varphi - \sin\varphi_0 \cdot \varphi = \frac{c_0 u}{k} + c \quad \ldots\ldots\ldots [18]$$

In it the two constants φ_0 and c_0 are defined by

$$\tan\left(\varphi_0 - \frac{\pi}{3}\right) = \frac{\sqrt{3}k}{2-k}, \qquad c_0 = \sqrt{k^2 - k + 1} \quad \ldots\ldots [19]$$

At the tip of the conical shell for $x = x_1$, $u = 0$ and $\sigma_a = 0$. This boundary condition is satisfied if in the expression for σ_a Equation [15] $\sin(\varphi + \varphi_0) = 0$. Since φ cannot become negative on account of the logarithm appearing in Equation [18], we cannot make $\varphi = -\varphi_0$ but have to take for $u = 0$; $\varphi = \pi - \varphi_0$ at the tip of the shell. With this condition, the integration constant c in Equation [18] is determined, and finally for the variable u the equation

$$u = \frac{k}{c_0}\left[(\pi - \varphi_0 - \varphi)\sin\varphi + \cos\varphi_0 \cdot \log_e\left(\frac{\sin\varphi}{\sin\varphi_0}\right)\right] \quad [20]$$

is obtained. Equations [15], [16], and [20] express the distribution of the stresses σ_a and σ_t in conical shells. By choosing a few values for φ, the corresponding co-ordinates $x = x_1 e^u$ can be computed from Equation [20], and the stresses σ_a and σ_t from Equations [15] and [16].

After substituting for $u = \log_e(x/x_1)$ in Equation [20] and after joining the two terms containing the logarithms, Equation [20] can also be rewritten in a form in which it is solved for the co-ordinate x (or for the radius $r = r_1 \frac{x}{x_1} = x \tan\alpha$)

$$\frac{x}{x_1} = \frac{r}{r_1} = \left[\frac{\sin\varphi}{\sin\varphi_0}\right]^{\frac{k}{c_0}} \cdot e^{\frac{k}{c_0}[\pi - \sin\varphi_0 \cdot (\varphi_0 - \varphi)]} \quad \ldots [20a]$$

The total resultant force for nosing the portion $r_1 < r < r_2$ of a conical shell is given by

$$P = 2\pi r_2 h\,[\sigma_a]_{r_2} \cdot \cos\alpha \quad \ldots\ldots\ldots\ldots [21]$$

where σ_a is to be computed for that value of φ for which in Equation [20] $u = \log_e(r_2/r_1)$.

When the constant k given by Equation [11] varies between the limits $0 < k < 1$ the angle φ_0 defined by Equation [19] varies between

$\frac{\pi}{3} < \varphi_0 < \frac{2\pi}{3}$. The variable φ varies between $0 < \varphi < \pi - \varphi_0$.

The variation of the constant k (which was introduced in Equation [11]) with the cone angle α and with the friction coefficient μ has been indicated in Fig. 5. A further curve in Fig. 5

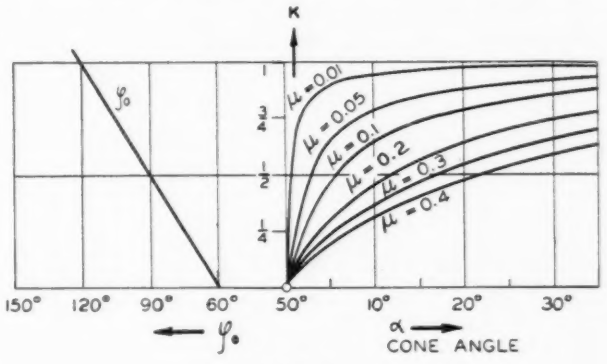

FIG. 5

shows also the values of the constant angle φ_0 appearing in several of the equations.

In the differential Equation [17], the term $\cos(\varphi + \varphi_0)$ appears in the denominator on the right side. Since the interval for φ is usually limited by the values zero and $\pi - \varphi_0$, we must note that when $\cos(\varphi + \varphi_0) = 0$ or when $\varphi = \frac{\pi}{2} - \varphi_0$, $d\varphi/du = \infty$. This condition may or may not occur in the applications. It may occur if $\varphi_0 < \pi/2$ and since always $\varphi_0 > \pi/3$ it may occur if the constant angle φ_0 which was defined by Equation [19] has values $\frac{\pi}{3} < \varphi_0 < \frac{\pi}{2}$.

As an illustration for such an occurrence an example has been

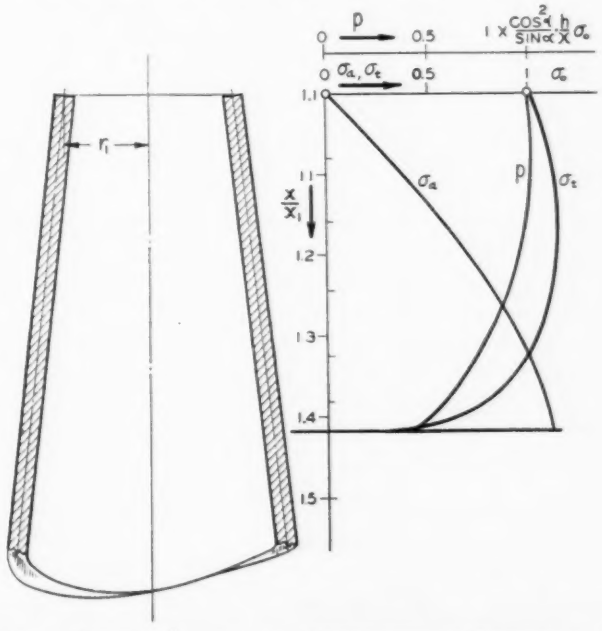

FIG. 6 PRESSURES, AXIAL AND CIRCUMFERENTIAL STRESSES IN A CONICAL SHELL

worked out numerically by choosing for the angle $\varphi_0 = 75$ deg $= 5\pi/12$. The corresponding values of the constants are $k = 0.2680$, $c_0 = 0.897$, $\cos \varphi_0 = 0.2588$, and $\sin \varphi_0 = 0.9659$. The distribution of the stresses σ_a and σ_t and of the pressure p for this case is shown in Fig. 6. It is interesting to note that the curve for the tangential stress σ_t ends abruptly with a vertical tangent at the value of the co-ordinate $x = 1.421$. The conical shell cannot extend beyond this value of x at which the meridian stress σ_a just reaches its maximum value

$$\sigma_a = -2\sigma_0/\sqrt{3} = -1.155\sigma_0$$

Special Conical Shells of Uniform Thickness

There are a few interesting special cases of flow in conical shells which should be considered by assuming for the constant k, defined by Equation [11], special values.

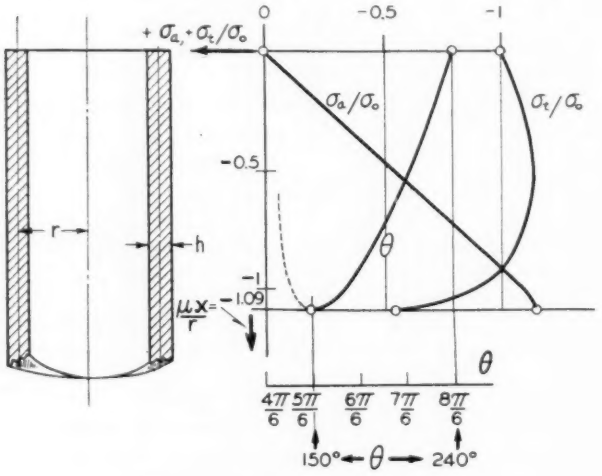

Fig. 7 Stresses in a Cylinder

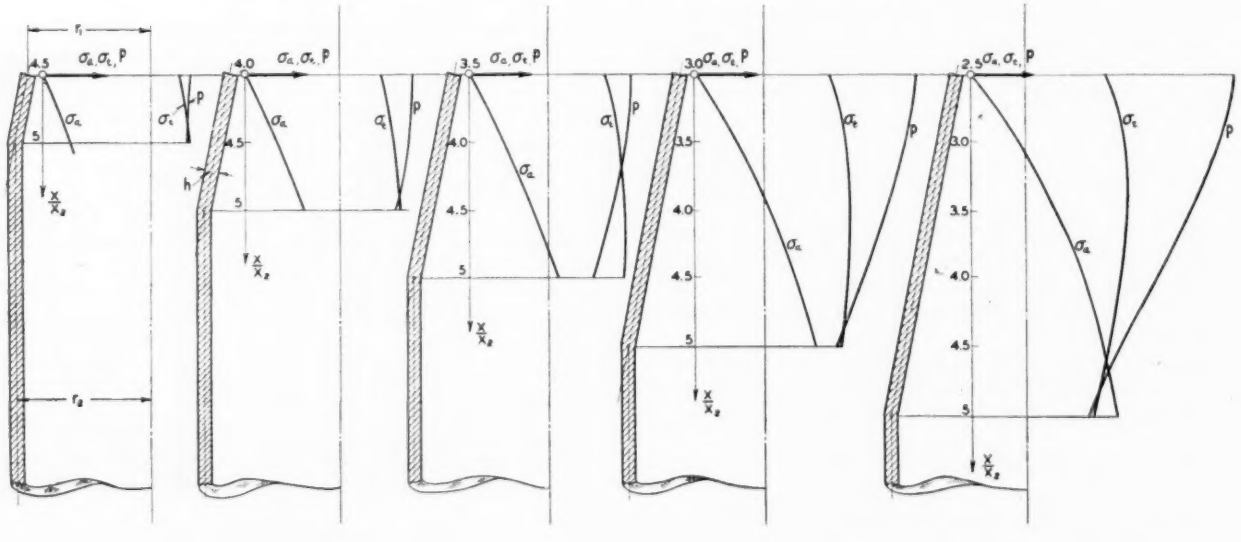
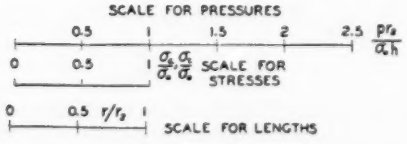


(*a*) *Cylindrical Shells.* If $k = 0$ we have $\varphi_0 = \pi/3$. In this case $\alpha = 0$. This corresponds to a cylindrical shell, for example a short tube, or a bushing which is being pushed forward under axial compression forces into a tightly fitting die. An example for a stress distribution of this kind is shown in Fig. 7 in which the ordinates represent $\mu x/r$ or the distances x measured from the free (upper) end of the cylinder (μ friction coefficient, r mean radius of cylinder) and the abscissas the ratios σ_a/σ_0 and σ_t/σ_0. Both stress components σ_a and σ_t are negative and represent compression stresses. The pressure p in the case of a cylinder is $p = -h\sigma_t/r$ proportional to the circumferential stress σ_t and has for this reason not been represented by an additional curve.



This plastic equilibrium shows a peculiarity of the solution. The plastic field has a natural boundary beyond which the solution does not exist. It is marked in Fig. 7, by the value $\mu x/r = 1.09$ at which the curve for the circumferential stress has a horizontal tangent and at which the axial stress σ_a reaches its maximum[5] value $2\sigma_0/\sqrt{3}$.

Cases of this kind in cylinders have important further practical applications for predicting the stresses in the portions of thick-walled tubes which are worked under heavy pressures during drawing or in similar forming operations when the stresses in the axial direction are of a tensile nature. Such cases cannot be treated in this report.

(*b*) *Special Case When* $\alpha = \beta$. If the friction angle β defined by $\mu = \tan \beta$ is equal to the angle α of the cone, the constant k becomes equal to $k = 1/2$. In this case $\varphi_0 = \pi/2$, $\cos \varphi_0 = 0$, and the factor before the logarithmic term in Equation [20] vanishes.

[5] In Fig. 7, a third curve was traced which carries the designation θ. It represents a certain parameter θ analogous to the variable φ which was used for expressing the solution. The curve representing θ in function of the distances x has also a horizontal tangent for $\mu x/r = 1.09$, and a continuation of it is shown by a dotted line. Thus $\theta = f(x)$ is not a single-valued function of x. These details are mentioned because they are important when the range of the different variables has to be considered and errors can easily result by overlooking some of these details.

Figs. 8–12 Pressures, Axial and Circumferential Stresses in Conical Shells in the Plastic State; ($\mu = \tan \alpha = 0.2$)

This simplifies considerably the computation since, in this case, u is given by

$$u = \frac{1}{\sqrt{3}}\left(\frac{\pi}{2} - \varphi\right) \quad \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

The distribution of the stresses for a conical shell satisfying this condition ($\alpha = \beta$) is expressed in the simple form

$$x = x_1 e^{\frac{1}{\sqrt{3}}\left(\frac{\pi}{2} - \varphi\right)}, \quad \sigma_a = -\frac{2\sigma_0}{\sqrt{3}}\cos\varphi,$$

$$\sigma_t = -\frac{2\sigma_0}{\sqrt{3}}\sin\left(\frac{\pi}{6} + \varphi\right) \ldots [23]$$

valid for $0 < \varphi < \pi/2$.

A series of five conical shell noses has been considered as an example under this assumption, having the same angle $\alpha = 11°32' = \beta$ corresponding to a friction coefficient of $\mu = 0.2$ and the same outside radius r_2. The distributions of the stresses σ_a and σ_t and of the pressures p are shown in Figs. 8 to 12, for the five reductions of the mean radii at the tip of the nose, given in Table 1.

TABLE 1 CONICAL PLASTIC SHELL

Case $\alpha = \beta = 11° 32'$

Reduction of radii at tip of nose, per cent	$\frac{r_1}{r_2} =$	Meridian stress at base of nose	Maximum pressure at tip of conical shell	Nosing force
10	0.9	$\sigma_a = -0.209\sigma_0$	$p = 1.09\sigma_0 h/r_2$	$P = 1.29\sigma_0 h r_2$
20	0.8	$-0.434\sigma_0$	$1.23\sigma_0 h/r_2$	$2.67\sigma_0 h r_2$
30	0.7	$-0.668\sigma_0$	$1.40\sigma_0 h/r_2$	$4.11\sigma_0 h r_2$
40	0.6	$-0.894\sigma_0$	$1.63\sigma_0 h/r_2$	$5.50\sigma_0 h r_2$
50	0.5	$-1.076\sigma_0$	$1.96\sigma_0 h/r_2$	$6.62\sigma_0 h r_2$

In the last column of Table 1, the nosing force is shown which was computed from the formula

$$P = 2\pi r_2 h \cos\alpha \cdot (\sigma_a)_{r=r_2} \ldots\ldots\ldots\ldots\ldots [24]$$

using the values of the meridian stress σ_a at the bottom of the nose ($r = r_2$) which appear in one of the previous columns. (σ_0 is the yield stress.)

It is instructive to note from the curves in Figs. 8 to 12, and data in Table 1, how the pressures p required for nosing increase with the reduction of the radii at the tip of the shell. The meridian stresses σ_a increase toward the base of the nose the longer the conical shells become, while the circumferential stresses remain practically constant over the entire length of the shell nose.

(c) *Vanishing Friction Forces.* A third special case of interest occurs when $\mu = 0$ when the friction is negligible (corresponding to the value of $k = 1$ and to $\varphi_0 = 2\pi/3$). Equation [20] simplifies somewhat to

$$u = \frac{\sqrt{3}}{2}\left(\frac{\pi}{3} - \varphi\right) - \frac{1}{2}\log_e\left(\frac{2\sin\varphi}{\sqrt{3}}\right) \ldots\ldots [25]$$

while the stresses σ_a and σ_t and the pressure p are now to be computed from the formulas

$$\sigma_a = -\frac{2\sigma_0}{\sqrt{3}}\sin\left(\frac{2\pi}{3} + \varphi\right), \quad \sigma_t = \frac{2\sigma_0}{\sqrt{3}}\sin\left(\frac{\pi}{3} + \varphi\right),$$

$$p = -\frac{\cos^2\alpha}{\sin\alpha}\cdot\frac{h}{x}\cdot\sigma_t \ldots\ldots\ldots\ldots\ldots [26]$$

Equations [25] and [26] have the peculiarity that the expressions for the variable $u = \log(x/x_1)$ and for the stresses σ_a and σ_t do not depend upon the angle α of the cone. In Fig. 13, the

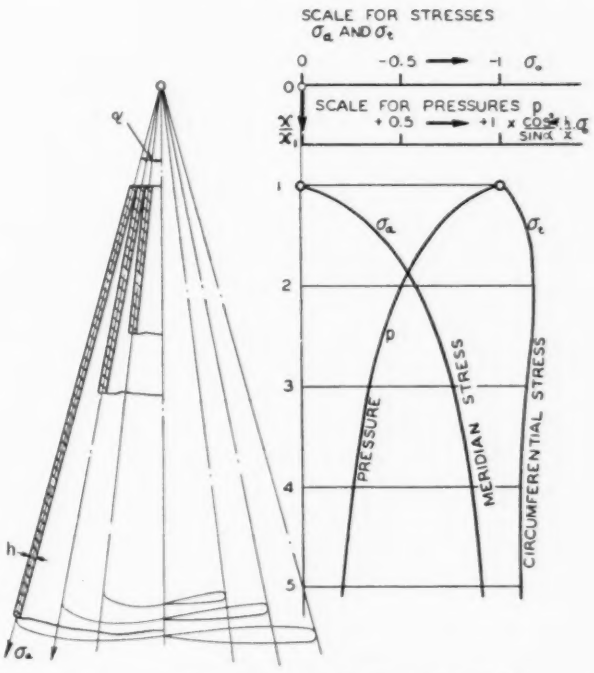


FIG. 13 PERFECTLY PLASTIC CONICAL SHELLS OF EQUAL THICKNESS; ($\mu = 0$, h = CONST)

stresses σ_a and σ_t and the pressures p have been plotted for this state of perfectly plastic conical shells. This set of curves for σ_a, σ_t, p can be used for any angle of inclination α of the cone. Referring to the curve representing the distribution of the pressures p the ordinates represented in Fig. 13 should be multiplied with a dimensional factor equal to

$$\frac{\cos^2\alpha}{\sin\alpha}\cdot\frac{h}{x_1}\cdot\sigma_0$$

The following two limiting cases of circular conical shells are included in these expressions (Equations [25] and [26]):

1 *Cylinder:*

When $\alpha = 0$ the conical shell becomes a circular cylinder. The angle φ loses its significance, but if it is taken equal to $\varphi = \pi/3$ Equation [25] is identically satisfied since $\sin\varphi = \sqrt{3}/2$. The expressions for σ_a and σ_t Equations [26] give

$$\left.\begin{aligned}\sigma_a &= -\frac{2\sigma_0}{\sqrt{3}}\sin\left(\frac{2\pi}{3} + \frac{\pi}{3}\right) = 0\\ \sigma_t &= -\frac{2\sigma_0}{\sqrt{3}}\sin\left(\frac{\pi}{3} + \frac{\pi}{3}\right) = -\sigma_0\end{aligned}\right\} \ldots\ldots [27]$$

when $\alpha = 0$ the factor $\cos\alpha/x_1 \sin\alpha = r_1$ becomes equal to the constant radius r_1 of the cylinder in the expression for the pressure p, Equation [26], and since $\cos\alpha = 1$ for the pressure p

$$p = -\frac{h\sigma_t}{r_1} = \frac{h\sigma_0}{r_1} \ldots\ldots\ldots\ldots\ldots [28]$$

the elementary formula of a cylinder under external pressure is obtained.

2 *Plane Disk:*

When, on the other hand, $\alpha = \pi/2$ the conical shell degenerates into a plane disk of equal thickness. Since $\cos\alpha = \cos\pi/2 = 0$ the pressure $p = 0$, the special case of a pure radial flow in a thin plane disk having a circular hole is obtained, which is stressed in

its plane by a uniform compression stress $\sigma_a = -\sigma_0$ at large distances from the center of the disk. This case of flow in a thin disk has been treated by the author on several occasions. For this special case of an infinite disk having a central hole of the radius a which is yielding under the action of a uniform compression stress, the following formulas were previously derived

$$\frac{r^2}{a^2} = -\frac{\sqrt{3}}{2} \cdot \frac{e^{\sqrt{3}\left(\psi - \frac{7\pi}{6}\right)}}{\cos \psi} \quad \ldots\ldots [29]$$

$$\left.\begin{aligned} \text{radial stress} \quad \sigma_r &= \frac{2\sigma_0}{\sqrt{3}} \sin\left(\psi - \frac{\pi}{6}\right) \\ \text{tangential stress} \quad \sigma_t &= \frac{2\sigma_0}{\sqrt{3}} \sin\left(\psi + \frac{\pi}{6}\right) \end{aligned}\right\} \quad \ldots\ldots [30]$$

$$\frac{7\pi}{6} < x < \frac{3\pi}{2} \quad \ldots\ldots [31]$$

Verification:

Simple considerations show that if the variable parameter φ for conical shells is taken equal to

$$\varphi = \frac{3\pi}{2} - \psi \quad \ldots\ldots [32]$$

Equation [25] transforms into

$$2 \log \frac{r}{a} = \sqrt{3}\left(\frac{\pi}{3} - \varphi\right) - \log\left[\frac{2 \sin \varphi}{\sqrt{3}}\right]$$
$$= \sqrt{3}\left(\psi - \frac{7\pi}{6}\right) - \log\left[\frac{2}{\sqrt{3}}(-\cos \psi)\right] \quad \ldots\ldots [33]$$

which indeed is obtained from Equation [29] by taking the logarithms on both sides of Equation [29]. Equations [26] similarly transform when Equation [32] is introduced into the formulas for the stresses σ_a and σ_t Equation [30] of the plane disk. Therefore our formulas for the plastic states of conical shells, when they are applied to the two special extreme cases of the circular cylinder or the plane disk, lead to the correct expressions which were previously obtained for these simpler cases of flow.

(*d*) *Uniformly Compressed Conical Shells When* $\mu = 0$. A further simple plastic state of stress in a conical shell should be mentioned which is obtained after assuming uniform stresses throughout the whole shell

$$\sigma_a = \sigma_t = -\sigma_0 = \text{const} \quad \ldots\ldots [34]$$

From Equation [9], we note that the pressure p required for the equilibrium of such a shell is equal to

$$p = \frac{\cos^2 \alpha}{\sin \alpha} \cdot \frac{h}{x} \sigma_0 = \cos \alpha \cdot \frac{h\sigma_0}{r} \quad \ldots\ldots [35]$$

p decreases according to a hyperbolic function of the axial distances x or the radii r of the shell.

Simplified and Abbreviated Theory of Plastic Cones

The previous examples which have been discussed in detail demonstrate conclusively that, in a conical shell in the plastic state, the circumferential stress σ_t very nearly remains constant. This is particularly true in shorter shells. Based on these observations it will therefore be permissible to introduce the assumption that $\sigma_t = -\sigma_0 = \text{const}$, throughout the whole shell. This amounts to assuming that instead of the plasticity condition in its general form, given by Equation [10], a flow condition

$$\sigma_t = -\sigma_0 \quad \ldots\ldots [36]$$

holds. In other words this amounts to substituting a horizontal line for the arc of "the plasticity ellipse" in Fig. 4 along which the required values of σ_a and σ_t lie. This is equivalent also to postulating that "the maximum-shear theory" expresses the condition of flow.

Under this assumption, from Equation [12], follows

$$\frac{d}{dx}(x\sigma_a) = -\frac{\sigma_0}{k} = \text{const} \quad \ldots\ldots [37]$$

or with the condition $x = x_1$, $\sigma_a = 0$ (at the tip of the conical nose) we obtain

$$\sigma_a = -\frac{\sigma_0}{k}\left(1 - \frac{x_1}{x}\right) \quad \ldots\ldots [38]$$

The pressure p is found from Equation [9] equal to

$$p = \frac{\cos^2 \alpha}{\sin \alpha} \cdot \frac{h}{x} \cdot \sigma_0 = \frac{\cos \alpha \cdot h\sigma_0}{r} \quad \ldots\ldots [39]$$

It should be emphasized that none of these equations should be used beyond those values of x which will make

$$|\sigma_a| > 2\sigma_0/\sqrt{3}$$

The total axial resultant force for deforming the shell is now expressed by the approximate formula

$$P = \frac{2\pi r_2 h\sigma_0\left(1 - \frac{r_1}{r_2}\right)\cos \alpha}{k} \quad \ldots\ldots [39a]$$

in which r_1 and r_2 are the mean radii of the conical shell at the tip and bottom of the shell, k is the constant given by Equation [11], h, the wall thickness, and σ_0, the yield stress for compression.

Standard Shell Nose

We assume that the shell nose is a portion of a torus shell of constant thickness, or of a body of revolution which is obtained

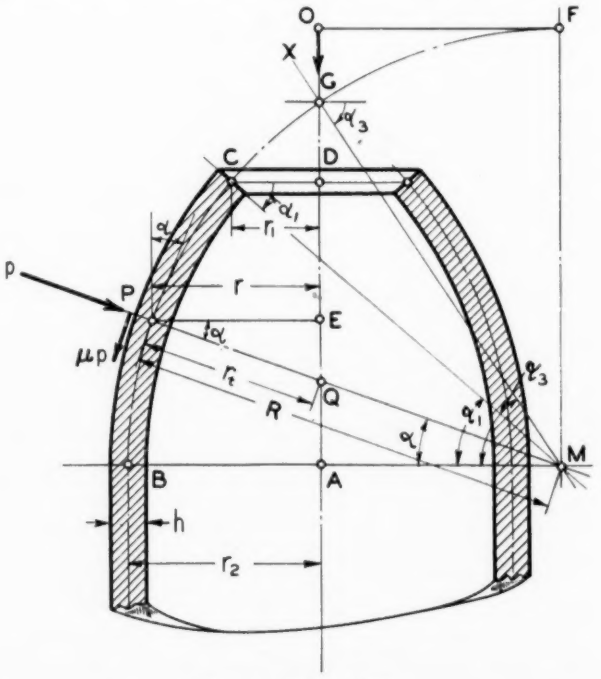

Fig. 14 Shell Nose

by rotating around an axis the area of a ring of constant thickness bounded by two concentric circles, Fig. 14. We designate by R the radius of the mean meridian circle of the shell nose and introduce rectangular co-ordinates x and r of a point P of the meridian circle. $x = OE$ is measured from the origin O downward (Fig. 14), $r = EP$ from the axis of the shell. The origin O is assumed in the distance $AO = R$ above the base of the nose (above the base plane MAB in Fig. 14). The wall thickness h is constant. The tip of the shell has the co-ordinates x_1 and r_1, the bottom, the co-ordinates x_2 and r_2. Using the angle of inclination α of the tangent to the mean meridian circle in point P, we have for

$$\left.\begin{aligned} x &= R(1 - \sin\alpha) \\ r &= r_2 - R(1 - \cos\alpha) \end{aligned}\right\} \quad \ldots\ldots\ldots\ldots [40]$$

Referring to Equation [4], expressing the first equilibrium condition of the shell, we note that the angle α' which was introduced in Fig. 2 is the complement of the angle α introduced in Fig. 14, or that $\alpha' = \frac{\pi}{2} - \alpha$. Since the direction of the friction force in Fig. 14 appears in the opposite sense relatively to the origin O from that in the sketch showing a shell element in Fig. 2, the sign before the term containing μ in Equation [4] has to be reversed and Equation [4] now takes the form

$$\frac{d}{dr}(hr\,\sigma_a \cos\alpha) + pr[1 + \mu \operatorname{cotan}\alpha] = 0 \quad \ldots\ldots [41]$$

In this equation we have to introduce from the geometric relations Equations [40] $dr = -R \sin\alpha\, d\alpha$ and the friction angle β. This gives

$$\frac{d}{d\alpha}(hr\,\sigma_a \cos\alpha) - \frac{Rr \sin(\alpha + \beta)}{\cos\beta} p = 0 \quad \ldots\ldots [42]$$

or after solving this for p

$$p = \frac{\cos\beta \cdot \dfrac{d}{d\alpha}(hr\,\sigma_a \cos\alpha)}{Rr \sin(\alpha + \beta)} \quad \ldots\ldots [43]$$

A second expression for p is taken from Equation [6], after noting that the radius of curvature r_a of the meridian curve or PM is now $r_a = R = \text{const}$, since the meridian is an arc of a circle drawn around point M as center in Fig. 14. For the same reason, the second radius of curvature $r_t = PQ$ of the shell is given by $r_t = r/\cos\alpha$. Equation [6] therefore takes the form

$$p = -\frac{h}{R}\left(\sigma_a + \frac{R \cos\alpha}{r} \cdot \sigma_t\right) \quad \ldots\ldots [44]$$

The last condition to be satisfied in a plastic shell is assumed

$$\sigma_t = -\sigma_0 = \text{const} \quad \ldots\ldots [45]$$

which must be substituted for the plasticity condition Equations [8] or [11].

Combining Equation [44] with Equation [43], assuming also that $h = \text{const}$, the following differential equation for the unknown meridian stress σ_a is obtained

$$\cos\beta \cdot \frac{d}{d\alpha}\left(\frac{r\sigma_a}{R}\cos\alpha\right) + \sin(\alpha + \beta)\cdot\left(\frac{r\sigma_a}{R} - \sigma_0 \cos\alpha\right) = 0 \ldots [46]$$

After introducing a new dependent variable

$$\sigma = \frac{r\sigma_a}{R} \quad \ldots\ldots [47]$$

and after rearrangement of terms, this differential equation takes the form

$$\frac{d\sigma}{d\alpha} + \tan\beta \cdot \sigma - \frac{\sin(\alpha + \beta)}{\cos\beta}\sigma_0 = 0 \quad \ldots\ldots [48]$$

in which β (the friction angle) and σ_0 are given constants. Equation [48] has the complete integral

$$\sigma = ce^{-\mu\alpha} - \sigma_0 \cos(\alpha + 2\beta) \quad \ldots\ldots [49]$$

where $\mu = \tan\beta$ and c is an integration constant.

The boundary condition to be satisfied is that at the tip of the shell nose for $\alpha = \alpha_1$ the stress $\sigma_a = 0$. Therefore, for $\alpha = \alpha_1$, $\sigma = 0$. This determines the integration constant

$$c = \sigma_0 e^{\mu\alpha_1} \cos(\alpha_1 + 2\beta)$$

and for σ

$$\sigma = \frac{r\sigma_a}{R} = \sigma_0\left\{[\cos(\alpha + 2\beta) - e^{(\alpha_1 - \alpha)}\cos(\alpha_1 + 2\beta)]\right\} \ldots [50]$$

is obtained. The meridian stress in the shell is therefore equal to

$$\sigma_a = -\frac{R\sigma_0}{r}[\cos(\alpha + 2\beta) - e^{\mu(\alpha_1 - \alpha)}\cos(\alpha_1 + 2\beta)] \ldots [51]$$

The circumferential stress is

$$\sigma_t = -\sigma_0 = \text{const} \quad \ldots\ldots [52]$$

and the pressure p in the contact area between shell nose and the die is found equal to

$$p = \frac{h\sigma_0}{r}\left\{\cos\alpha + \cos(\alpha + 2\beta) - e^{\mu(\alpha_1 - \alpha)}\cos(\alpha_1 + 2\beta)\right\} \quad \ldots\ldots [53]$$

The variable radius r appearing in Equations [51] and [53] is given by Equation [40], or by the expression

$$r = r_2 - R(1 - \cos\alpha) \quad \ldots\ldots [54]$$

The meridian stress σ_a reaches its maximum value at the bottom of the shell nose for $\alpha = 0$, where also $r = r_2$ so that we find

$$\sigma_{a\,\max} = -\frac{R\sigma_0}{r_2}[\cos 2\beta - e^{\mu\alpha_1}\cos(\alpha_1 + 2\beta)] \ldots [55]$$

while the total nosing force is found equal to

$$P = 2\pi r_2 h|\sigma_{a\max}| = 2\pi Rh\sigma_0[\cos 2\beta - e^{\mu\alpha_1}\cos(\alpha_1 + 2\beta)] \ldots [56]$$

Nosing forces P expressed by Equation [56] have been plotted as a function of the friction angles β in Fig. 15, for three angles of inclination $\alpha_1 = 5$ deg, 10 deg, and 15 deg at the tip of the nose. Along the abscissa axis, a second scale has been shown on which the corresponding values of the friction coefficients μ have been indicated. The figures shown along the ordinate axis have to be multiplied by the factor $2\pi Rh\sigma_0$ ($\pi = 3.14$, R mean radius of meridian, h wall thickness, σ_0 yield stress).

In practical nosing, a disturbance sometimes occurs which has been reported from various shell-forging plants. The wall thickness at the base of the nose is found sometimes to have increased. This local swelling of the wall thickness can also occur in the curved portion of the nose. Although there might be different reasons which cause the local bulging, and in some cases it may have been confused with local collapse of the wall due to plastic buckling, one important cause for it should be mentioned, namely, probably excessive friction. More precisely a condition must be

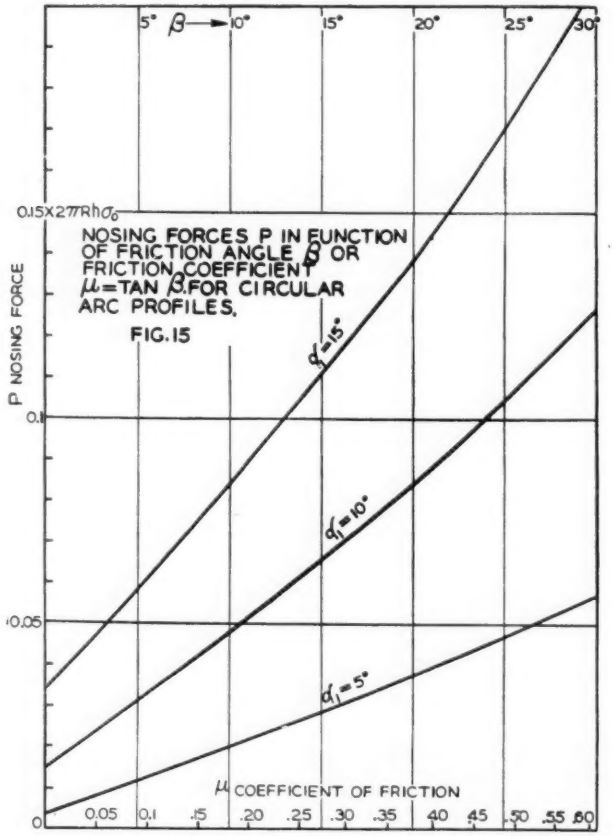

FIG. 15

satisfied during the nosing operation. It is not desirable that the meridian stress σ_a at the bottom of the nose for $\alpha = 0$ should reach the yield value for pure compression because this would have the consequence that the cylindrical portions of the shell adjoining the nose would also yield.

The condition which must be imposed on the nosing to avoid local bulging or swelling of the wall at the base of the nose is, therefore, expressed by

$$\alpha = 0, \; |\sigma_{a\max}| < \sigma_0 \quad \ldots\ldots\ldots\ldots\ldots\ldots [57]$$

or by

$$R[\cos 2\beta - e^{\mu\alpha_1} \cos(\alpha_1 + 2\beta)] \geqq r_2 \quad \ldots\ldots\ldots\ldots [58]$$

If the angle α_3 is introduced which refers to the point G in which the extension of the meridian circle intersects the axis of the shell, Fig. 14, we can write for

$$r_2 = R(1 - \cos\alpha_3)$$

and condition Equation [58] can also be expressed as follows

$$\cos\alpha_3 + \cos 2\beta - e^{\mu\alpha_1} \cos(\alpha_1 + 2\beta) \geqq 1 \quad \ldots\ldots\ldots\ldots [59]$$

If this inequality is satisfied no local swelling of the shell wall should occur at the base of the shell nose. For a given shell profile α_1 and α_3 are given angles; inequality [59] therefore imposes a condition on the friction.

Summing up the foregoing remarks, we can state that two independent causes must be quoted which limit the use of our equations for nosing. The first is that the condition of flow expressed by Equation [45] is good only when $|\sigma_a| < \sigma_0$; the second is that local swelling at the base of the nose should not occur. This condition is expressed by the same inequality, namely, $|\sigma_a| < \sigma_0$ at the base of the nose, or its equivalent inequality [59].

When $\mu = 0$, ($\beta = 0$) or when the friction is neglected Equations [51] and [53] take the simple form

$$\left.\begin{aligned} \sigma_a &= -\frac{R\sigma_0}{r}(\cos\alpha - \cos\alpha_1), \; \sigma_t = -\sigma_0 \\ p &= \frac{h\sigma_0}{r}(2\cos\alpha - \cos\alpha_1) \end{aligned}\right\} \quad \ldots\ldots\ldots [60]$$

If we again make use of the angle α_3 in expressing r_2 by

$$r_2 = R(1 - \cos\alpha_3)$$

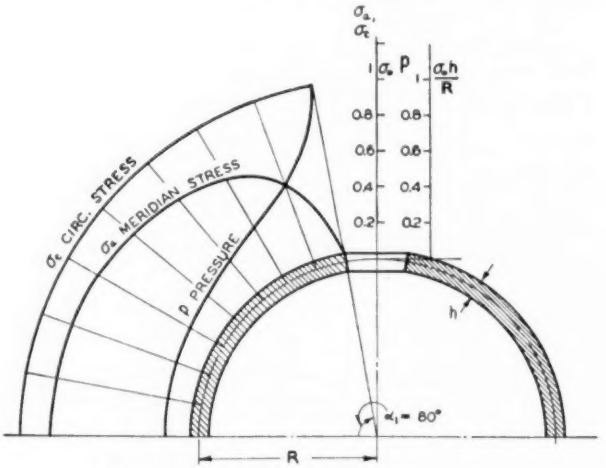

FIG. 16 STRESSES IN A SPHERICAL SHELL

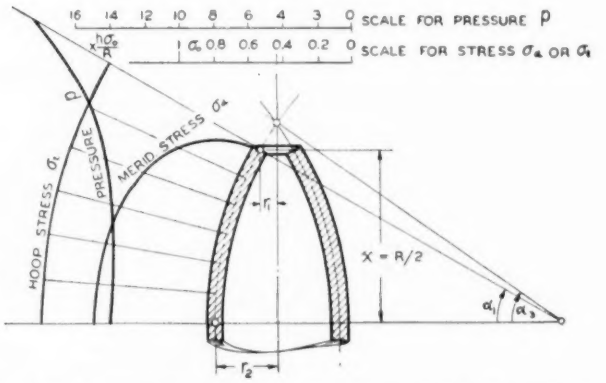

FIG. 17 PRESSURES, AXIAL AND CIRCUMFERENTIAL STRESSES IN STANDARD SHELL NOSE; ($\mu = 0$)

and the variable radius by

$$r = r_2 - R(1 - \cos\alpha) = R(\cos\alpha - \cos\alpha_3)$$

these formulas can be rewritten as follows

$$\left.\begin{aligned} &\text{meridian stress } \sigma_a = -\sigma_0 \cdot \frac{(\cos\alpha - \cos\alpha_1)}{(\cos\alpha - \cos\alpha_3)}; \; \sigma_t = -\sigma_0 \\ &\text{pressure} \qquad p = \frac{h\sigma_0}{R} \cdot \frac{(2\cos\alpha - \cos\alpha_1)}{(\cos\alpha - \cos\alpha_3)} \end{aligned}\right\} \quad \ldots [61]$$

expressing the state of stress in a plastic shell of circular profile when $\mu = 0$.

A special case of these latter equations refers to a hemisphere having a hole. We obtain after taking $\alpha_3 = \pi/2$

$$\sigma_a = -\sigma_0\left(1 - \frac{\cos\alpha_1}{\cos\alpha}\right),\quad \sigma_t = \sigma_0,\ p = \frac{h\sigma_0}{R}\left(2 - \frac{\cos\alpha_1}{\cos\alpha}\right) \ldots [62]$$

An example for a distribution of stresses in a hemisphere is shown in Fig. 16. The angle α_1 was assumed $\alpha_1 = 80$ deg. The pressure p shows a sharp rise near the edge of the comparatively small hole. From the last set of equations proceeding now to the limiting case of an infinitely small hole by assuming also that $\alpha_1 = \pi/2$ we note that they condense down to

$$\sigma_a = \sigma_t = -\sigma_0, \quad p = 2h\sigma_0/R \ldots [63]$$

or to the formulas for the elementary case of a spherical shell stressed by a uniform pressure p.

In a last example, a rather slender shell nose of this kind has been considered. For the angle of inclination at the tip of the nose $\alpha_1 = 30$ deg and $\alpha_2 = 35$ deg was assumed. This shell is reproduced in Fig. 17. It had the following dimensions

$$r_1 = R(\cos 30\text{ deg} - \cos 35\text{ deg}) = 0.0570R,\ r_2 = R(1 - \cos 35\text{ deg}) = 0.1910R$$

the height between tip and bottom of nose was R sin 30 deg $= 0.5000R$, where R is the radius of the mean meridian circle

The distribution of the stresses and of the pressures can be seen in Fig. 17. The pressures p reach their peak values at the tip of the nose, where a pressure maximum

$$p_{max} = 15.2\,\frac{h\sigma_0}{R}$$

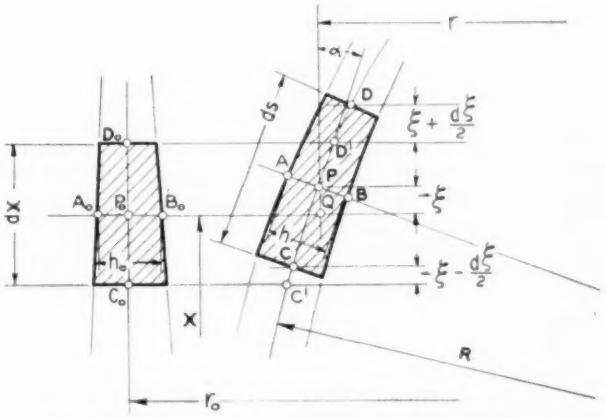

FIG. 18 ELEMENT OF SHELL BEFORE AND AFTER NOSING

was found. The maximum of the meridian stress occurs at the base of the nose ($\alpha = 0$) and was found equal to

$$\sigma_{a\,max} = -0.701\sigma_0$$

or equal to 70 per cent of the yield stress.

STRAINS IN THE SHELL NOSE

In the majority of the shell-producing plants, experiments were carried out for finding the exact contour lines of the rough original shell profiles which after nosing would produce the desired shapes of the shell noses prescribed by the Army Ordnance with due allowance for finish-machining. Simple geometric considerations facilitate this task which will be described briefly.

For this purpose, the shape of a small element of the original shell profile must be compared with its distorted shape after nosing is accomplished. This is shown in Fig. 18, in two cross-sections of the element contained in a plane passing through the axis of the shell. This latter is not shown in Fig. 18, but should be assumed as a vertical line on the right side of the figure.

The shell element in its original position is shown on the left side of Fig. 18, and, after nosing the shell, it is represented in an inclined position on the right side of this figure in the correct relation relative to its original position. All quantities referring to the first position of the element are designated by the subscript zero, and those referring to the final position without a subscript. The length $A_0B_0 = h_0$ changes into the length $AB = h$; $C_0D_0 = dx$ becomes an element of arc of a circle $CD = ds$; the original radius r_0 is contracted until it becomes the radius r, etc. The co-ordinate x of the point P_0 is changed into the co-ordinate $x + \xi$ of the point P. Point P_0 during the forging of the shell is displaced essentially in the radial direction but it is also slightly displaced in the axial direction by a small amount $\xi = PQ$.

Assuming that the meridian curve $C'CPD'D$ is a circle of the radius R we have

$$\left.\begin{aligned} x &= R\sin\alpha \\ r &= r_0 - R(1 - \cos\alpha) \end{aligned}\right\} \ldots [64]$$

Angle α is the angle of inclination of the tangent to the meridian curve in point P. The small shell element which has been shown in its cross sections in Fig. 18, must have the same volume before and after nosing. The first is expressed by $2\pi r_0 h_0 dx$ the second by $2\pi r h ds$. Therefore

$$r_0 h_0 dx = r h ds \ldots [65]$$

which can also be written as follows

$$\frac{r}{r_0}\cdot\frac{h}{h_0}\cdot\frac{ds}{dx} = 1 \ldots [66]$$

The original thickness h_0 of the shell before nosing could immediately be computed if the assumption could be made that all points P_0 during the nosing would be displaced in the radial directions only. The finished shell would in this case have to have the same length as the original one. In this case $\frac{dx}{ds} = \cos\alpha$ and the original thickness h_0 would have to be

$$h_0 = \frac{rh}{r_0\cos\alpha} \ldots [67]$$

Actually the plasticity theory predicts that the axial displacement ξ cannot vanish, but must increase (from the value $\xi = 0$ at the base) toward the tip of the nose. At the tip of the nose, the shell is stressed in pure compression in the circumferential direction. If we designate by ϵ_t, ϵ_a, ϵ_n the permanent (conventional) strains of the shell along the direction of the circumference, meridian, and normal at point P, these strains are defined by the three factors on the left side of Equation [66]

$$\frac{r}{r_0} = 1 + \epsilon_t,\quad \frac{h}{h_0} = 1 + \epsilon_n,\quad \frac{ds}{dx} = 1 + \epsilon_a \ldots [68]$$

and Equation [66] is also expressed by

$$(1 + \epsilon_t)(1 + \epsilon_n)(1 + \epsilon_a) = 1 \ldots [69]$$

If two of these strains are known, the third can be computed from this last equation.

Since the projections of the small portions CC' and DD', Fig. 18, of the meridian circle in a direction parallel to the axis of the shell are $\xi - \frac{d\xi}{2}$ and $\xi + \frac{d\xi}{2}$ respectively, the projection of the extended arc element $ds = CD$ in the same direction or $ds \cdot \cos\alpha$ must be equal to

$$ds\cdot\cos\alpha = dx + d\xi$$

Therefore

$$1 + \epsilon_a = \frac{ds}{dx} = \left(1 + \frac{d\xi}{dx}\right) \cdot \frac{1}{\cos \alpha} \quad \ldots\ldots\ldots [70]$$

defines the permanent strain ϵ_a along the meridian of the shell. The axial displacements $\xi = f(x)$ are naturally dependent upon the plastic behavior of the metal. On the other hand, the function $\xi = f(x)$ can be obtained from direct observations which were carried out at several shellmaking plants. Some attempts in this direction will be described in the following experimental portion of this report. A precise statement concerning the strains must be based upon a knowledge of this function.

Using Equations [66] and [70], we can now establish the correct expression which can serve to compute the original thickness h_0 of the shell. It is given by

$$h_0 = \frac{rh}{r_0 \cos \alpha} \cdot \left(1 + \frac{d\xi}{dx}\right) \quad \ldots\ldots\ldots [71]$$

It is easy to see that a shell must become longer after nosing. At the tip of the nose the metal has been stressed in pure compression in the circumferential direction, and in the whole neighborhood of the tip of the nose, we have seen that the meridian stresses σ_a are small. If the points P_0 would have moved in the radial direction only ($\xi = 0$), the shell elements would have stretched only in the proportion in which the arc lengths ds become longer than the lengths dx. Actually, they must stretch by far more in the axial direction due to the additional lateral expansion in this (and in the radial) direction, which must accompany a heavy circumferential compression of the metal. All shell elements become longer axially by additional amounts corresponding to the circumferential compression. Since at the tip of the nose $\epsilon_a = \epsilon_n$ we must obtain there the axial strain

$$\epsilon_a = \frac{1}{\sqrt{1 + \epsilon_t}} - 1 = \sqrt{\frac{r_0}{r}} - 1 \quad \ldots\ldots\ldots [72]$$

It must, however, be emphasized that the whole state of plastic strain near the tip of a shell nose is actually much more complicated than the simple state of strain which is present in a shell with thin walls. The simple geometric relations just used can serve only as a guide for judging the deformations in those portions of the shell in which the wall thickness remains a fairly small fraction of the mean radius.

Dependence of Constant σ_0 in Condition of Flow on Speed of Deformation and on Temperature

A few remarks are in order concerning the constant σ_0 appearing in many of the preceding equations of this report. Constant σ_0 was introduced in the condition of plasticity Equations [6] and [6a], and in subsequent equations as a material constant. According to the form in which the condition of flow was introduced, it was assumed that the constant σ_0 expresses the absolute value of the yield stress either in pure tension or in pure compression.

Various series of experiments performed at the Westinghouse Research Laboratories during past years have proved that an equivalent shearing stress τ_0 exists in the strain-hardening range of the ductile metals which is a given function of a certain permanent strain γ_0 which measures the intensity of cold work. Stress τ_0 is introduced as the shearing stress in the octahedral planes of the stress tensor. It depends upon the principal stresses $\sigma_1, \sigma_2, \sigma_3$ and is equal to

$$\tau_0 = \frac{1}{3} \cdot \sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2} \quad \ldots [73]$$

For not too large strains, the intensity of strain can be expressed by means of the permanent unit shearing strains γ_0 active in the octahedral planes or by

$$\gamma_0 = \frac{2}{3} \sqrt{(\epsilon_1 - \epsilon_2)^2 + (\epsilon_2 - \epsilon_3)^2 + (\epsilon_3 - \epsilon_1)^2} \quad \ldots [74]$$

where $\epsilon_1, \epsilon_2, \epsilon_3$ designate the principal permanent strains, which for small strains also satisfy the condition of constant volume

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \quad \ldots\ldots\ldots [75]$$

Although these relations can be extended to the further case in which the permanent conventional strains $\epsilon_1, \epsilon_2, \epsilon_3$ become of finite magnitude[6] by introducing the natural strains defined by $\bar{\epsilon} = \log (1 + \epsilon)$, no use of these relations was made in this theoretical part of the investigation because, for hot-nosing, strain-hardening is not of importance and some simpler means may suffice to express the influence of the temperature and of the speed of deformation in the formulas which have been given. This can be done by assuming that σ_0 or the equivalent shearing stress τ_0 is functions of the temperature and of the speed of plastic straining. From Equation [73], we see that in the case of pure tension $\sigma_1 = \sigma_0$, where σ_0 designates the yield stress in tension and $\sigma_2 = \sigma_3 = 0$; hence the equivalent octahedral shearing stress τ_0 is equal to $\tau_0 = \frac{\sqrt{2}}{3} \cdot \sigma_0$.

At forging temperature, we can make the assumption that τ_0 (or σ_0) is a given function of the permanent rates of shear $d\gamma_0/dt$ (or the strain rates $d\epsilon/dt$)

$$\tau_0 = f\left(\frac{d\gamma_0}{dt}\right) \quad \ldots\ldots\ldots [76]$$

It was found from numerous recent tests that, at a given permanent strain at even comparatively low temperatures (in the strain-hardening range), such a relation holds for the ductile metals.[7] At low temperatures τ_0 slowly increases with the rates of shear $v = \dot{\gamma}_0 = \frac{d\gamma_0}{dt}$ according to a logarithmic function

$$\tau_0 = \tau^* \left(1 + \log_e \frac{v}{v^*}\right) \quad \ldots\ldots\ldots [77]$$

τ^* and v^* are two material constants. Equation [77] should be used for $v > v^*$.

At forging temperatures this speed dependence of the stresses τ_0 becomes much more pronounced. Just a few experiments of this kind are available in this important range of the temperature at the large rates of straining used in forging presses.[8] From these and from some work which has been done at much lower rates of flow (at strain rates of the order $\frac{d\epsilon}{dt} = 10^{-4}$ up to 10^{+1} per sec), it seems probable that a hyperbolic sine function

$$v = \frac{d\gamma_0}{dt} = v^* hyp \sin \frac{\tau}{\tau^*} \quad \ldots\ldots\ldots [78]$$

expresses the speed dependence at a given temperature, but comparatively little information is yet available about the numerical

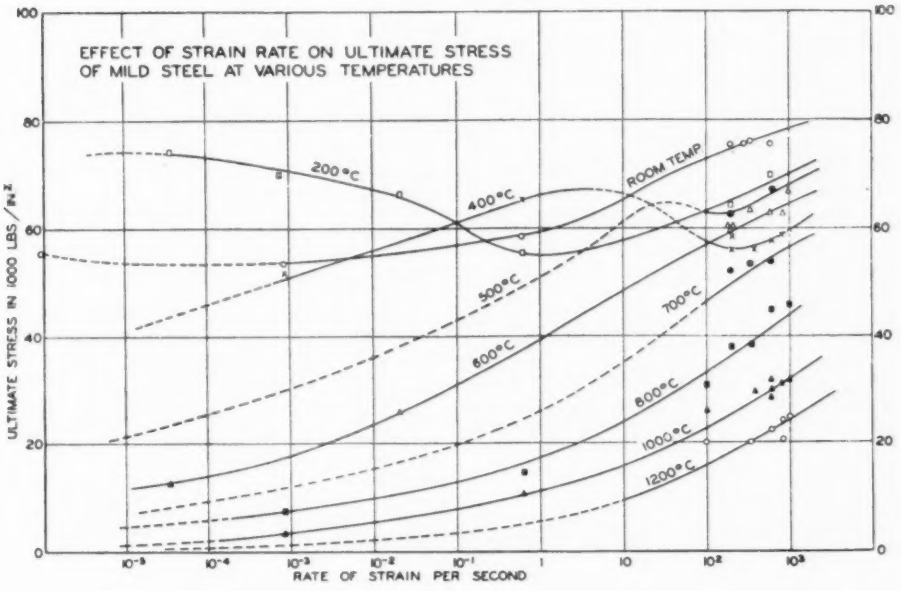

FIG. 19

values of the material constants v^* and τ^* appearing in this function.

In Figs. 19 and 20, the results of a series of tension tests are reproduced indicating the dependence of the ultimate stress on the rates of strain for a mild steel at various temperatures. These curves may be helpful to estimate values of our constant σ_0 by identifying it with the "ultimate stress" of a tensile test. On the right side of Fig. 19, appear the results which were observed at the highest rates of stretching. The abscissas in Fig. 19, represent the conventional rate of strain $d\epsilon/dt$ of a tensile test. They are plotted on a logarithmic scale. The ordinates in Figs. 19 and 20 are the corresponding ultimate stresses. The high rates of $d\epsilon/dt = 10^3$ 1/sec correspond to high-speed tension tests in which the bars were broken in less than 0.001 sec. The range of the investigated temperatures extended from room temperature to 1200 C = 2192 F. The range between the two curves for 1000 C = 1832 F, and for 1200 C, covers the temperatures of interest in shell-making at forging heats. Both curve sheets indicate at least the order of magnitude of the effect of plastic deformation and of temperature which must be expected under forging conditions in a steel.

SUMMARY

The theory of curved shells has been extended to cover cases in which the metal is in a plastic state of equilibrium. Although the three general equations for shells, whose middle surface is a surface of revolution, have been established for the plastic state and for variable wall thickness in this investigation only shells with uniform wall thickness were considered. These equations were fully developed for the case of conical shells, including the two limiting cases of cones, namely, the cylindrical shell, and the plane disk of uniform thickness. The distribution of the meridian and circumferential stresses σ_a and σ_t, of the pressures p for forming such shells through contact with a hollow die were studied in a number of special cases and in examples for different values of the friction coefficient, defining the resistance against gliding between the die and shell. A simplified and abbreviated theory was also given for the case of a conical shell and also for the standard shell nose whose meridian curve is a circle leading to workable and even quite simple expressions for the total nosing force. It was shown that the plastic states of stress in such

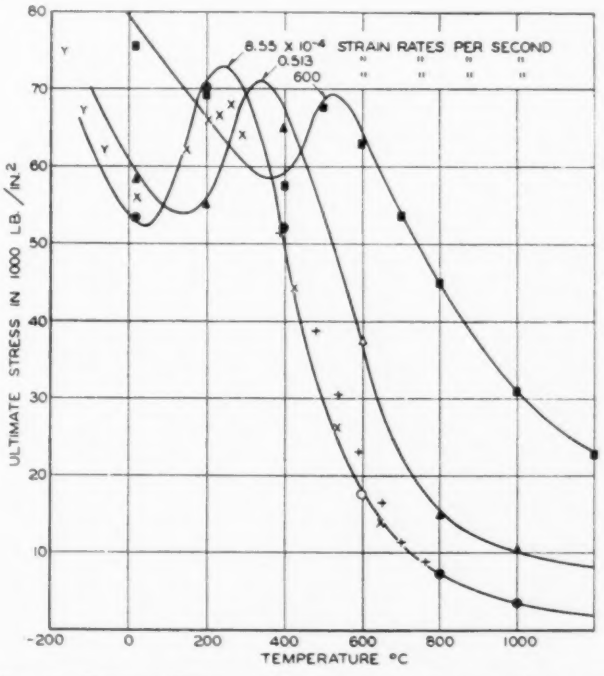

FIG. 20 TENSION TESTS OF MILD STEEL AT VARIOUS TEMPERATURES AND RATES OF STRAIN

curved shells in first approximation can be described by assuming a uniform circumferential stress σ_t. It was furthermore shown that certain limiting conditions are imposed on nosing through the friction. The condition for preventing local swelling of the wall thickness at the base of the nose was expressed.

The distortion of the elements of the metal during the formation of the nose of a shell was described, and expressions were given permitting to predict the original contour of the shell which after nosing furnishes a prescribed profile in the nose of a shell.

ACKNOWLEDGMENTS

Acknowledgments are due to Dr. M. Stone, Chairman, and to

Prof. W. Trinks, Projects Director of the A.S.M.E. Research Committee on Forging of Steel Shells for having disclosed to the author important details concerning difficulties encountered in forging of shells. The author also acknowledges the helpful assistance received from Dr. L. W. Chubb, Director of the Westinghouse Research Laboratories, which made this theoretical and the companion experimental investigation with the assistance of Mr. R. K. Carlson possible.

The following references concerning the related problem of the deep drawing of thin hollow bodies should be quoted.

An Experimental Investigation of the Nosing of Shells

By R. K. CARLSON,[1] PITTSBURGH, PA.

Objects of the Investigation

THE general object of the work done at the Westinghouse Research Laboratories under the auspices of the A.S.M.E. Special Research Committee on Forging of Steel Shells was to study the nature of the nosing process in the forging of shells. In particular, plans were made to study the effects of temperature, lubrication, and speed on the forces required for nosing shells of various sizes. It was not, of course, possible to work with full-sized shells; and, consequently, small models were used in the experimentation.

The huge amount of experimenting undertaken by the industry before entering shell production seems to indicate that the model tests can, at best, serve only to confirm conclusions already reached by the great number of shell manufacturers. Nevertheless, it is hoped that the results of the work described in this report will prove of some interest to those having to do with shell-forging processes.

Description of Apparatus

A consideration of the capacities of presses used in the forging of shells in steel plants indicated that a press of about 15 tons capacity would be required for the experimental work which was contemplated. The apparatus, Fig. 1, consists essentially of a 15-hp 220-v d-c shunt motor driving a Hydro-Power Systems, Inc., rotary pump capable of delivering 60 gpm of oil (at 900 rpm) against 500 psi pressure continuously, or 1000 psi flash. The pump discharges into a 7-in. hydraulic cylinder (1) (see Fig. 1) through a four-way, hand-operated control valve (3). The cylinder has a stroke of 12 in., and, at 1000 psi pressure, a load of about 20 tons can be applied. Valves were purchased from the Logansport Machine Company, Logansport, Ind., and the cylinder was manufactured by Hanna Engineering Works, Chicago, Ill. The specimen holder (4) (see also Fig. 2) was used as a positive stop in conjunction with the die (see Fig. 4). The die was heated to approximately 1000 F by means of a resistance heater (6). The induction coil, used to heat the shell before forging, operated on a frequency of 9600 cycles per sec. A Maihak Diesel-engine indicator (2) was used to obtain records of cylinder pressure as a function of the displacement of the cylinder. In order to obtain various speeds of the cylinder, a field rheostat was used with the motor, making it possible to vary the delivery of the pump.

Apart from some vibration of the equipment at the very low speeds (400 rpm of the motor) and at the high speeds (over 1000 rpm), no particular difficulties were encountered in the operation of the equipment.

Description of Specimens

Details of the specimen used for the majority of the tests are shown in Fig. 3. This specimen has approximately the same length-diameter and wall thickness - diameter proportions as the regular 155-mm shell. Commercial open-hearth cold-rolled steel was used in making the specimens. Stress-strain curves of this material tested in compression are shown in Figs. 5 and 6. While the carbon content of this steel is lower than that of the steel ordinarily used in shell production, it was felt that the forgeability at temperatures above 1500 F would not be greatly different.

The die employed throughout the experiments is shown in Fig. 4. The die was made from one of the high-temperature alloys (K-42-B) developed at Westinghouse for use in gas turbines and similar applications. To simulate the amount of nosing done on the 155-mm shell, $2^1/_4$ in. of the specimen was made to enter the die, giving a maximum reduction in the mean diameter of from 65–70 per cent.

In order to produce less severe nosing than that obtained in forming the larger shells, the specimen shown in Fig. 3 was made short enough to allow 1.45 in. to enter the die. A reduction of about 33 per cent in the mean diameter was obtained in this manner. This amount of nosing corresponds to that on the 105-mm shell.

For the few nosing tests which were run cold, the specimen shown in Fig. 7 was used. The outside diameter is the same as that of specimen *A*, but the inside diameter is made slightly

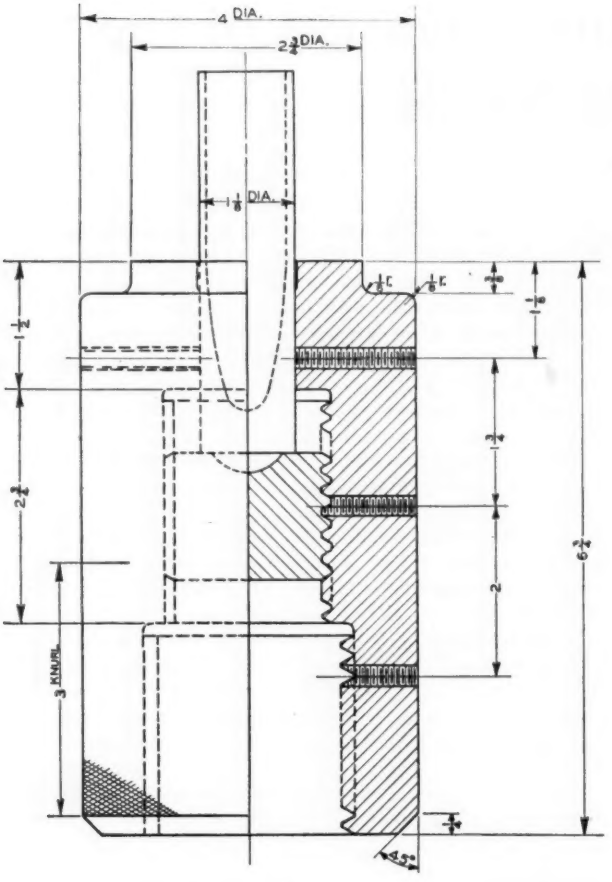

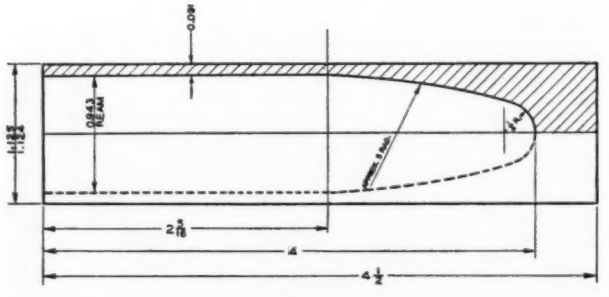

FIG. 2

SPECIMEN A
SCALE 2:1

FIG. 3

smaller. In the smaller shells, namely, the 75 and 90 mm (those most often nosed cold), the thickness - diameter ratio is slightly greater than for the larger shells.

TESTING PROCEDURE

Prior to any testing, considerable experimenting was necessary to obtain the proper temperature distribution along the specimen by means of induction heating. Several coils were tried before satisfactory results were achieved. To measure the temperature distribution, six chromel-alumel thermocouples were placed along the shell model. Temperature readings were made by means of an eight-point thermocouple switch leading to a 0–2000 F Wheelco instrument. The temperature distributions possible for the two lengths of noses are shown in Figs. 8 and 9. In running a particular test, only two couples were used, both near the tip of the specimen; the temperature at the tip was taken, then, as characterizing the distribution. Check runs with six couples were made occasionally to see that the same temperature distributions were maintained.

In preparation for a test, it was necessary to heat the die for about 1 hr to bring it to 1000 F. The motor speed was then properly adjusted by means of field control. After placing the specimen in the fixture on top of the cylinder, the induction coil was moved into place and the shell heated. About 1 min was required to heat the shell to testing temperature—from 1600 F to 2000 F at the tip. When the shell reached a temperature somewhat above that at which nosing was to take place, the coil was

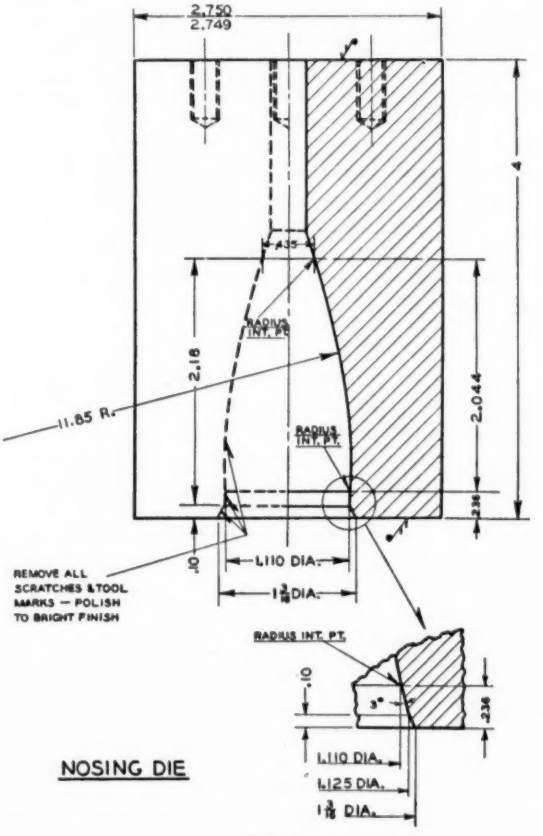

FIG. 4

quickly removed and the 4-way valve opened to allow oil to enter the cylinder. Since the temperature of the specimen dropped 100–150 F in bringing the shell up to the die, the temperature at which the shell actually entered the die was observed and recorded as the temperature condition for the test. Lubrication of the die was done by means of asbestos swabs saturated with the lubricant. The lubrication was done just before removing the induction coil and starting the cylinder upward. The time of nosing was of the order of 1 sec. More information concerning speed of testing will be given later.

Naturally, an attempt was made to keep the testing procedure uniform throughout the whole of the experimentation.

EXPERIMENTAL RESULTS

The tests which were run during this investigation may be divided into several groups, as follows:

1 Nosing equivalent to that on 105-mm shells.
2 Nosing equivalent to that on 155-mm shells.

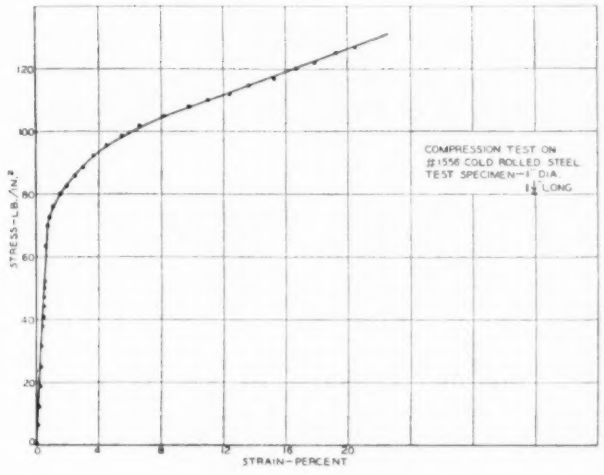

FIG. 5

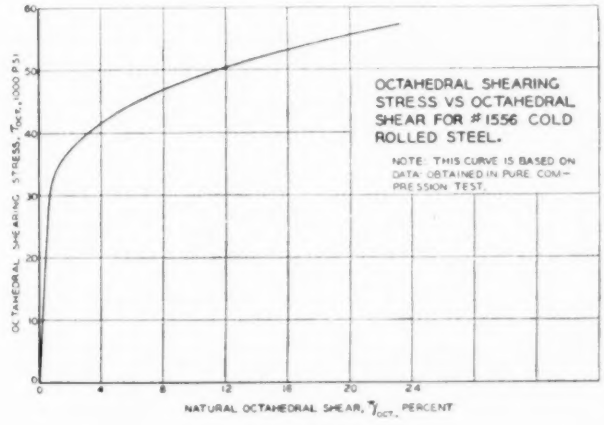

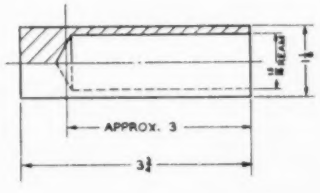

FIG. 6

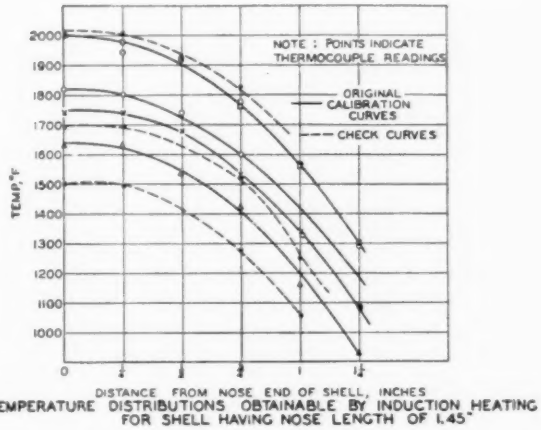
COLD NOSING SPECIMEN

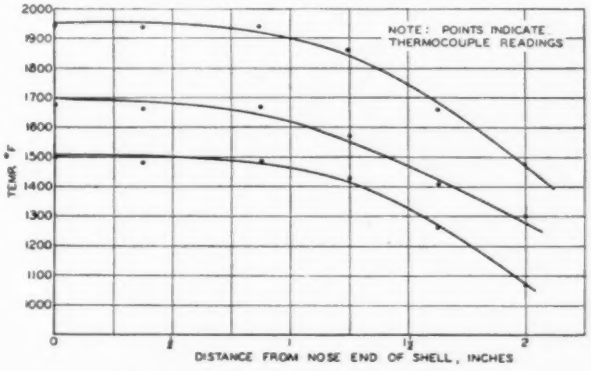
FIG. 7



3 Cold-nosing.

4 Lubrication tests.

In describing the experimental results, a brief discussion of each of these series of tests will be given, followed by a general interpretation.



1 The invariant in the first two groups of tests listed was lubrication, a mixture of 325-mesh graphite and machine oil being used throughout. It was found during the experimenting with various lubricants that this mixture gave favorable results in comparison with a number of commercial hot-forging lubricants.

The nosing equivalent to that on the 105-mm shell corresponds to about a 33 per cent reduction in the mean diameter. In Fig. 10, four typical specimens belonging to this series are shown. It should be noted that at the present time, most shell-forging plants have presses capable of cold-nosing the 105-mm shell, and it is

only where the press capacity is low that this shell is hot-nosed. As can be seen in Fig. 10, only a small amount of deformation takes place.

Test conditions were varied as follows: nose-tip temperatures in the range 1600 F to 1900 F were combined with piston speeds of from 1.5 to 2 in. per sec. Attention is again called to

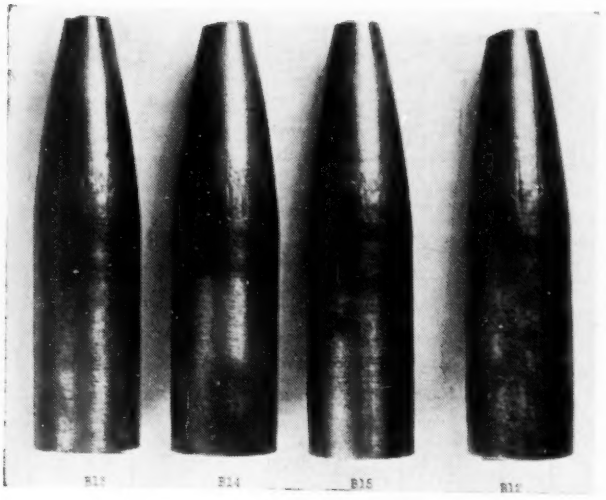

FIG. 11

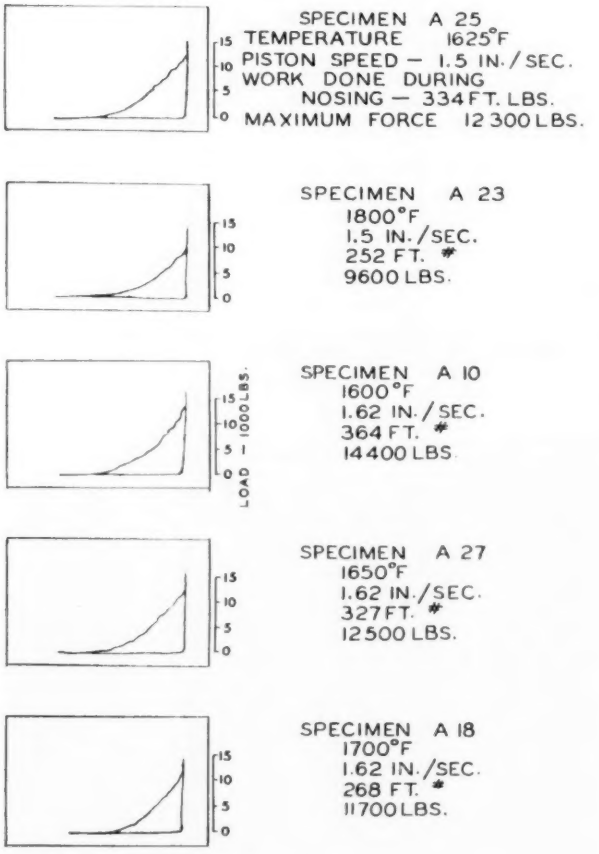

FIG. 12

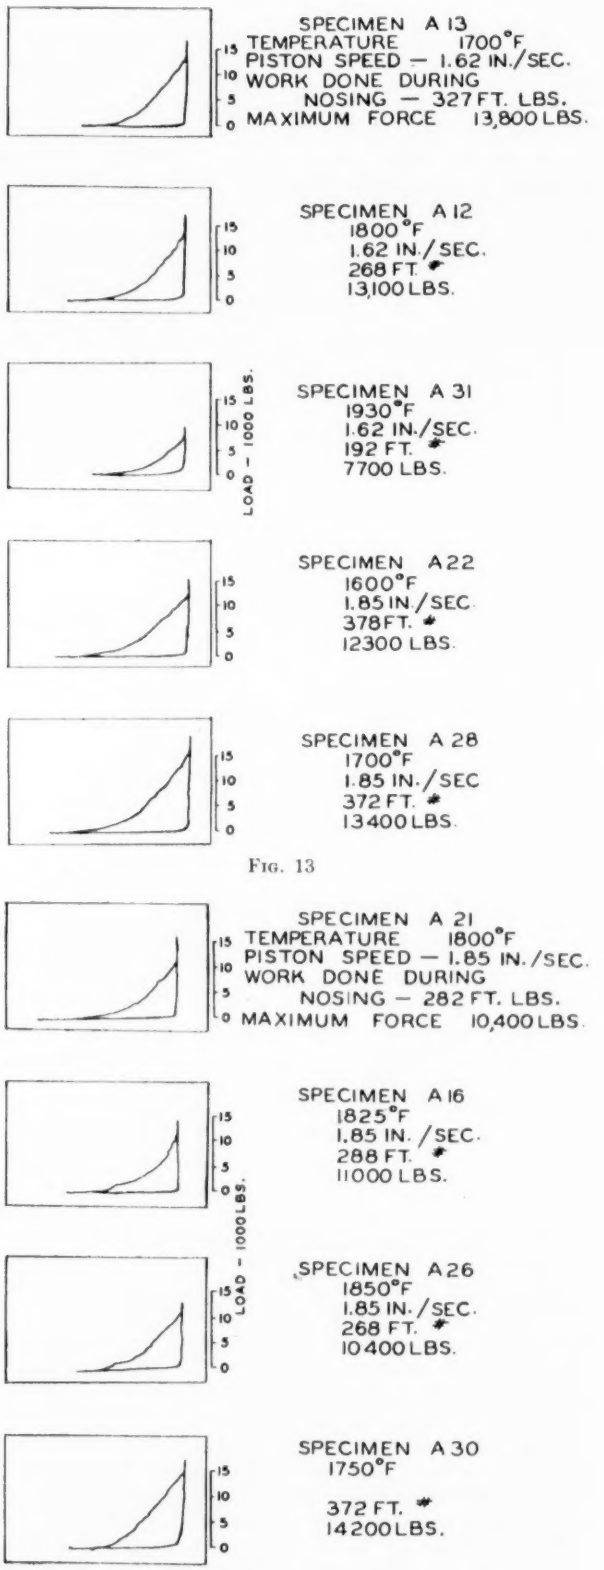

FIG. 13

FIG. 14

Fig. 8, where the temperature distributions along the nose of the shell for various tip temperatures are given.

In Figs. 12, 13, and 14 are shown the original indicator diagrams for this group of tests. All pertinent information for each test is given in the figures. Some remarks concerning the characteristics of the indicator diagrams will be made in the general discussion to follow.

The quantitative information which was derived from the nosing tests, namely, the maximum force during nosing and the total work done, has been plotted in Figs. 17 and 18. The curves of work done versus temperature are fairly regular, that is, there is no excessive scattering. However, the maximum-force curves do

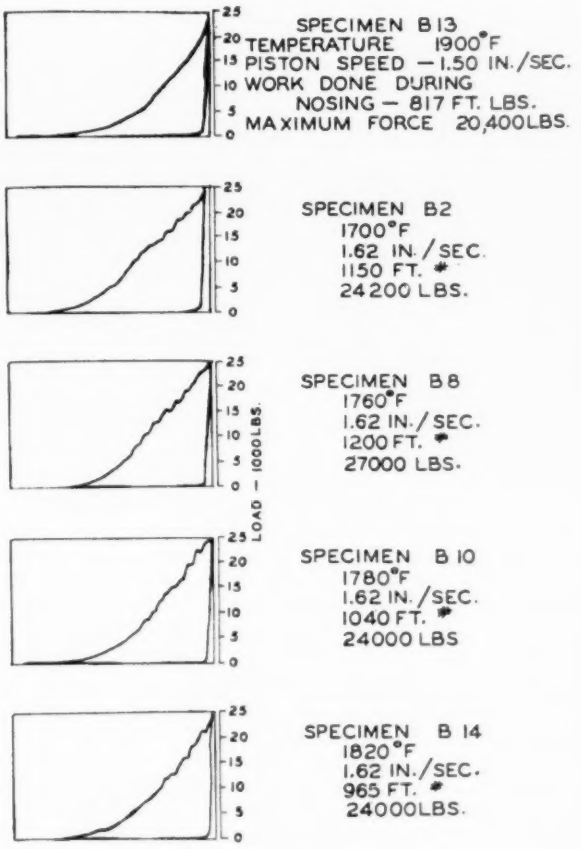

FIG. 15

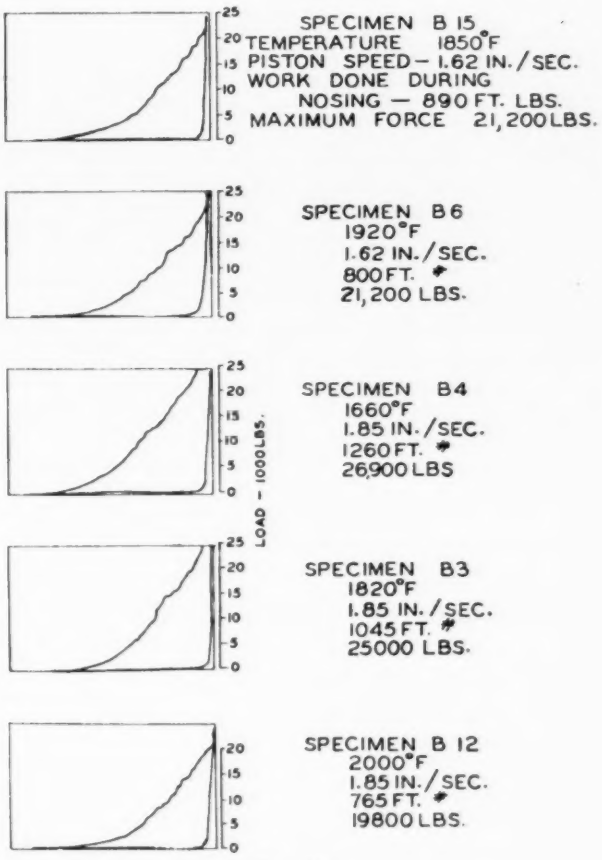

FIG. 16

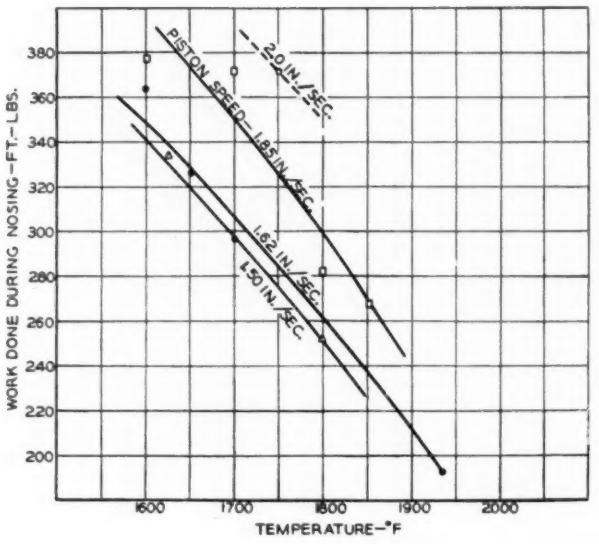
show considerable scattering. Perhaps the original indicator diagrams (Figs. 12, 13, and 14) provide the key to this; it should be evident that the determination of the maximum force from these diagrams is a much more sensitive task than the determination of the area (that is, the work) by means of a planimeter. Further discussion of these curves will follow.

2 The amount of nosing on the 155-mm shell corresponds to about a 67 per cent reduction in the mean diameter. Four typical specimens having approximately this reduction in diameter are shown in Fig. 11. The original indicator diagrams of the majority of the tests in this group are shown in Figs. 15 and 16.

Test conditions for the greater amount of nosing were very similar to the conditions of the tests in group 1. A temperature range from 1600 F to 1900 F (one test at 2000 F) was covered at piston speeds of 1.5 to 1.8 in. per sec. Plots of work done and maximum forces as functions of temperature are shown in Figs. 19 and 20. Again, the work-temperature curves show very little scattering, while the maximum force determination is apparently critical and not a good measure to use as a quantitative characteristic of the test.

3 The cold-nosing was done with the specimen shown in Fig. 7. Since maximum forces of the order of 30,000 lb were required to nose this shell, this specimen was nearly the longest that could be forged with the equipment which was employed. Several cold-nosing lubricants were tried: a commercial mill lubricant; palm oil; lauric acid; and several other commercial lubricants. No apparent differences in the amount of work required to nose the shell were noticed for these lubricants. It would appear that the problem of lubrication during cold-nosing is a much simpler one than that in hot-nosing.

4 The choice of a lubricant for hot-nosing full-sized shells is a very complicated one. The many factors entering into the problem of lubrication—die life, ease of nosing, ease of application, cost, availability, etc.—make it dangerous to draw any too definite conclusions from such tests as reported herein concerning the desirability of one lubricant over another.



Some twelve different lubricants, most of them commercial products, were used. At least two tests were run using each of the lubricants. The results of the tests on each lubricant were interpreted to obtain a value of work necessary for nosing at a nose-tip temperature of 1900 F, and a piston speed of 1.82 in. per sec. The tests were all made on specimen *A*, the amount of nosing being equivalent to that on the 155-mm shell. Table 1 shows the range of values obtained for the work necessary for the forging operation. Names of the commercial lubricants employed are omitted.

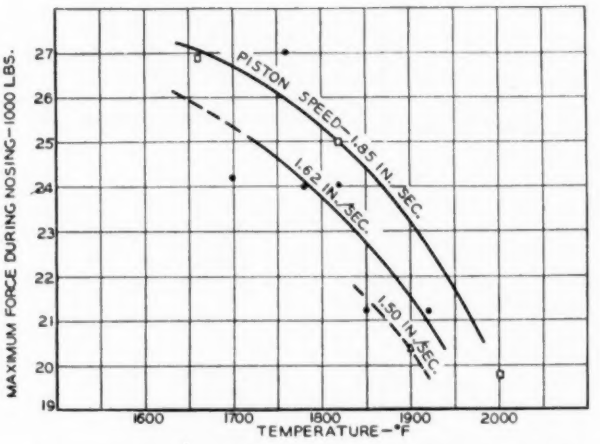

FIG. 18

general, it was found that the heavier lubricants gave the best results. It was noted that the better lubricants, while apparently having just as low a flashpoint as the poorer ones, left a spongy deposit on the die after burning. It is thought that this residue helped to hold the graphite on the die surface.

INTERPRETATION AND DISCUSSION OF NOSING EXPERIMENTS

Perhaps a brief description of the difficulties encountered in forging small model shells will aid a critical evaluation of the results obtained. At the time the experiments were started, shell manufacturing was proceeding satisfactorily, that is, most of the practical difficulties had been eliminated. Naturally, therefore, we were aware of the problems which would probably be met in forging models.

Undoubtedly, proper heating of the shell is one of the more im-

TEST RESULTS FOR NOSING CORRESPONDING TO A 67% REDUCTION IN MEAN DIAMETER

FIG. 19

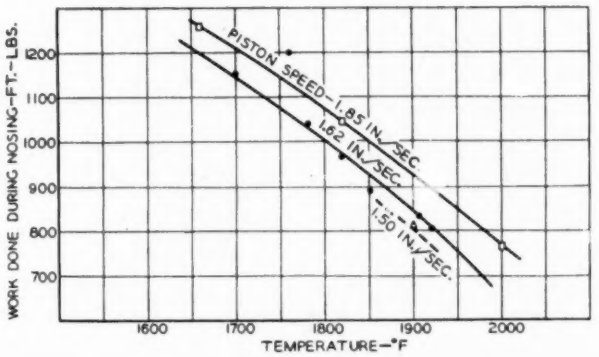

FIG. 20

FIG. 21

portant preparations which must be made before nosing. The danger of improper heating is demonstrated very clearly in Fig. 21. The two shells at the right were among the first trials on the equipment and little attention had been given to the temperature distribution along the shell. Obviously, a hot band of material was formed below the tip of the nose which gave way under the forces required to deform the tip. The shell specimen at the left was tested with a controlled temperature distribution designed to show the unsatisfactory results obtained by improper heating. The temperature at the tip of the shell was 1500 F, and about halfway down the shell it rose to 1800 F. It is clear from the illustration that very little deformation of the tip was possible before the mid-portion of the shell buckled. Trouble similar to this had been encountered in the industry.

When discussing plans for carrying out the experimental work, the question of the cooling of the small model shell during forging was brought up. It was realized that the small mass of metal in the specimens would not stay at the proper temperature, if forging was attempted with a cold die. The die was therefore heated to about 1000 F by means of a resistance heater. Several observations of the temperature drop at the tip of the shell during a test were made and it was found that, if the temperature of the shell at the tip was 1900 F just as the shell entered the die, the temperature would drop to between 1500 F and 1550 F at the end of the forging operation. It is possible of course that the temperature readings at the end of the test are in error since the thermocouples might easily be disturbed by the deformation of the tips. Observations made at Case by the Shell Forging Committee indicated a drop from 1775 F to 1550 F during the forging of a 155-mm shell. It might have been desirable to heat the die somewhat higher than 1000 F, but with the original furnace, it was not possible to obtain a higher temperature; and it was felt that the conditions were satisfactory enough to warrant not designing a new heater.

The application of a lubricant to the die is a problem of some importance in the industry. A method must be employed that is quick, safe, and which provides for effective spreading of the lubricant. It has been noted in shell-manufacturing plants that special care must be taken to see that the lubricant is distributed evenly over the die; for if the die is not completely lubricated, the shell tip will not be flat perpendicular to the axis of the shell. Some difficulty of this sort was encountered early in the testing.

One of the chief problems confronting shell manufacturers at the outset of production was that of designing the profile of the shell before nosing so as to give the desired finished shape after forging. Some remarks concerning this question will be made in the discussion of the flow tests made on full-size shells.

It must be admitted that, in general, the test results were erratic. The nosing operation is a complicated one and slight variations in temperature and friction conditions from test to test result in considerable scattering of the data. However, force measurements taken from successive forgings of full-sized shells did not give consistent values for the maximum observed forces. The reliance placed on the curves, shown in Figs. 17, 18, 19, and 20, should be tempered by a consideration of the scatter of the plotted points.

The expected temperature influence was observed. It can be seen from Fig. 17 that for a 33 per cent reduction in diameter, a change in the nose-tip temperature from 1600 F to 1900 F reduced the work required for the nosing operation by about 40 per cent. For a 67 per cent reduction in the mean diameter, the same temperature change (1600 F to 1900 F) reduced the work required by 35 per cent, Fig. 20. The maximum force - temperature curves are very similar in shape to the work-temperature curves. Thus for 33 per cent nosing a 40 per cent decrease in the maximum force was observed when the nose-tip temperature was raised from 1600 F to 1900 F. The maximum-force curves for 67 per cent nosing seem to be flatter than the others, that is, the temperature rise from 1600 F to 1900 F results in only about a 15 per cent decrease in the forces required for forging.

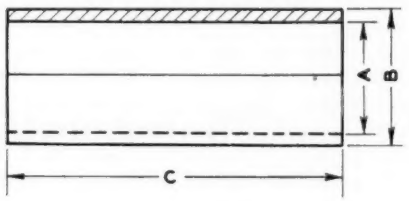
The effect of speed on the forces and work required for nosing is a little remarkable. For 33 per cent nosing at 1800 F, a 33 per cent rise in piston speed, from 1.50 in. per sec to 2 in. per sec, increased the work necessary for nosing by 40 per cent. Again, at 1800 F, a 20 per cent rise in piston speed, from 1.50 in. per sec, to 1.85 in. per sec, results in a 20 per cent rise in the work done. A 20 per cent increase in piston speed changes the work necessary for 67 per cent nosing at 1900 F by about 15 per cent. These large increases in the work required can hardly be explained by the change in resistance to plastic deformation due to changes in speed. Tests by Nadai and Manjoine[2] indicated that in the region of the rates of strain imposed on the shells, from 0.2 to 0.5 in. per in. per sec, there is very little speed effect. The considerable change in work must be explained then in another way. It is to be expected that at higher speeds the lubrication will not be as effective as at the lower speeds. However, it seems improbable that the friction would be changed by any considerable amount for a 20 or 30 per cent change in speed. Perhaps the combination of the effects of speed on lubrication and resistance to deformation is sufficient to produce the observed results.

From the test results reported, it would seem advisable to forge at as low a speed as is compatible with production requirements. However, it is very probable that on full-sized shells, the effect of speed on the geometry of the metal flow will be an important consideration. It is impossible to predict the nature of this phenomenon from the model tests.

Buckling Tests

Unless a shell is properly designed it may buckle under the forces necessary for nosing. In most cases, the shell wall is so thick that the proportional limit of the material will be reached before the equilibrium of the shell becomes unstable; and the buckling, if it occurs, is plastic. If the shell is nosed cold, there are well-established formulas for predicting the critical buckling load, given the ratio of the thickness of the shell wall to the diameter. In hot-nosing, however, the critical load is a function of the temperature distribution along the nose of the shell as well as of the wall-thickness diameter ratio, that is, if the temperature distribution is not correct, a sort of "semibuckling" occurs. This semibuckling is a result of the improper flow of metal imposed by the external load. A thickening, or bulge, near the bottom of the nose, usually on the inside, resulting from an improper temperature distribution caused considerable difficulty when shell production first began. Of course, when buckling of the shell wall occurs during nosing, either the shell-wall profile must be redesigned or the temperature at the tip of the nose made higher to reduce the forces required. The elastic buckling of cylindrical shells is treated by Timoshenko.[3] Timoshenko obtains the following formula for the stress necessary to cause buckling

$$\sigma_{cr} = \frac{Eh}{a\sqrt{3(1-\nu^2)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$



where

E = modulus of elasticity, psi
h = thickness of shell, in.

COMPRESSION SPECIMENS FOR BUCKLING TESTS

FIG. 22

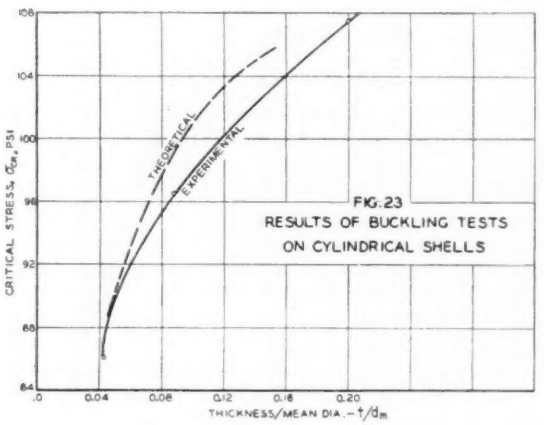

FIG. 23

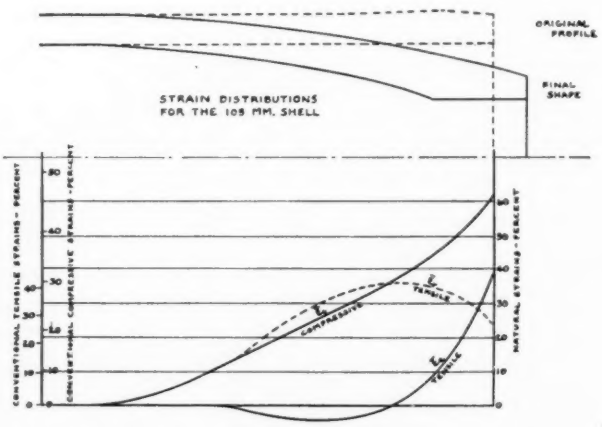

FIG. 24

a = radius of shell, in.
ν = Poisson's ratio

This formula applies only when the critical stress is below the proportional limit of the material. If buckling occurs at higher stresses, an approximate formula may be used to obtain the critical stress

$$\sigma_{cr} = \frac{E_R h}{a\sqrt{3(1-\nu^2)}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

Here, E_R, the so-called "reduced modulus," is a function of the stress-strain diagram of the material. An analytical expression for E_R for a rectangular cross section has been given by von Kármán and others

$$E_R = \frac{4EE_T}{[\sqrt{E} + \sqrt{E_T}]^2}$$

E_T is the "tangent modulus," or the slope of the stress-strain curve at σ_{cr}. While this value for E_R applies rigorously only to rectangular cross sections, it may be used as an approximation to E_R for the cylindrical shell.

In order to verify the buckling formulas given for wall thickness - diameter ratios in the range found in shells, a number of tests were made using the specimens shown in Fig. 22. A range of thickness diameter ratios from about 0.04 to 0.20 was covered by the few tests which were made.

A 200-ton Amsler press was used in making the buckling tests. The critical load was taken as the load at which an appreciable amount of radial motion took place without any increase in load. In all cases, buckling took place well within the plastic range of the material.

The results of the tests are shown in Fig. 23. The dotted line is a theoretical curve based on Equation [2]. As can be seen, the use of the reduced modulus, calculated from the stress-strain curve, gives very satisfactory results.

If the stress-strain characteristics of the material to be used for making shells are known, and the maximum forces required, it is possible for the engineer to estimate fairly closely whether there will be danger of buckling of the shell wall. Of course an estimate based on the previous experience of shell manufacturers would probably be just as reliable. Usually, information about the physical properties of materials in the plastic state is unavailable, and it is difficult to apply theoretical formulas.

Tests on Full-Sized Shells

A fairly accurate picture of the strains imposed on shells during the nosing operation was obtained by measuring rather carefully 75-mm, 105-mm, 5-in. Navy shells, and a 240-mm shell before and after nosing.

It was difficult to obtain the strain distributions for the 75-mm shell, because of the small amount of deformation which takes place when this shell is nosed. Therefore no strain curves are shown.

The distributions of the strains for the 105-mm shell are shown in Fig. 24. It should be noted that the so-called "natural" strains have been plotted. The advantage of using the natural strains is that their sum remains zero, even for large plastic strains. Thus if ϵ_z is the axial strain (measured tangent to the nose contour); ϵ_t the circumferential strain, or the reduction in diameter; and ϵ_r the increase in thickness of the shell wall, the condition of constant volumn means that

$$(1 + \epsilon_z)(1 + \epsilon_t)(1 + \epsilon_r) = 1$$

or

$$\log_e(1 + \epsilon_z) + \log_e(1 + \epsilon_t) + \log_e(1 + \epsilon_r) = 0$$

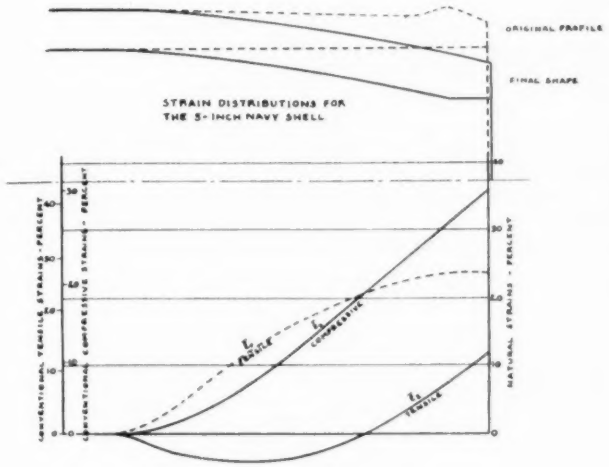

FIG. 25

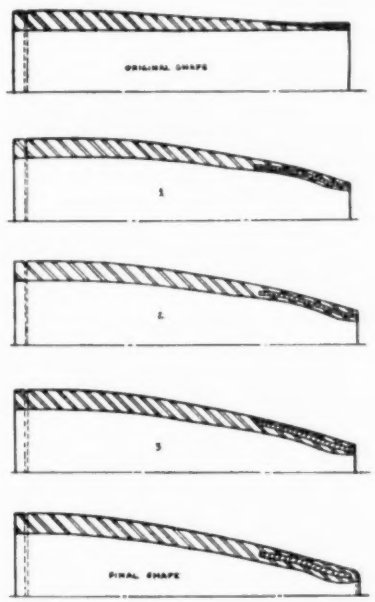

FIG. 26

Therefore, we define $\bar{\epsilon}_z$, $\bar{\epsilon}_t$, and $\bar{\epsilon}_r$ as follows:

$$\bar{\epsilon}_z = \log_e(1 + \epsilon_t)$$

$$\bar{\epsilon}_t = \log_e(1 + \epsilon_t)$$

$$\bar{\epsilon}_r = \log_e(1 + \epsilon_r)$$

and the sum of $\bar{\epsilon}_z$, $\bar{\epsilon}_t$, and $\bar{\epsilon}_r$ remains zero for any amount of plastic deformation. Conventional strain scales have been plotted on the left ordinate; a tensile strain must be considered positive, indicating an increase in length in the direction of the strain; a compressive strain must be considered negative, indicating a decrease in length.

As can be seen in Fig. 24, the maximum reduction in diameter on the 105-mm shell is about 45 per cent, giving a natural strain of something over 60 per cent. The 105-mm shell elongates considerably, resulting in a maximum conventional strain of

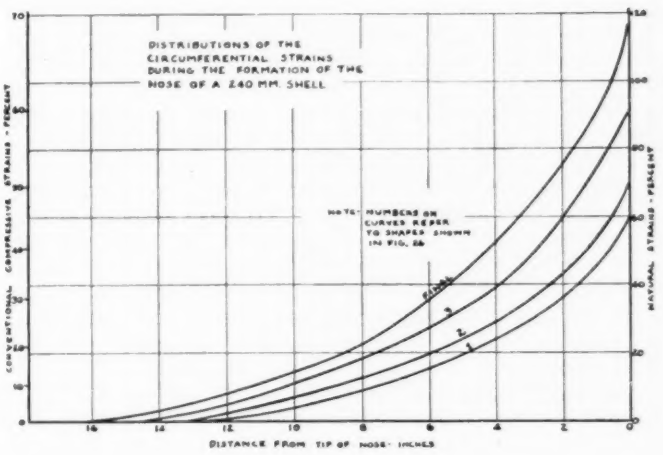

FIG. 27

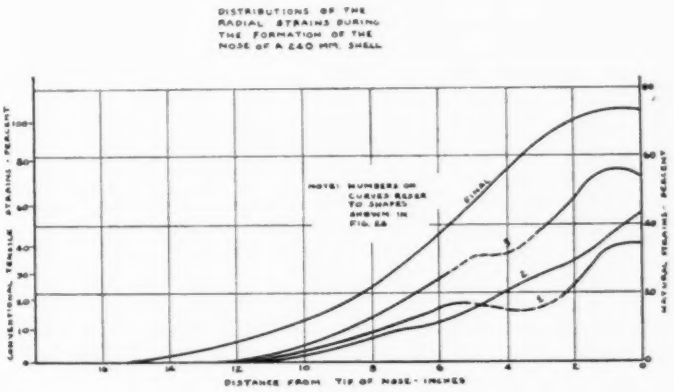

FIG. 28

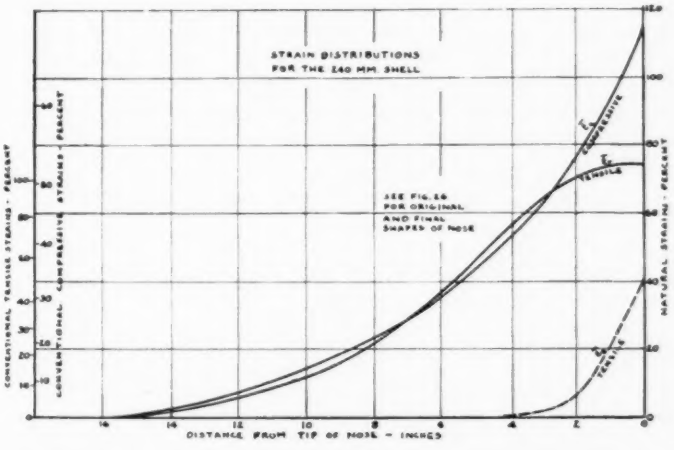

FIG. 29

about 45 per cent. The curve of the thickness change $\bar{\epsilon}_r$, is dotted, since it was obtained by making the sum of the three natural strains zero.

The strain distributions for the 5-in. Navy shell, Fig. 25, are very similar to those for the 105-mm shell. However, there is only a very slight elongation of the 5-in. shell during nosing, and, consequently, the axial strain reaches a maximum value of only 12 per cent.

A valuable set of data on the formation of the nose of a 240-

mm shell was furnished us by the committee. This shell is ordinarily nosed in one step; but in order to follow the flow of metal throughout the very great deformation, the nosing die was stopped when approximately one quarter, one half, and three quarters of the shell nose had entered the die. Thus a series of five shells, cross sections of which are shown in Fig. 26, was obtained. The thickening of the shell wall at the tip of the nose is remarkable: A radial strain of over 100 per cent occurs. The reduction in mean diameter of about 75 per cent is also an unusual amount of deformation for a single stroke of the nosing press. Curves of the radial and tangential natural strains are shown in Figs. 27 and 28. A plot of all three natural strains for the final shape is shown in Fig. 29. It is interesting to note that there is hardly any axial strain in the main body of the shell; in other words, the entire lengthening of the shell (approximately $^5/_8$ in.) takes place very near the tip of the nose.

It must be remembered that all the strain distributions which are shown have been determined on the basis of the deformation of a "mean line" in the profile of the nose. In other words, the values shown are average strains only. This method of measurement is probably justified for the major portion of the shell, but the complicated local deformation at the tip of the nose needs closer attention.

The determination of the proper nose profile to use, in order to obtain a certain finished shape after nosing, involves a consideration of the strains existing in the shell nose. This problem is one which cost the shell-forging industry thousands of dollars, and perhaps necessarily so, since there appears to be no easy way to predict what the original profile of the nose should be. In the following paragraphs a method of attacking this problem will be indicated and its limitations stated.

It has been observed that certain sizes or shapes of shells elongate considerably during nosing, while in others there is practically no axial extension. For those shells which do not elongate, it can be assumed that each element of the shell wall moves radially only; this is not, of course, an exact picture, but serves to simplify the problem considerably. The position of an element of the shell both before and after nosing can now be stated in terms of a single co-ordinate, x, that is, an element at x in the undeformed shell remains at x after nosing. Selecting as an element a ring of material having a length dx in the undeformed state and a length ds in the deformed state, we may write the following equation expressing the constancy of volume of the element

$$2\pi r_0 h_0 dx = 2\pi r h ds \qquad \left.\begin{matrix} r_0 \\ h_0 \end{matrix}\right\} \text{ original radius and thickness}$$

$$\therefore \frac{h_0}{h} = \frac{r}{r_0}\frac{ds}{dx} \qquad \left.\begin{matrix} r \\ h \end{matrix}\right\} \text{ final radius and thickness}$$

or

$$\frac{h_0}{h} = \frac{r}{r_0 \cos \alpha} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

where α is the slope of the nose contour at x.

Equation [3] may be used to approximate the original thickness variation when the final shape of the nose is given and a constant value of r_0 (or a particular $r_0[x]$) may be assumed.

If the shell elongates considerably, an element originally at x goes to $x + \xi$ after the nosing, where ξ, the axial displacement of the element, is some function of x. Again, we may write the constant-volume condition as

$$2\pi r_0 h_0 dx = 2\pi r h ds$$

Now, however, r, h, and ds must be measured at $x + \xi$ when r_0 and h_0 are measured at x. Since

$$ds = d(x + \xi)/\cos \alpha$$

where α is the slope of the nose profile at $x + \xi$, we have

$$\frac{h_0}{h} = \frac{r}{r_0 \cos \alpha}\left(1 + \frac{d\xi}{dx}\right) \quad \ldots\ldots\ldots\ldots [4]$$

r, h, and α are calculated at $x + \xi$ when r_0, h_0, and ξ are calculated at x. Suppose we assume a power function as representing the variation of ξ with x (the selection of a power function is, of course, entirely arbitrary). Then if

$$\xi = \xi_{max}\left(\frac{x}{l_0}\right)$$

ξ_{max} is the maximum extension occurring at the tip of the nose, $x = l_0$, we have

$$\frac{h_0}{h} = \frac{r}{r_0 \cos \alpha}\left[1 + \frac{n\xi_{max}}{l_0^n} x^{n-1}\right] \quad \ldots\ldots\ldots\ldots [5]$$

The constants n and ξ_{max} occurring in the expression for $\xi(x)$ must be estimated from experience. If one of these can be estimated rather closely, the other may be determined approximately as follows:

If we assume that at the tip of the shell a state of pure compression exists in the circumferential direction, we should expect the strains in the axial and radial directions to be close to one half the circumferential strain. Knowing the reduction in diameter, the maximum circumferential strain can be calculated, and, consequently, we obtain the following relations

$$\epsilon_x = \frac{1}{\cos \alpha}\left(1 + \frac{d\xi}{dx}\right) - 1$$

For the maximum value of ϵ_x at the tip of the shell

$$\frac{1}{\cos \alpha}\left(1 + \frac{d\xi}{dx}\right) - 1 = -\frac{\epsilon_t}{2} \quad \ldots\ldots\ldots\ldots [6]$$

$$\frac{d\xi}{dx} = \left(1 - \frac{\epsilon_t}{2}\right)\cos \alpha - 1$$

Thus since

$$\frac{d\xi}{dx} = \frac{n\xi_{max}}{l_0^n} x^{n-1}$$

or, for $x = l_0$

$$\frac{d\xi}{dx} = \frac{n\xi_{max}}{l_0}$$

we obtain

$$\frac{n\xi_{max}}{l_0} = \left(1 - \frac{\epsilon_t}{2}\right)\cos \alpha - 1 \quad \ldots\ldots\ldots\ldots [7]$$

Thus, if either n or ξ_{max} is known, Equation [7] makes it possible to determine both the constants.

Equation [3] has been used to determine the original profile for the 5-in. shell, which does not elongate appreciably. Results of this calculation are shown in Table 2.

Equation [5] has been applied to the 240-mm shell. The value of n used in the expression for ξ was calculated from the known total axial extension ξ_{max}. Results of this calculation are shown in Table 3.

It should be apparent from the foregoing discussion that the method suggested for determining the original shell profile, know-

x is measured from a point 18.75 in. below tip of nose.

ing the final shape, will, at best, give only a rough answer to the problem. For instance, the proper shape for the tip of the nose, the most important part of the profile, cannot be determined using this method. The deformation at the tip is a complicated function of the die finish, lubrication, temperature, and speed of nosing. It is to be expected that, because of differences in equipment employed and in the technique of production, different shell manufacturers will find it necessary to use different original shapes to obtain the same final shapes.

Summary

The results of a number of model tests designed to show the effects of temperature, lubrication, and speed on the nosing process have been given. Quantitative information given in the report for the small models may be adjusted to apply to larger shells (geometrically similar to the models) by multiplying the values of the forces required to nose the models by the square of the ratio of the size of the larger shell to the size of the model. Of course, the quantitative results only have meaning for large shells when temperature and friction conditions can be assumed equivalent to those existing in the model tests.

An analysis of the strain distributions in several shells has been made; and a method has been indicated whereby the nose profile necessary to produce a desired finished shape may be determined.

Acknowledgment

The writer wishes to thank Dr. A. Nadai for many valuable suggestions offered during the course of the investigation.

Graphitization Caused by Testing Conditions on Carbon-Molybdenum Tubular Creep-Test Specimens

By H. J. KERR,[1] NEW YORK, N. Y., AND F. EBERLE,[2] BARBERTON, OHIO

In December, 1942, the final report on tubular creep tests was made to the Society.[3] This report included data from two tubular specimens, known as F-10, which were tested for 9000 hr at 900 F, with a stress in the cylinder of 15,143 lb and 9240 lb in the hemispherical end, and specimen F-11 which was tested for 14,230 hr at 1050 F with 5800 lb stress in the cylinder and 3960 lb stress in the hemispherical end. The object of the present paper is to present results of examination of these two tubular creep-test specimens of carbon-molybdenum steel, with particular reference to graphitization caused by the testing conditions.

THE preparation of the carbon-molybdenum tubular creep coupons, for purposes of the studies to be discussed, is described in the report by Norton and Soderberg.[3] Briefly, they consisted of 4-in-OD × 1/8-in-wall machined tubes with welded-on hemispherical ends, the over-all length being 28 3/4 in. The cylindrical part of each specimen was made from a seamless tube, while the hemispherical ends were fabricated of plate made from a forged billet.

The cylindrical part of the coupons consisted of basic open-hearth carbon-molybdenum steel, of the following analysis:

	Per cent	Per cent
Carbon	0.15	0.146
Manganese	0.53	0.54
Silicon	0.21	0.21
Phosphorus	0.016	0.015
Sulphur	0.016	0.018
Molybdenum	0.56	0.53
Aluminum	0.020	0.017
Aluminum oxide	0.007	0.007
Chrome	0.20	0.21

This material was deoxidized with 1 lb of aluminum per ton.

The plate from which the hemispherical ends were made was forged from a carbon-molybdenum-steel billet. Its analysis was as follows:

	Per cent
Carbon	0.15
Manganese	0.54
Silicon	0.20
Phosphorus	0.016
Sulphur	0.025
Molybdenum	0.44
Aluminum	0.022
Aluminum oxide	0.010
Chrome	0.06

The deoxidation practice used in melting this material was not obtained since it formed no part of the test program.

FIG. 3 COUPON F-11: HEMISPHERICAL END, GRAPHITE IN LOW-TEMPERATURE REGION OF WELD-AFFECTED ZONE

Thermal Treatment of Materials Prior to Welding. The $4^1/_2$-in-OD × $^3/_4$-in-wall tube from which the creep coupons were subsequently machined was annealed in a car-type gas-fired furnace by holding 1 hr at 1350 F, followed by slow furnace cooling (50 F per hr) to 1100 F, from which temperature they were air-cooled. The hemispherical ends received the following heat-treatment after the hot-cupping operation was finished:

(*a*) Heated to 1650 F, held for 30 min, and air-cooled.

(*b*) Reheated to 1620 F, held for 30 min, and furnace-cooled.

Welding Conditions. The cupped ends were welded to the cylindrical part of the coupons with an oxyacetylene torch (neutral flame) and without preheating. The filler rod consisted of $^1/_8$-in-diam carbon-molybdenum steel wire. The finished coupons were stress-annealed in a box through which a continuous flow of nitrogen was maintained by holding at 1200 F for $1^1/_4$ hr, followed by furnace cooling.

Microscopic Examination. The microscopic examination was conducted with transverse sections, as shown in Figs. 1 and 2, which also show the locations at which photomicrographs were taken. Additional specimens were removed from the center of the cylindrical portions of the coupons. Examination of these samples indicated the following:

Coupon F-10 (9000 hr at 900 F)

1—Cylindrical part; stress, 15,143 lb.

(*a*) Some small graphite nodules at the inside surface were found in the low-temperature region of the heat-affected zone, where the carbide was totally spheroidized. This is marked, F-10-1 in Fig. 1.

(*b*) Carbide in the low-temperature region of the heat-affected zone, predominantly but not totally spheroidized.

(*c*) The weld-affected zone at a distance from the weld metal of about $^1/_8$ in.; coarse-grained and acicular.

(*d*) The weld metal extremely coarse-grained and acicular.

(*e*) Heat-unaffected metal at the center of cylindrical portion, partially spheroidized.

2—Hemispherical end; stress, 9240 lb.

(*a*) Graphite at the inside and outside surfaces in the low-temperature region of the weld-affected zone, marked F10-6 and -8 in Fig. 1.

(*b*) Center of wall thickness in low-temperature region of heat-affected zone, free from graphite. Carbide partially spheroidized and coalesced in grain boundaries, Fig. 1, at F10-7.

(*c*) Weld-affected zone at a distance from the weld metal of about $^1/_8$ in., extremely coarse-grained and acicular.

Coupon F-11 (14,230 hr at 1050 F)

1—Cylindrical part; stress, 5800 lb.

(*a*) Some scattered small graphite nodules in low-temperature region of weld-affected zone marked F11-18, -19, -22 in Fig. 2.

(*b*) Carbide in the low-temperature region of the weld-affected zone totally spheroidized.

(*c*) Weld-affected zone at a distance from the weld metal of about $^1/_8$ in., coarse-grained and spheroidized, but acicular pattern retained.

(*d*) Weld-unaffected metal at about $1^3/_4$ in. distance from the weld metal almost totally spheroidized but acicular carbide pattern still visible.

(*e*) Heat-unaffected metal, at center of cylindrical portion, predominantly spheroidized.

2—Hemispherical end; stress, 3960 lb.

(*a*) Scattered medium to small graphite nodules in low-temperature region of weld-affected zone, marked F11-10 and -12 in Fig. 2.

(*b*) Some scattered grain-boundary graphite near inside and outside surfaces beyond low-temperature region of weld-affected zone; marked F11-11 and -13, in Fig. 2.

(*c*) Carbide in the low-temperature region of weld-affected zone totally spheroidized and partially coalesced.

(*d*) Weld-affected zone at a distance from the weld metal of about $^1/_8$ in., fine-grained and spheroidized with original acicular pattern almost totally obliterated.

(*e*) Weld metal fine-grained and totally spheroidized.

Fig. 3(*a* to *e*), shows photomicrographs indicating the arrangement and extent of the graphitization which has taken place in the hemispherical end of the F-11 tubular specimen.

Chemical Analysis. A section of material taken from positions 10 and 12 of F-11, $^3/_8$ in. wide × 1 in. long, was sent to the Bureau of Standards, which reported graphite as 0.060 per cent. On another section of the hemispherical end, on which no graphite was found under the microscope, the Bureau's blank test showed the value of 0.004 per cent.

A sample from another position of the same section was analyzed by Mr. Herzig, of the Climax Molybdenum Company laboratory, at Detroit, and showed graphite of 0.032 per cent.

Grain Size and McQuaid-Ehn Characteristics. The grain size and McQuaid-Ehn characteristics of the materials involved were as follows:

	Actual grain size, A.S.T.M. no.	McQuaid-Ehn grain size, A.S.T.M. no.	McQuaid-Ehn normality
Specimen F-10			
Cylinder.....	6	6–7	Abnormal
Cupped end..	8	8	Abnormal
Specimen F-11			
Cylinder.....	6	6–7	Abnormal
Cupped end..	8	8	Abnormal

To sum up, both creep coupons showed graphitization in the low-temperature region of the weld-affected zones. In coupon F-10, which had been at 900 F for 9000 hr, graphitization was confined to the surface layers, while coupon F-11, which had been at 1050 F for 14,230 hr, displayed graphitization through the whole wall thickness of the low-temperature region of the heat-affected zones. Furthermore, graphitization was more pronounced in the hemispherical ends than in the cylindrical sections. This holds true for both coupons. Graphitization was in all cases only slight.

The two carbon-molybdenum steels involved were aluminum deoxidized in a manner which produced a fine-grained abnormal McQuaid-Ehn case. The hemispherical-end material was more pronounced in its abnormality and was finer-grained than the steel from the cylindrical sections. The hemispherical ends displayed a greater propensity to graphitize than the cylindrical sections. It should also be remembered that the steel of the cylindrical sections had been spheroidized-annealed prior to the final welding and stress-relieving treatment, while the hemispherical ends were in an annealed condition prior to the welding and final stress-relieving operation.

The occurrence of graphite near the surface of the low-temperature heat-affected zone of coupon F-10 is not readily explainable. Microscopic evidence points to the fact that the surface layers were spheroidized to a greater degree than the interior portion of the wall thickness. This might have been brought about by cold work from the previous machining operation.

These data are presented since they give definite information on the formation of graphite under a given life span, a given

stress, and a given temperature, which may be of help to those now engaged in the study of this phenomenon.

ACKNOWLEDGMENT

Acknowledgment is made of assistance rendered in this investigation by Dr. G. E. F. Lundell and Mr. H. A. Bright, M.S., of the National Bureau of Standards, Dr. Russell Franks, Union Carbide and Carbon Research Laboratories, Inc., and Mr. Alvin J. Herzig, Chief Metallurgist, Climax Molybdenum Company laboratory.

Carbide Instability of Carbon-Molybdenum Steel Piping

By R. W. EMERSON,[1] PITTSBURGH, PA.

An investigation of the complete failure of a carbon-molybdenum-steel steam pipe adjacent to a weld revealed the failure to be the result of graphite segregation. The examination of a number of specimens taken from other welded joints in high-temperature steam lines has shown that graphitization occurs in the base metal at the extremity of the heat-affected zone of the weld. Graphite may be present in either the "chain" or "nodular" form, depending upon the grain size and microstructure of the material as originally welded. Visual observation, bend testing, and microscopic examination have been found to give good correlation when examining specimens for segregated graphite. The use of relatively large quantities of aluminum as a deoxidant in steel is believed to affect carbide stability adversely. The postheating or stress-relieving temperature used after welding is believed to be a most important factor in determining whether or not segregated graphite will occur in a steel which has inherent carbide instability.

Introduction

A COMPLETE failure of a carbon-molybdenum-steel steam pipe adjacent to a weld occurred approximately 1 year ago. The investigation of this failure, and a number of other similar carbon-molybdenum steel pipe joints which had not failed, revealed that an extremely narrow band of iron-carbide or complex iron-molybdenum carbide was placed in a definite metastable condition at a distance of approximately $^1/_8$ to $^3/_{16}$ in. from the fusion line of the weld as a result of the welding heat on the base metal. This narrow band of unstable carbide, though existent at the time welding is complete, is decomposed to the more stable form of ferrite and graphite as a result of subsequent long-time subcritical heating in the temperature range of 850 to 1000 F, the operating temperature used in high-pressure generating stations. The decomposition of the carbide results in graphite precipitation which in turn gives rise to weakness, particularly from the standpoint of ductility. Sudden shock, either mechanical or thermal, on a joint which is severely graphitized may easily result in complete rupture. The width of the graphitized zone has been found to vary, but is usually of the magnitude of 0.001 to 0.01 in.

Two Types of Graphitization Discussed

A section of the fractured surface of a steam pipe which completely failed as a result of intergranular graphitization is shown one-half size in Fig. 1. Observation of this figure indicates that the failure occurred along the fusion line of the weld since each layer of welding, as it was deposited, is clearly revealed on the fractured surface. Contrary to this, however, it was found that upon sectioning the failure, the fusion line of the weld was completely intact. The failure had occurred in the base metal parallel to, but at a distance of approximately $^1/_8$ in. from, the fusion line of the weld. A second pipe joint was removed from the line, sectioned, polished, and etched as shown in Fig. 2.

Fig. 1 Section of C-Mo Pipe Failure Adjacent to Weld (Failure resulted from intergranular graphitization; ×1/2.)

The dark overlapping lines of segregated graphite at the extremity of the heat-affected zone (about $^1/_8$ in. outside the fusion line of the weld) on each side of the weld are clearly visible in this figure. It is the path of the overlapping lines of segregated graphite, as shown in Fig. 2, which represents the path of rupture as shown in Fig. 1. Figs. 3 to 5, inclusive, are presented to develop both the pattern of the graphite with respect to the metal structure, and the detail of the graphite itself in a structurally coarse-grain carbon-molybdenum pipe material as shown in Fig. 2, having originally a Widmanstätten carbide structure.

The intersection of two "isotherms" or "eyebrows"[2] of graphite, as observed in Fig. 2, is shown in Fig. 3, at a magnification of 100 diam. It is to be noted that the graphite nodules follow predominantly the periphery of the coarse Widmanstätten carbide grains. These nodules, due to their number and gradual growth in service, eventually in some cases become connected to form a semi-continuous to continuous chain of graphite. "Chain graphite,"

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

[2] Since the dark, curved, narrow bands of graphite in Fig. 2 represent lines of constant temperature, in the vicinity of 1350 to 1400 F, at the time each of the welding beads was deposited during the welding of the joint, the term "isotherm" has been used when referring to the individual curved graphitized bands. These bands have also been called "eyebrows" or "whiskers."

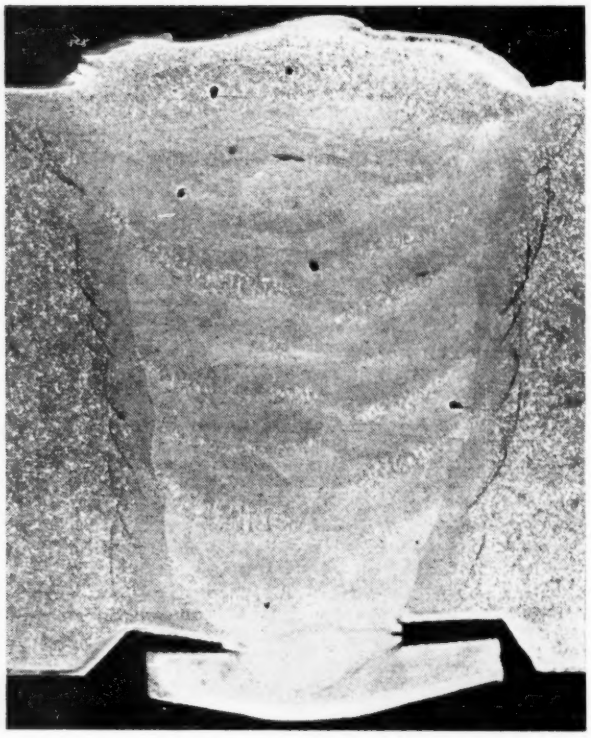

FIG. 2 WELDED JOINT EXHIBITING INTERGRANULAR GRAPHITIZATION AT EXTREMITY OF WELD HEAT-AFFECTED BASE MATERIAL
(Graphitization occurred during 5½ years' service at 935 F average service temperature; ×2.)

as it has then been named, is made up fundamentally of graphite nodules. This type of graphitization, however, is not to be confused with so-called "nodular" graphitization.

The graphitization shown in Fig. 3 is considered by the author to be sufficiently connected both around and between the Widmanstätten carbide grains to be identified as "chain" graphitization. The enclosed area of Fig. 3 definitely contains a long "chain" of overlapping graphite nodules, in fact the graphite appears as a semicontinuous void or crack. This area is shown in Fig. 4, at a magnification of 250 diam. Details of both the more dispersed graphite nodules as well as the overlapping nodules which make up the graphite "chain" can be seen. To develop further the detail of the graphite nodules which make up the chain, the enclosed area in Fig. 4 is shown in Fig. 5 at 850 diam magnification. It is believed this illustration provides ample detail to prove the nodular make-up of this graphite chain.

In contrast to Figs. 3 to 5, inclusive, graphitization of a fine-grained pearlitic structure in a cast carbon-molybdenum-base elbow is shown in Fig. 6 at both 100 and 600 diam magnification. Since at 100 diam, the graphite nodules are lined up, this might be considered by some as "chain" graphite. Close observation, however, reveals that, while the average nodule size is larger than that shown in Fig. 3, definite separation of most nodules is apparent. This is further substantiated at 600 diam. For this reason the author chooses to consider this as "nodular" rather than "chain" graphite. Although a condition such as shown in Fig. 3 is believed to be more hazardous than that shown in Fig. 6(*a*), it is not to be inferred that the latter type of graphitization cannot become equally as hazardous.

A bend test made through the heat-affected zones of a weld joining an upset pipe end to a valve casting, is shown in Fig. 7. Graphitization in the valve casting while in a more advanced stage than shown in Fig. 6 was of the nodular type. It can be seen that complete fracture of the casting occurred along the graphitized zone. Graphitization was also present on the pipe side of the weld, though to a lesser degree, as evidenced by the greater angle of bending, and the opening of only one "isotherm." It is to be mentioned that graphitization on the pipe side of this joint was of the chain type, but only partially developed.

EFFECT OF GRAIN SIZE AND METAL STRUCTURE ON CARBIDE INSTABILITY

Observation of graphitization in numerous specimens of both cast and rolled carbon-molybdenum piping material adjacent to welds indicates that graphitization will occur in both structurally fine- and coarse-grain material having either a pearlitic or Widmanstätten carbide type of microstructure.

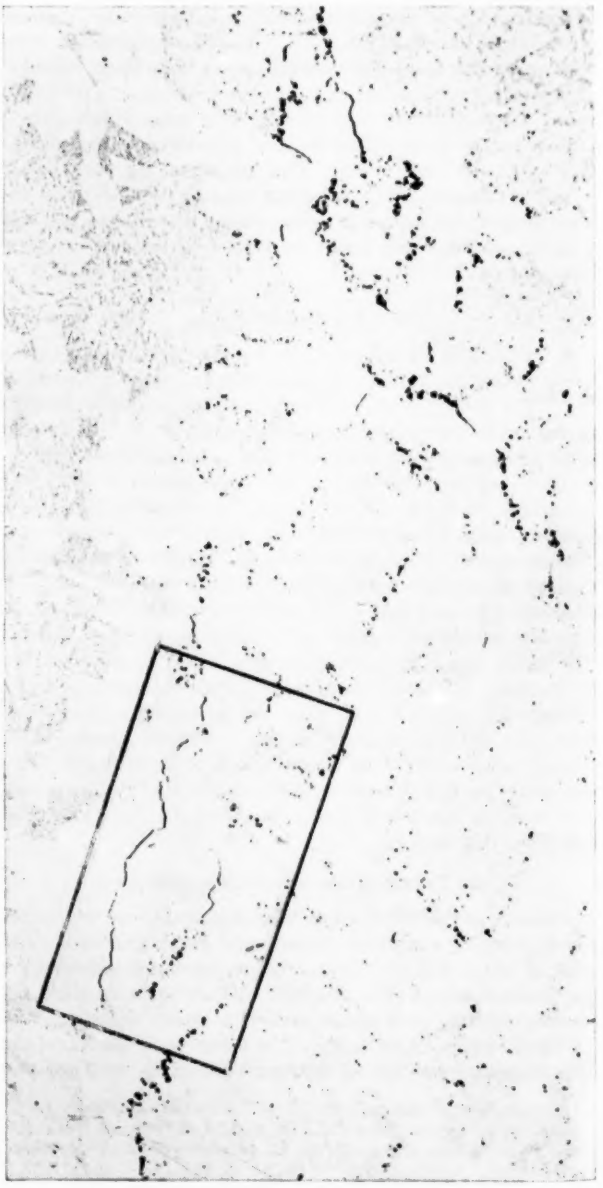

FIG. 3 "CHAIN" GRAPHITE
(Intersection of isotherms showing graphitization to be predominantly intergranular in nature; ×100.)

The only two carbide structures usually encountered are the Widmanstätten and pearlitic types, although the grain size associated with each of the two types has been found to vary from "fine" to "coarse." As previously pointed out, a fine-grain pearlitic structure results in "nodular" graphitization, while a coarse-grain Widmanstätten carbide structure results in "chain" graphitization. The type of graphitization encountered is believed to be primarily dependent upon the grain size, rather than upon the carbide structure. This hypothesis is based on the well-established fact that the alpha-gamma transformation in steel occurs first at the grain boundaries. If a steel specimen is gradiently heated, as is the case during welding, there will be a certain location on the specimen where the temperature reached is just sufficient to produce grain-boundary transformation.

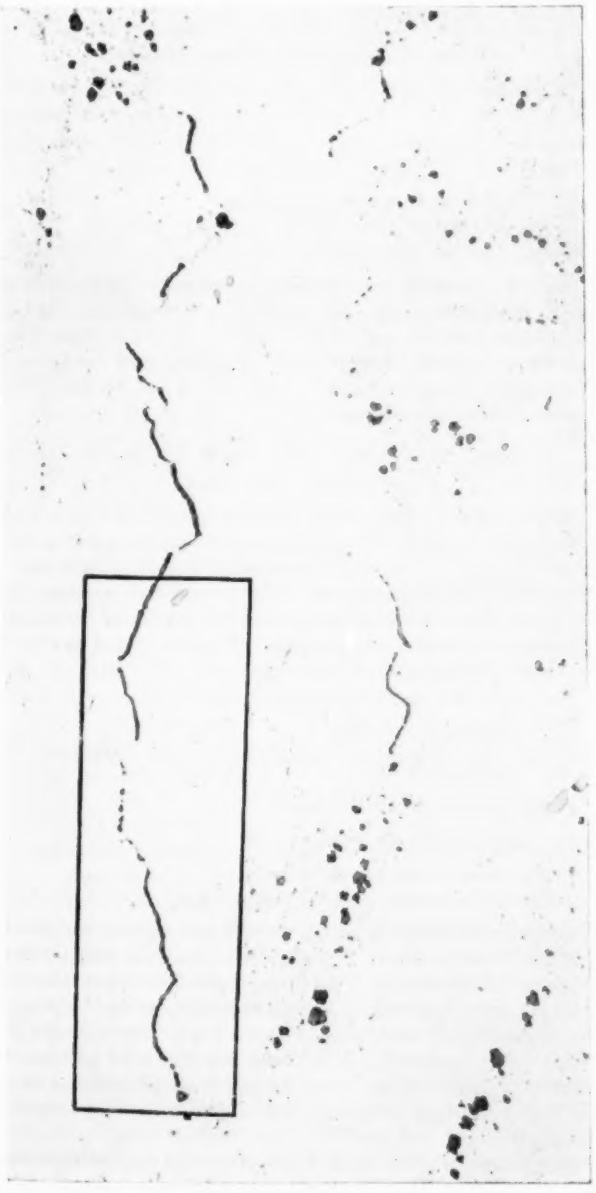

FIG. 4 VIEW OF ENCLOSED AREA IN FIG. 3, AT HIGHER MAGNIFICATION
(Note graphite detail showing "chain" graphite to consist of small connected graphite nodules; ×250.)

FIG. 6 NODULAR GRAPHITIZATION ADJACENT TO WELD IN A FINE-GRAIN CAST C-MO ELBOW

For purpose of discussion, we may consider the pearlitic- or carbide-containing grain in a fine-grain steel to consist essentially of grain boundary, and we may therefore assume the entire grain to transform. On the contrary, a coarse-grain material would transform only at the grain boundary. Since microscopic observation reveals that it is the grain-boundary structure which transforms at the approximate temperature level of the Ar_1 (1350 F) during welding, which subsequently decomposes to graphite upon long-time heating in the temperature range of 850 to 1000 F, it seems logical that the coarse-grain structure would be completely enveloped by graphite within the zone of Ar_1 boundary

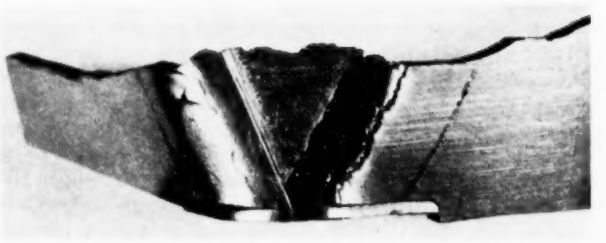

FIG. 7 BEND TEST ON UPSET PIPE END WELDED TO C-MO VALVE CASTING

(Note fissure in pipe and complete fracture of valve casting; ×3/4.)

transformation, while the entire grain of a fine-grain pearlitic carbide structure would graphitize.

DETERMINATION OF SEGREGATED GRAPHITE

Three relatively simple tests, all of which give good correlation, can be applied to reveal the existence of segregated graphite. These tests, all of which have been previously illustrated, are as follows:

1 Visual or macroscopic observation.
2 Bend testing.
3 Microscopic examination.

Heavily segregated graphite can be revealed by all three methods, as illustrated by Figs. 2, 3, and 7; while moderate segregation can be detected only by the latter two methods (Figs. 3 and 7). Graphite present in either a highly dispersed condition or in a partially developed state of segregation can be found only by microscopic examination.

FACTORS RESPONSIBLE FOR CARBIDE INSTABILITY AND SUBSEQUENT GRAPHITIZATION

The factors responsible for carbide instability and subsequent graphitization may be divided into two categories, namely, those factors which are responsible for the formation of unstable iron or complex iron-molybdenum carbide in carbon-molybdenum steel, and those factors which are responsible for the actual breakdown of the unstable carbide to graphite. These are listed in what is believed to be the order of their importance.

Factors responsible for the metastable carbide:

1 Steel-melting practice.
2 Gradient heating and quenching of steel during welding process.
3 Grain size and metal structure.

Factors responsible for graphitization:

1 Operating steam temperature.
2 Service hours at operating temperature.

Considering first the actual breakdown of the carbide to graphite, there seems to be sufficient evidence to indicate that graphite (unless present in submicroscopic dispersion) does not exist adjacent to a weld in carbon-molybdenum steel piping at the actual time of completion of such a joint. On this basis, the actual graphitization which has been found to exist adjacent to welds is produced by the operating steam temperature to which the piping has been subjected (850–1000 F), over an extended period of time (4 to 6 years).

Graphitization produced in such a manner progresses with time and is accelerated by increased operating temperatures up to some undetermined maximum which is believed to be in the vicinity of 1050 to 1150 F.

Since operating a high-pressure steam-generating station without employing steam temperatures in the 850 to 1000 F range

would be most unsatisfactory, emphasis must be placed not upon the service conditions (within reasonable limits) which break down the unstable carbide to graphite, but rather upon those factors which are responsible for the formation of the unstable carbide, and the elimination of such an unstable structure.

Considering this phase of the problem, there is convincing evidence that steel-melting practice, which has already been found to have a pronounced influence on the creep characteristics of both plain-carbon and carbon-molybdenum steel, has a definite effect on carbide instability at elevated subcritical temperatures.

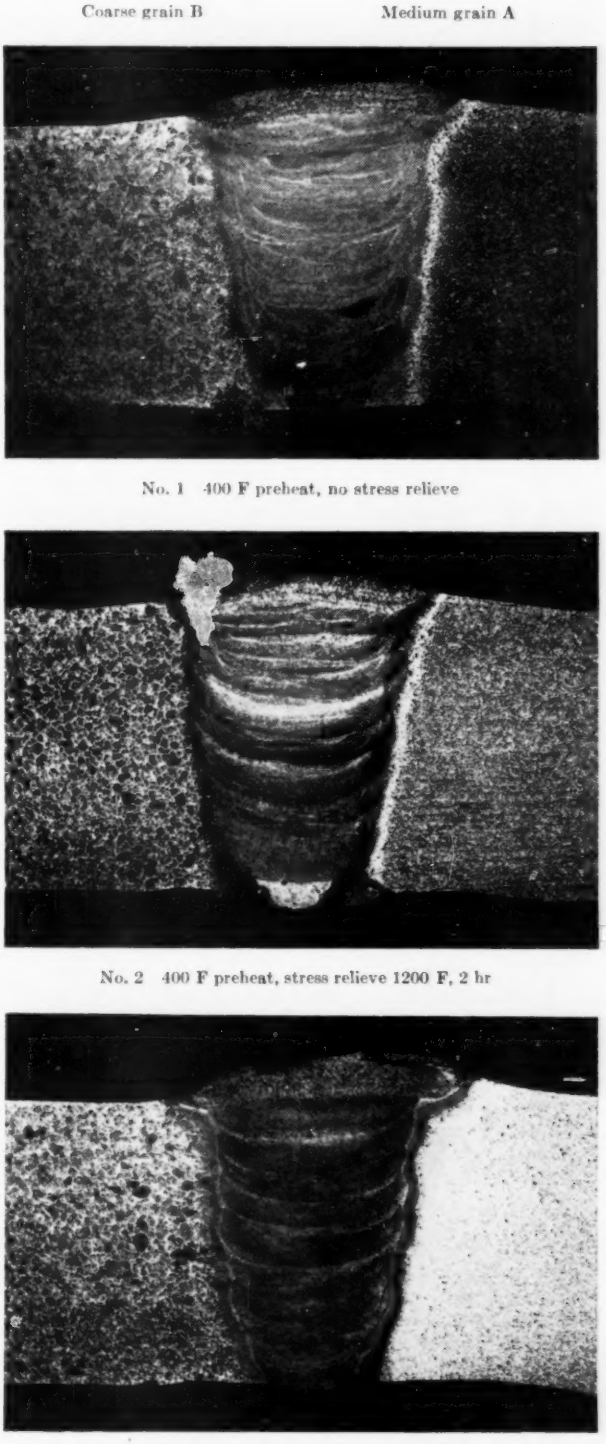
Evidence of this is based upon the fact that the weld which was common to the pipe that failed (Fig. 1) as a result of intergranular graphitization was also common to a forged superheater outlet header having for all practical purposes the same chemical analysis. The analysis of the header, weld deposit, and pipe are given in Table 1.

There was, however, no evidence of structural instability of the forged header adjacent to the weld. The thermal history, as a result of the welding procedure, including preheating, welding, and stress relieving, was again for all practical purposes identical to that of the pipe which failed.

TABLE 1 CHEMICAL ANALYSIS OF SUPERHEATER-HEADER, WELD DEPOSIT, AND PIPE

	Chemical analysis, Per cent								
	C	Mn	P	S	Si	Mo	Cr	Ni	Remarks
Forged header	0.10	0.45	0.008	0.020	0.16	0.60	[a]	[a]	No graphite
Weld deposit	0.11	0.45	0.028	0.018	0.07	0.60			No graphite
Pipe	0.14	0.49	0.014	0.018	0.17	0.50	[a]	[a]	Segregated graphite

[a] Spectrographic analysis indicated residual Cr and Ni in header to be higher than in pipe, but less than 0.10 per cent.



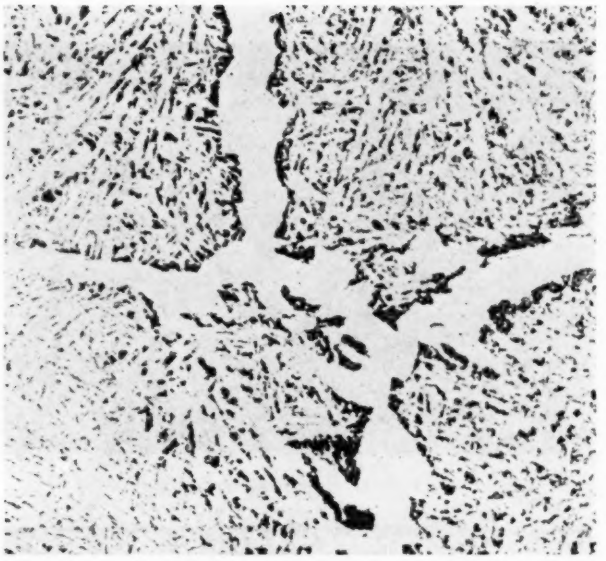
Assuming identical thermal history of the two materials adjacent to the weld throughout the entire welding procedure, it may be further assumed that the time-temperature cycle, which produced the narrow zone of unstable or sensitized carbide on the pipe side of the weld, must have likewise produced a potentially unstable zone in a similar location on the header side of the weld.

Due to differences in the inherent carbide stability of the two steels, however, the narrow zone of carbide on the header side of the weld which was placed in a state of least resistance to graphitization, proved stable, whereas the zone in the same location on the pipe side (likewise in a state of least resistance) proved unstable as evidenced by graphitization.

This is believed unquestionably to be a steel-melting problem. On the basis of this case, as well as several others all of which were welded pipe to forging joints, it is believed that the entire problem could be solved by the use of the proper deoxidation practice alone, or in combination with the use of a small alloy addition to this material which would stabilize the carbide phase regardless of the grain size and microstructure. One of the known differences in the manufacture of steels which have a stable carbide structure, as contrasted with those which do not, is in the amount of aluminum used for deoxidation. Those steels which have a stable structure have been found to be deoxidized principally with silicon, aluminum being used to the extent of $^1/_4$ lb per ton or less. Those which have proved unstable have been given a final deoxidation treatment of 1 to $2^1/_2$ lb of aluminum per ton. Structural grain size and possibly microstructure of the material prior to welding, as previously discussed is believed to effect only the general pattern of graphitization rather than directly effecting graphitization itself. Structural grain size and microstructure, for this reason, are considered to be of secondary importance.

Duplication of Graphite and Its Elimination

At the present time, there are hundreds of tons of carbon-molybdenum steel piping in service, a large percentage of which has been found to be in various stages of graphitization. There are also considerable quantities of this material undergoing fabrication which will then be used in high-temperature installations. For this reason it seemed advisable to reproduce, if possible, the condition of graphitization as found adjacent to welded



No. 1 400 F preheat, no stress relieve

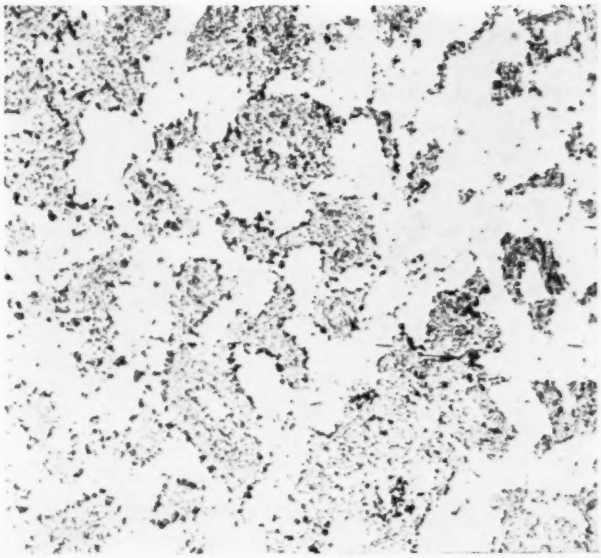
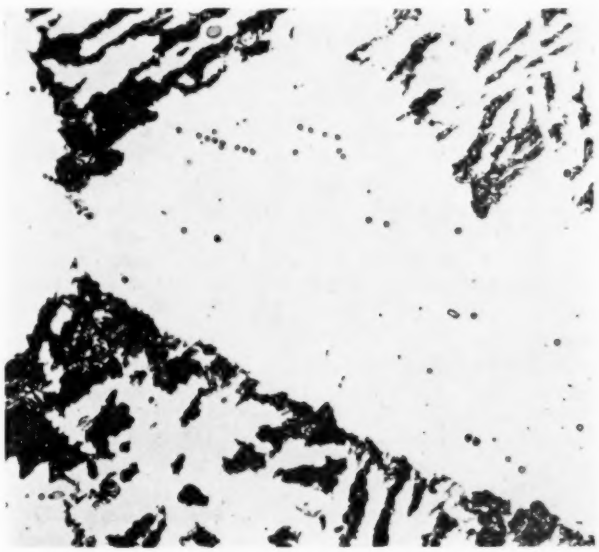
joints, and keeping in mind practical methods for its elimination.



The procedure adopted in this investigation is as follows:

Test Procedure. A $12^{3}/_{4}$-in.-OD × $1^{7}/_{16}$-in. wall thickness carbon-molybdenum steel pipe section 14 in. long, containing a circumferential weld at the center, was removed from a steam line which had had $5^{1}/_{2}$ years of service at an average temperature of 935 F. It was believed that graphitization could be reproduced in this section of pipe since graphitization had already been encountered in other sections of this piping in service.



The entire weld was removed together with approximately $^{3}/_{4}$ in. of pipe on either side of the weld. Upset pipe ends were used in the original installation which were not completely removed with the weld. One of the two pieces of pipe without further heat-treatment was rebeveled for welding near the extremity of the upset end. The remaining piece was placed in an upsetting furnace and heated to a temperature of 2600 to 2800 F for 1 hr in order to produce a condition of exaggerated grain growth. The pipe after heating was cooled in still air, rebeveled, and welded to the piece having no heat-treatment. The joint was then preheated to 400 F and welded in the fixed horizontal position. After welding, a number of longitudinal specimens were removed from the pipe, numbered, and given one of three different stress-relieving treatments, namely, (*a*) no stress relieve, (*b*) 1200 F stress relieve for 2 hr, (*c*) 1300 F stress relieve for 20 hr. Two sets of specimens were subsequently placed in a furnace which operated through a 28-day temperature cycle of 950–1050–1150–1050–950 F, etc., the temperature being changed weekly for a total of 1968 hr. These specimens were accordingly marked 1S, 2S, and 3S. Both the procedure and the results are shown in condensed form in Table 2.

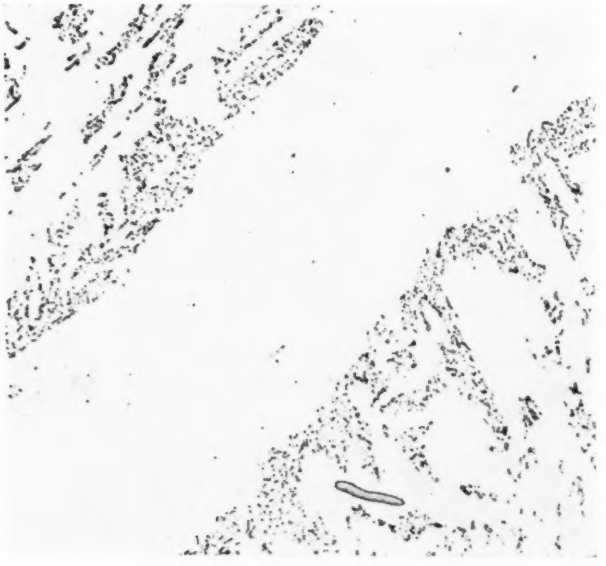
[a] A 14-in. length of 12¾-in-OD × 1⁷/₁₆-in-wall C-Mo pipe containing upset ends and a circumferential weld at the center was removed from a main steam line having had 5½ years of service at 935 F average. The weld and a portion of each upset was removed. Of the two pieces of pipe, one was rebeveled and the other reheated to 2600–2800 F as noted, air-cooled, and rebeveled for welding. The experimental joint was preheated to 400 F, and welded in the fixed horizontal position. Slices were then cut from the joint and treated as shown in Table 2.



[b] This heat-treatment is the approximate previous heat-treatment of the pipe which was removed from the main steam line at the location of the experimental weld.

FIG. 11 CONTACT ZONES OF SPECIMEN 3
(Note: Structure at grain boundaries fully spheroidized.)

Discussion of Results. Specimens 1, 2, and 3 after polishing and etching in hot 50 per cent hydrochloric acid are shown in Fig. 8. It is to be observed that etching produced little if any visible difference in heat-affected zones[3] A, specimens 1 and 2.

Heat-affected zone A, specimen 3, however, reveals no white band at its extremity as do specimens 1 and 2. A more defined line of fusion and a narrower heat-affected zone are also shown. As in the case of A, little or no difference is visible in heat-affected zones B, specimens 1 and 2. Specimen 3, however, has a much more diffused heat-affected zone than specimens 1 and 2. Both contact zones[4] A and B of specimens 1, 2, and 3 (Fig. 8) are shown in Figs. 9, 10, and 11, at a magnification of 100 and 500 diam. These illustrations are of interest since they show the type of microstructure which exists in the contact zone after welding but prior to service. Specimen 1B, Fig. 9, shows an almost continuous grain-boundary transformation to have occurred in the coarse-grain material. It is to be noted that no graphite is detectable although subsequent steam service is believed to result in complete envelopment of the large Widmanstätten carbide grains by graphite nodules, as shown in Fig. 3. Grain-boundary transformation of specimen 1A has resulted in the formation of a dense discontinuous carbide. Again, it is believed to be this dense carbide which is first graphitized by subsequent subcritical heating.

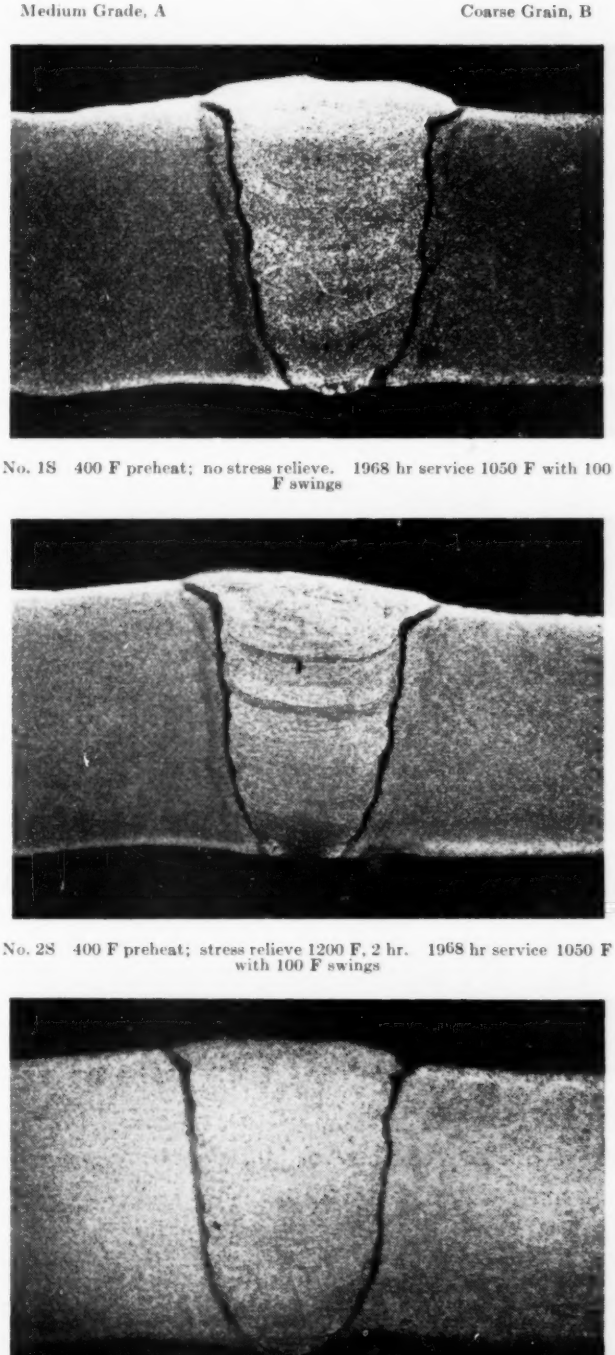
The effect of a 1200 F stress relieve for 2 hr on the microstructures observed in Fig. 9 is shown in Fig. 10. It is to be noted that only a slight change in microstructure has occurred.

[3] The use of heat-affected zone A or B refers to the heat-affected zone adjacent to the medium- or coarse-grain base metal, respectively.

[4] The term "contact zone" is used to refer to the narrow band of potentially unstable carbide at the extremity of the heat-affected zone. It is this band which may subsequently graphitize in service.

FIG. 12 GRAPHITIZATION AFTER 5½ YEARS' SERVICE OCCURS PRINCIPALLY WHERE GRAIN-BOUNDARY TRANSFORMATION ONLY OCCURRED DURING WELDING; ×500

Referring to specimen 3, Fig. 11, which received a 1300 F stress relieve for 20 hr, it is to be observed that spheroidization and homogenization of the heterogeneous iron-carbide or complex iron-molybdenum-carbide phase of the contact zone has occurred.



That subsequent graphitization occurs at the location of grain-boundary transformation resulting from welding, is further substantiated in Fig. 12. The graphite nodules in this figure, which have formed principally at the Widmanstätten carbide grain boundary, are in the process of complete envelopment of the carbide-containing grain.

Corresponding to specimens 1, 2, and 3, specimens 1S, 2S, and 3S, which received 1968-hr service temperature in a laboratory furnace as previously discussed, are shown in Fig. 13. Contact zone B (coarse grain size), specimen 1S may be seen to exhibit the same "isotherms," as shown in Fig. 2. Contact zone A (medium grain size), specimen 1S, however, resulted in a condition of dispersed graphitization though of a more continuous nature. This is in agreement with macroscopic observations of graphitization as encountered in fine-grain material, as contrasted with the observation of "isotherms" in a coarse-grain material.

A significant point is believed to be the fact that although specimen 1S received no stress-relieving treatment, identical results would have been obtained if this specimen had received an 1150 F stress relieve for 2 to 4 hr. This assumption is made on the basis that this short time at 1150 F would be insignificant in view of the 650 hr at 1150 F which the specimen received during the subsequent heating cycle to accelerate graphitization.

Close observations of specimen 2S reveals that the condition of incipient graphitization, as shown in specimen 1S, has not been completely eliminated by a 1200 F stress-relieving heat-treatment, that which is considered standard commercial practice.

A stress-relieving heat-treatment of 1300 F for 20 hr, however, shows no tendency toward graphite segregation adjacent to either side of the weld (specimen 3S).

No. 1S 400 F preheat; no stress relieve. 1968 hr service 1050 F with 100 F swings

No. 2S 400 F preheat; stress relieve 1200 F, 2 hr. 1968 hr service 1050 F with 100 F swings

No. 3S 400 F preheat; stress relieve 1300 F, 20 hr. 1968 hr service 1050 F with 100 F swings

FIG. 13 MACROSPECIMENS ETCHED IN HOT 50 PER CENT HYDROCHLORIC ACID; ×1

Unfortunately the maximum temperature of 1150 F used, in an effort to accelerate graphitization, was such that the size and pattern of the original grain structure were completely obliterated. This may be seen by contrasting the base-metal structure of specimens 1, 2, and 3 with those of specimens 1S, 2S, and 3S.

Fig. 14 shows the microstructure of the weld heat-affected zone,

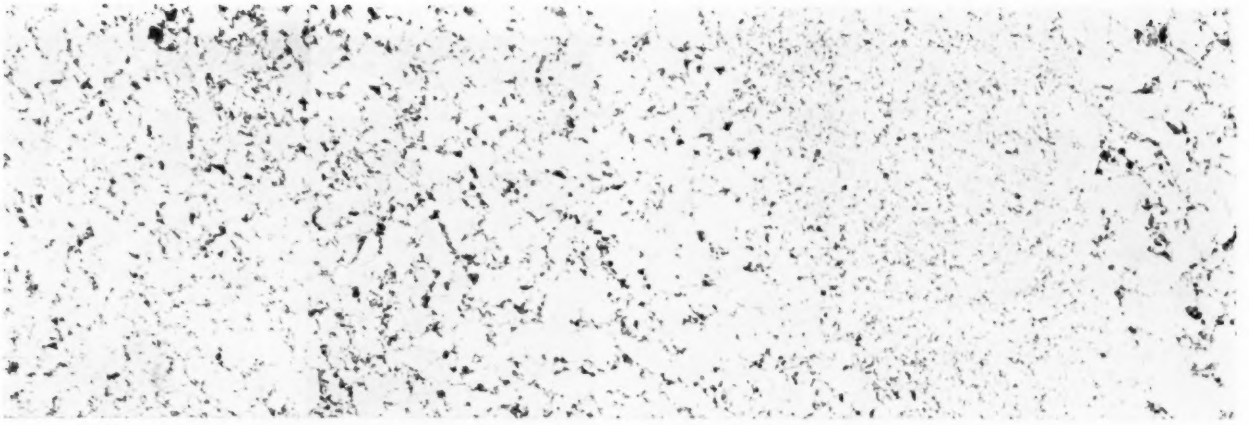


FIG. 14 WELD, HEAT-AFFECTED ZONE, AND PARENT METAL, SPECIMEN 1S-A MEDIUM GRAIN
(After 1968 hr at 1050 F average with 100 F swings weekly; ×60.)

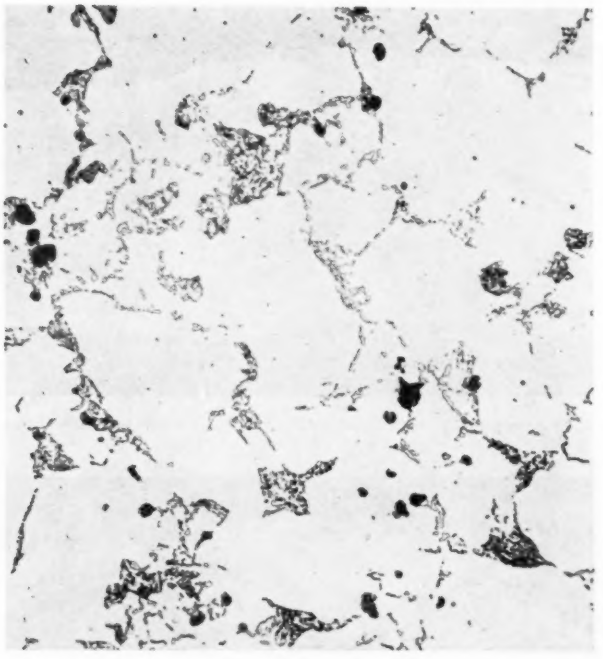

FIG. 15 CONTACT ZONE SPECIMEN 1S-A, MEDIUM GRAIN, EXHIBITING DISPERSED GRAPHITIZATION AND HIGHLY SPHEROIDIZED CARBIDE; ×500

and base metal of specimen 1S-A. The graphite nodules are of insufficient size and number to be seen at 60-diam magnification.

The microstructure of the contact zone of specimen 1S-A is shown in Fig. 15, at a magnification of 500 diam. A highly spheroidized carbide structure and dispersed graphite nodules are visible in this figure.

The contact zone of specimen 1S-B is shown unetched at 100-diam magnification in Fig. 16. The graphite nodules in this photomicrograph follow the path of the "isotherms" observed in contact zone 1S-B, Fig. 13. A view of this area in the etched condition is shown in Fig. 17 at a magnification of 500 diam. This structure, with the exception of the better alignment of the small graphite nodules, may be observed to be similar to that of Fig. 15.

A $^{5}/_{32}$-in-thick slice of specimen 1S was bent through both contact zones A and B. No failure occurred through contact zone

FIG. 16 CONTACT-ZONE SPECIMEN 1S-B, COARSE GRAIN, EXHIBITING INCIPIENT "CHAIN" GRAPHITIZATION; UNETCHED, ×100

A. Several small ruptures occurred in contact zone B, however, shown in Fig. 18.

CONCLUSIONS

1 A narrow zone of graphite is found to exist in carbon-molybdenum steel piping in proximity of welded joints in this material.

2 This narrow band occurs at the extremity of the heat-affected zone ($^{1}/_{8}$ to $^{3}/_{16}$ in. from the fusion line) of the weld, and may vary from 0.001 to 0.01 in. in thickness.

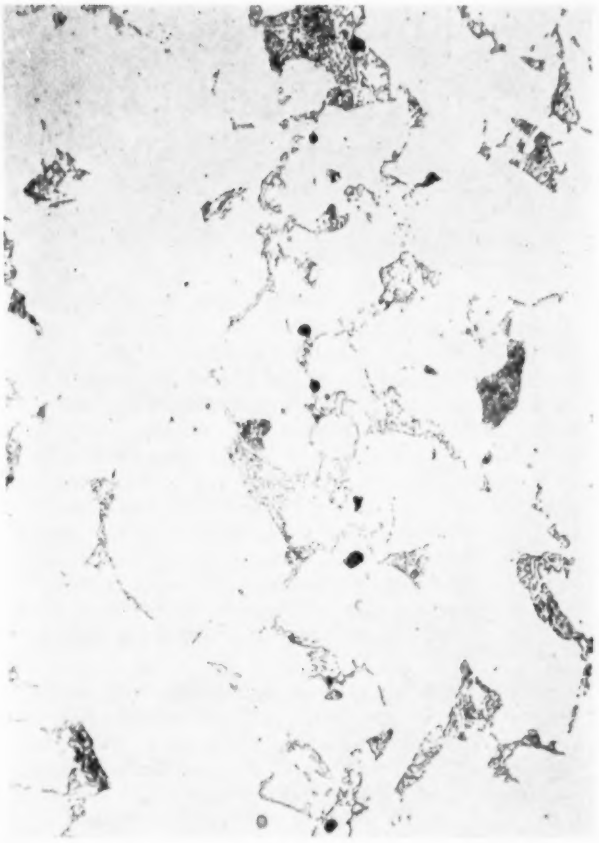

FIG. 17 CONTACT-ZONE SPECIMEN 1S-B, COARSE GRAIN, EXHIBITING INCIPIENT "CHAIN" GRAPHITIZATION AND HIGHLY SPHEROIDIZED CARBIDE; ×500

3 Grain size and possibly the microstructure of the base metal are believed to determine the pattern of the graphitized structure but to have no significant influence on the actual occurrence of graphite.

4 Tests which give good correlation in determining the presence of segregated graphite are visual observation, bend testing, and microscopic examination.

5 Gradiently heating and quenching carbon-molybdenum steel, as accomplished by the welding process, places the narrow zone of carbide adjacent to the weld in a state of least resistance to graphitization.

6 Graphitization of this narrow band of potentially unstable carbide, during steam service, is dependent upon the inherent carbide stability of the steel.

7 Inherent characteristics of steel are, in part, a function of steel-melting practice.

8 Relatively large quantities of aluminum used to deoxidize carbon-molybdenum steel are believed to affect adversely the carbide stability of this material when used for elevated-temperature service. The addition of carbide-stabilizing elements, on the contrary, are believed to enhance the carbide stability of this material.

9 The postheating or stress-relieving temperature used after welding is believed to be a most important factor in determining whether or not segregated graphite will occur in a steel which has inherent carbide instability.

FIG. 18 SPECIMEN 1S-B, COARSE GRAIN, EXHIBITING FISSURING IN CONTACT ZONE UPON BENDING; ×1

10 Preliminary tests indicate that stress-relieving at a temperature as low as 1150 F will result in subsequent graphite segregation, while a temperature of 1300 F will eliminate this difficulty.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Mr. Mathew Morrow, inspector, The Hartford Steam Boiler Inspection and Insurance Company, for the valuable assistance given in the laboratory preparation of the many specimens used in connection with this paper. Acknowledgment is given to Mr. G. Sinding-Larsen, chief engineer, Pittsburgh Piping and Equipment Company, for his many helpful suggestions and constructive criticism. The author is indebted to those whose permission made possible the use of a number of the illustrations included in this paper.

A Possible Means of Avoiding Local Graphitization of Steels in Service at Elevated Temperatures

By G. V. SMITH[1] AND R. F. MILLER,[1] KEARNY, N. J.

The recent steam-pipe failure at the Springdale power-generating station of the West Penn Power Company, which resulted from excessive local graphitization, has become of great concern to the power industry inasmuch as examination of other steam lines both in the same station and in others has revealed similar instances of local graphitization. In this paper the line of thought is largely speculative, but its degree of validity cannot be established until the completion of experiments, now under way, which will require a long time because of the slowness of the processes involved in this phenomenon. Consequently, the authors present the data at this time in the hope that the ideas outlined may prove useful or at least suggest other approaches to the subject.

THE recent steam-pipe fracture at the Springdale power-generating station of the West Penn Power Company occurred around the entire periphery of a $12^3/_4$-in-OD $\times$ $1^7/_{16}$-in-wall aluminum-killed carbon-molybdenum steam pipe at a distance of approximately $^1/_{16}$ in. from the border of the fusion zone of the weld by which it was joined to the main steam header of the boiler. The reported welding conditions comprised a 400 F preheat and a subsequent stress-relief treatment of 3 hr at 1200 F. The pipe had been in service for $5^1/_2$ years at a steam temperature and pressure of 935 F and 1300 psi, respectively. Metallographic examination revealed a profuse amount of graphite, disposed in network fashion around the areas of Widmanstätten structure, in a narrow region on both sides of the fracture; this network of graphite, which in many places was continuous, provided an easy path for fracture and was clearly the source of the failure. This zone of graphitization occurred near the lower limit of the heat-affected zone of the base metal in a region which, from metallographic examination, apparently reached during welding a temperature of about 1300 to 1350 F, i.e., the lowest temperature at which transformation to austenite begins in this steel (its so-called lower critical temperature, A_1). Furthermore, the width of the graphite zone was so narrow that the path of fracture closely conformed to this approximately isothermal boundary of the individual weld passes. In the base metal of the pipe away from the weld there were occasional graphite nodules, although these, because they were scattered, are of no concern except in so far as they indicate the propensity of the material to graphitize slowly at 935 F.

Experiments to Determine Cause of Local Graphitization

In an attempt to discover the reason for this local graphitization, the authors made several experiments, based on a belief that the rate of graphitization would be increased by increasing the temperature, short of exceeding the critical, approximately 1335 F. As this, however, proved not to be so, we were led to a change in viewpoint and to an explanation of why graphitization can occur at 900 to 1000 F, but not at 1300 F, and the correctness of this view was proved by experiments, described elsewhere,[2] which will only be summarized here.

In alloy steels containing a carbide-forming element such as molybdenum, the carbide cannot be considered to be simply of the nature Fe_3C, which is known to be metastable with respect to graphite, but may contain molybdenum in solution, or may be of the nature MoC_y. Moreover, in a given steel, different types of carbide may be expected to exist at different temperatures or after different times at constant temperature, and more than one type may coexist under some conditions of temperature and time. Little information is available concerning the stability of the alloy carbides with respect to graphite although it seems certain that these carbide types are more stable than the simple Fe_3C type, and may, in fact, be completely stable.

Crafts and Offenhauer,[3,4] who recently studied the nature of the carbides in low-chromium-molybdenum steels, found that on quenching these steels and tempering below 500 to 550 C (930 to 1020 F), the existing carbide was of the simple Fe_3C type as indicated by X-ray diffraction study, but for higher-tempering temperatures was an alloy carbide. The alloy-carbide type in intermediate chromium steels was Cr_7C_3, in higher-chromium steels, Cr_4C, and in molybdenum steels, Mo_2C; all of these carbide types were found in chromium-molybdenum steels. They also found that in chromium steels, the chromium carbide exists after transformation of austenite in the pearlite range; the nature of the carbide in the pearlite after transformation of the molybdenum and chromium-molybdenum steels was not studied, but it seems probable that it would be an alloy type.

These results suggest an explanation of our inability to graphitize C-Mo steel at a temperature of about 1300 F, namely, that at such a temperature the stable carbide is of the Mo_2C type which may be assumed to be more stable than the Fe_3C type with respect to graphite and may even be completely stable. That this is actually true was proved by holding a sample of the Springdale station pipe, containing graphite, for several weeks at 1300 F; the graphite gradually reverted to a carbide.

Suggested Explanation of Localized Graphitization Near a Weld

In view of the finding that graphite which had formed in carbon-molybdenum steel during service at 935 F reverts to carbide at 1300 F, it may be well to inquire whether this fact sheds any light on the question of why a narrow zone of graphite should

have formed near the weld in the first place. No adequate explanation of this phenomenon has yet been reported; to stimulate thought on the matter, the following, admittedly speculative, idea, based upon the possibility of the existence of different types of carbide in the same steel, is offered.

It is supposed that the carbide of the ordinary pearlitic or Widmanstätten structure is of the Mo_2C type, or of the Fe_3C type containing molybdenum in solution, i.e., $(Fe, Mo)_3C$, and that, in either case, it is more stable, at the service temperature, with respect to graphite, than the simple Fe_3C type. Further, it is assumed that the lower the temperature at which the austenite of such an alloy steel transforms (the faster the cooling rate, the lower will this temperature be), the more likely will the carbide in the transformation product be of the graphitizable Fe_3C type. However, it may well be that the latter type forms only when the cooling rate is sufficiently fast to produce martensite initially, this martensite then precipitating Fe_3C on heating to the service temperature, a possibility which is in conformity with the results of Crafts and Offenhauer,[3,4] as pointed out previously.

Now, during the welding process, the portion of the pipe, which later graphitized, reached a temperature of approximately 1350 F, which is sufficient to cause austenite to begin to form at the carbide-ferrite interface and, as observed, to a greater extent at the boundaries of the Widmanstätten patches. This austenite, having formed just above the eutectoid temperature (A_1) and being therefore rich in carbon, transforms, on subsequent cooling, at a lower temperature than would austenite of the composition of the pipe as a whole; hence it may directly form carbide of the Fe_3C type. On the other hand, and perhaps more likely because of the large mass of cool metal adjacent to this zone, the local cooling rate may be sufficiently fast to form martensite, which on reheating to the service temperature precipitates carbide of the Fe_3C type.

Once the condition has been established that Fe_3C exists in a limited region, and Mo_2C or $(Fe, Mo)_3C$ elsewhere, it is easy to see how a limited region of graphitization may arise. The steeper the temperature gradient adjacent to the weld during welding (that is, the narrower the heat-affected zone), the faster will be the rate of cooling, and thus the greater the likelihood of obtaining the necessary condition for subsequent graphitization. This steepness of temperature gradient appears to correlate roughly with the prevalence of this type of graphitization in the instances which we have examined.

Another point of possible significance to the Springdale failure is that the carbon content of the narrow zone containing the graphite was evidently greater than the nominal composition of the steel; it may be that, had only the carbide of this section graphitized, there would not have been sufficient graphite to form the nearly continuous network which was the eventual source of failure. The greater carbon content is readily explainable by the considerations that graphite, being the stable phase, is less soluble in ferirte than is carbide, and forms by carbon diffusing through the ferrite solid solution to the graphite nucleus and there precipitating. Conceivably, then, graphite in a limited region could bring about, in time, the substantial depletion of carbide within an entire specimen.

Although the authors have never observed any instance of excessive local graphitization in plain-carbon steel, the formation of martensite or low-temperature product in a limited region, as suggested for the carbon-molybdenum steel, may account for its occurrence. It is not unreasonable to expect that the rate of graphitization should depend upon the initial structure, and that this rate may be greatest in an initially martensitic structure.

One disturbing fact which detracts from the validity of the argument just outlined is that graphitization did not occur in the heat-affected zone on the header side of the weld in question although its composition was similar to that of the pipe side. The steel on the header side did have a much smaller grain size, and it was of low-aluminum deoxidation practice as opposed to high-aluminum for the pipe. Factors such as these may suffice to tip the balance from a more to a less graphitizable condition for this particular temperature level.[5] Moreover, it is possible that during the stress-relief treatment subsequent to welding, conversion of the carbide on the header side to the stable alloy type went further than on the pipe side because of possible differences in temperature or composition. In any event the explanation is thought to be of sufficient merit to justify experimental study, which should yield further needed knowledge concerning the distribution of alloying elements between matrix and other phases in steel which has been treated in various ways. Work along this general line is contemplated.

A Possible Means of Avoiding Local Graphitization

Since C-Mo steel is extensively used under conditions which led to eventual failure at the Springdale Station, it is of interest to consider what may be done to reclaim welded joints now in service which show evidence of deterioration, and how, in the future, localized graphitization might be avoided.

To reclaim "diseased" joints, some engineers are considering removing the affected metal and rewelding or carrying out a heat-treatment above the transformation temperature. This is, however, no insurance against recurrence of the malady. Rohrig, Corey, and Crocker[6] suggest normalizing subsequent to welding as a possible means of avoiding graphitization. This presents practical difficulties in many instances. Moreover, it would seem to be necessary to treat the entire section of pipe and not just a portion of it, for, in this latter event, there may be temporary temperature gradients somewhat similar to those during welding such as might again cause danger of localized graphitization during subsequent service.

On the other hand, if the authors' explanation of localized graphitization near a weld is valid, a simple means of avoiding the narrow zone of graphitization is immediately evident, namely, to heat the metal in the heat-affected zone near the weld to a temperature of about 1300 F for a time long enough to convert the carbide to the more stable type. It is believed that the time required would be relatively short, perhaps 2 to 4 hr at temperature. Alternatively, but less satisfactorily, precautions might be taken to insure a wide heat-affected zone as, for example, by a higher preheat temperature or a slower rate of welding. It may also be pointed out that, if the explanation is correct, little would be gained by changing over to a chromium-bearing steel because according to Crafts and Offenhauer, the conditions would still be very similar to those for the carbon-molybdenum steel.

Finally, we wish again to emphasize that some of the preceding statements are speculative, and that a better understanding of the phenomenon must await the results of experiments, now under way, which will unavoidably take considerable time because of the slowness of some of the processes under investigation.

---

[5] It should be noted here that, at the somewhat higher temperature level of 975 F, graphitization has been found to occur in a carbon-molybdenum steel of coarse-grain deoxidation practice similar to that of the header in the Springdale Station.

[6] "The Effect of Normalizing on the Properties of Welds in Carbon-Molybdenum Steel Pipe," by I. A. Rohrig, D. H. Corey, and Sabin Crocker, *Welding Journal*, Welding Research Supplement, Oct., 1943, pp. 521S–527S.

Report on High-Temperature Pipe Weld Investigation[1]

By HERMAN WEISBERG,[2] NEWARK, N. J.

As a result of the failure of a carbon-molybdenum high-temperature steam pipe in one of the large power stations of the country due to graphitization, a study of the welds in the high-temperature piping systems at the stations of the Public Service Electric and Gas Company System was undertaken. This report covers the investigation during the period from May to November, 1943.

WELD prober specimens were removed from twelve welds in the high-temperature piping at the Essex, Burlington, and Kearny generating stations. Seven additional specimens were taken from test welds made at preheats from room temperature to 1200 F to study the effect of various preheating temperatures.

The specimens from the operating piping were taken across the weld parallel to the longitudinal axis of the pipe. Charts I to III show photomicrographs of these specimens. On each chart the first vertical row of photomicrographs shows the upstream parent metal; the second row, the contact zone between the parent metal and the heat-affected metal upstream; the third row, the weld metal; the fourth row, the contact zone between the heat-affected metal and the parent metal downstream; and the fifth row, the downstream parent metal. The photomicrographs represent the maximum graphitization observed in each area.

Included also on the charts are macrographs of the weld cross sections, photographs of bend bars made from the weld prober samples, material and weld specifications, heat-treatment of the pipe and welds, and a record of service conditions to which the piping and welds have been subjected.

Chart I, Essex Station; Boilers Nos. 25 and 26, Unit No. 7

The piping in this station was manufactured to A.S.T.M. Specification A 158-36 Grade Pl killed with 1.9 lb of aluminum per ton. The pipe ends were not upset. Of the four welds sampled three show a considerable segregation of graphite in the contact zone and a relatively small amount of graphite in the parent metal. One weld (specimen No. 5) shows no graphite in the contact zone but somewhat more graphite than the others in the parent metal. Miniature bend bars taken from each of the four samples show no loss in ductility.

Chart II, Burlington Station; Boilers Nos. 12 and 13 Unit No. 5

At this station the specimens include welds which were made on both aluminum- and silicon-killed steel, as well as steel castings and Croloy No. 2 pipe. No graphite was found in the silicon-killed steel nor the Croloy No. 2. Graphite was found segregated in the contact zone of the aluminum-killed steel and in one of the castings (specimen No. 4) which was killed with 2 lb of aluminum per ton. The bend bars show no loss in ductility, although the isothermals can actually be seen on the macrograph of one of the samples (No. 13 upstream lower left-hand corner of chart).

Chart III, Kearny Station; Mercury Boiler

The specimens at this station were taken from the 14-in-OD × 0.656-in. vapor piping between the mercury boiler and mercury turbine. All of this piping was originally carbon steel, and first went into service in 1933. Two specimens of carbon-steel pipe having 42,211 hr of service and one specimen of silicon-killed carbon-moly pipe having 17,939 hr of service were examined. The carbon-steel pipe was completely spheroidized and graphitized throughout, there being no difference between the contact zone and the adjacent portion of the parent metal which was sampled. Likewise the carbon-moly pipe was completely spheroidized and partially graphitized, there being no more graphite in the contact zone than in the parent metal. One of the carbon-steel specimens (specimen No. 8) shows an interesting concentration of graphite at one end with apparently no relation to the weld.

Chart IV, Test Welds

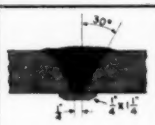
The test welds were made in a section of 12.75-in-OD × 1.312-in. carbon-moly pipe 12 in. long, killed with 1.8 lb of aluminum per ton. Longitudinal weld probes were taken from the pipe and the resulting voids filled in with weld metal at various preheat temperatures. The replacement welds were then probed at right angles to the original probes to obtain the specimens shown. The metal on each side of the weld being identical, photomicrographs are shown for one half of the specimens only. In no case was graphitization noted in the test welds. The welds were all sound; no cracks being found even in the weld made at room temperature. The variation of the width of the heat-affected zone and grain size of weld metal in these specimens is of interest.

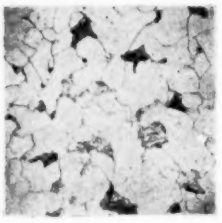
Summary Charts I to IV

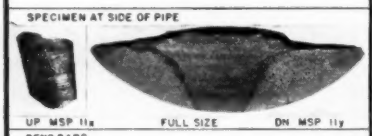
1 Graphite in various forms was found in the following types of steel investigated:

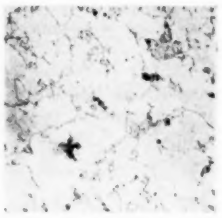
(*a*) Aluminum-killed carbon-moly pipe. Specimens Nos. 1, 2, 5, 6; 4 downstream and 13 upstream.
(*b*) Silicon-killed carbon-moly pipe. Specimen No. 10.
(*c*) Carbon-moly casting. Specimen No. 4 upstream.
(*d*) Carbon-steel pipe. Specimens Nos. 8 and 9.
(*e*) Carbon-steel weld metal. Specimen No. 8.

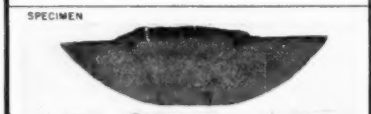
No graphite was found in Croloy No. 2 steel, specimen No. 3 upstream, or in any carbon-moly weld deposit.

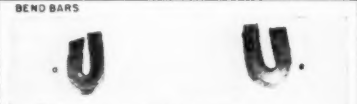


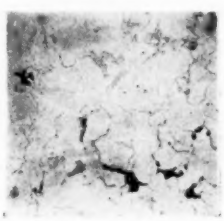


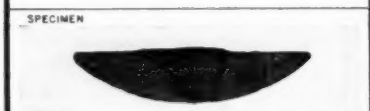


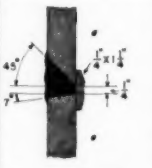


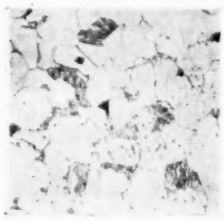












2 A concentration of graphite segregated in the contact zone of the welds was found in all but one of the aluminum-killed carbon-moly pipe specimens. One specimen (No. 5) of aluminum-killed carbon-moly pipe showed no segregation of graphite in the contact zone. This segregation in the contact zone was not found in any of the silicon-killed carbon-moly pipe or other metals examined except aluminum-killed carbon-moly pipe.

TABLE 1 ALUMINUM AND ALUMINUM-OXIDE DETERMINATION

Number of specimens	Material	Kill practice, lb/ton, aluminum	Aluminum, per cent	Aluminum oxide, per cent	Graphite after service
3	Aluminum-killed CMo	1.8–1.9	0.032–0.054	0.006–0.013	Segregated in contact zone
5	Silicon-killed CMo	0.5–1.0	0.007–0.014	0.004–0.010	Scattered or none
2	Silicon-killed CMo	0	0.002–0.005	0.008–0.041	None
3	Carbon	Unknown	0.002–0.003	0.007–0.026	Scattered or none

3 Table 1 is a recapitulation of Al and Al_2O_3 determinations given in Charts 1 to 4, along with several determinations not included in these charts. The figures show that Al rather than Al_2O_3, is an indication of tendency to segregation of graphite in the contact zone.

4 A concentration of graphite having no relation to the weld was found in one specimen (No. 8) of carbon-steel pipe.

5 Bend bars from several specimens with segregated graphite in the contact zone showed no loss in ductility.

Chart 5, Experimental Heating of Test Weld Specimens

In order to determine whether the graphite found could be expected, in time, to concentrate sufficiently to result in loss of ductility and also to determine, if possible, the cause of graphitization, specimens A, C, E, and No. 6 were heated in a laboratory oven for 936 hr at 1000 F. The specimens were loaded by means of a cantilever arrangement so that the contact zone was subjected to 15,000 psi stress while being heated. Also, portions of specimens A, C, and E, including the contact zone, were heated at the same temperature and for the same time without stress. The results are shown in Chart 5.

Graphite was formed in the contact zone of specimens A, C, and E, both with and without stress, but there is considerably more graphite in the stressed specimens. Preheat temperatures apparently had no marked effect on the tendency to graphitize. Specimen No. 6 showed a definite increase in size of the graphite nodules.

Additional Samples to Be Taken. In the second part of this program, now under way, whole sections of pipe have been removed and are to be examined more extensively, as well as tested for physical properties.

Acknowledgments

The work was carried out under the direction of Mr. F. P. Fairchild, chief engineer, electric-engineering department, Public Service Electric and Gas Company, and the help and advice of the following individuals, in the collection and assembly of the data, are acknowledged: Mr. H. J. Robar, metallurgist, and Mr. H. M. Soldan, assistant engineer, Public Service Electric and Gas Company; Mr. H. S. Blumberg, metallurgist, The M. W. Kellogg Company; Dr. C. L. Clark, research metallurgical engineer, The Timken Roller Bearing Company; Mr. H. J. Kerr, executive assistant, The Babcock & Wilcox Company; Dr. R. F. Miller, research metallurgist, United States Steel Corporation, Research Laboratory.

Discussion—Graphitization of Steel Piping

COMMENT ON PAPER BY H. J. KERR AND F. EBERLE (1)

I. A. ROHRIG.[1] This paper is a real contribution to the subject of subcritical graphitization of high-temperature steam-pipe material. The results of an examination made by The Detroit Edison Company, also on cylindrical creep-test sections, might be of interest.

Two sections of carbon-molybdenum seamless tubing $5^1/_2$ in. OD × $^3/_8$ in. wall thickness were arc-welded into an experimental steam line carrying steam at 380 psi and 925 F. The stress in the pipe wall at the welded joints was only 2610 psi.

The following tabulation summarizes the pertinent data concerning the material used and the results obtained:

	Sample 1	Sample 2
Type of steel	Open hearth	Electric furnace
Grain size	6–7	5–6
A.S.T.M. designation	A-158	A-158
Pipe size	$5^1/_2$ in. OD × $^3/_8$ in. wall	$5^1/_2$ in. OD × $^3/_8$ in. wall
Heat-treatment	N-1650 F D-1200 F	N-1650 F D-1200 F
Welding conditions	Arc-welded No preheat No stress relief	Arc-welded No preheat No stress relief
Exposure at 925 F	19604 hr	19480 hr
Composition: C	0.13	0.13
(per cent) Mn	0.40	0.49
P	0.014	0.010
S	0.014	0.011
Si	0.19	0.25
Mo	0.56	0.52
Cr	0.10	0.06
Ni	0.17	0.23
McQuaid-Ehn result	Normal	Abnormal
Graphitization	None	None

Although the exposure periods for our tests were considerably longer than those reported by the authors, no graphite was found in either sample. Since the welded joints were neither preheated nor stress-relieved, they are believed to have been in a condition susceptible to graphitization. Evidently, the pipe material used, even though it was of the aluminum-killed variety, was not readily susceptible to graphitization.

A review of our findings with those of the authors indicates that, from the present knowledge of the subject, each individual heat of this type of steel may have its own peculiar set of conditions under which it will graphitize, and that the graphitizing conditions used by the authors, such as exposure periods, stress, and temperature, are not necessarily applicable to different heats of steel with the assurance of graphitization.

COMMENT ON PAPER BY R. W. EMERSON (2)

SABIN CROCKER.[2] This paper is in the nature of a sequel to a report presented by the author at a special meeting arranged by A. N. Cartwright of the West Penn Power Company, in March, 1943, at Pittsburgh. The central-station industry and other users of high-temperature equipment are indebted to the management of that company for its frank report of the pipe-joint failure which had occurred at its Springdale plant.

Now that all affected joints in that plant have been replaced and investigations in other plants have been carried out to a point where the condition of their joints is known, the general situation has progressed from the emergency class, and causes and effects can be investigated from a long-range viewpoint. Hence it is fitting and proper that all interests involved in the subject of graphitization get together from time to time, to exchange ideas which will affect the future course of the several independent investigations now contemplated or under way.

A circular letter and questionnaire was sent out in April, 1943, by the Subcommittee on Metallurgy and Piping of the Edison Electric Institute's Prime Movers Committee to some 225 representatives of power companies, steel and pipe mills, boiler and turbine manufacturers, oil companies, insurance companies, etc. Approximately 150 different organizations were contacted in this manner, of which about one half made acknowledgment. Reports of their preliminary investigations of welded joints in carbon-steel and carbon-moly pipe have been received from 28 power companies and one oil company, six more plan to make investigations, while five do not intend to sample joints at this time. A total of 33 stations involving 38 different types of piping are covered in the 29 reports so far received. The extent of graphitization may be gaged to some extent by the following summary:

SUMMARY OF PIPING SYSTEMS EXAMINED

	Degree of graphitization			
	None	Severe	Moderate	Slight
High-aluminum carbon moly	10	4	5	1
Low-aluminum carbon moly	11	0	1	0
Carbon steel	3	1	2	0
Total, all materials	24	5[a]	8	1

[a] NOTE: Two of these are borderline cases between "severe" and "moderate" and ultimately may be classed as moderate.

The author's conclusion to the effect that "a large percentage (of carbon-moly piping) has been found to be in various stages of graphitization" is unwarranted and no such inference should be drawn from the foregoing statistics. As a matter of fact only nine companies (reporting on 15 stations) out of the 150 companies contacted have reported graphite, and it is to be assumed that those most likely to have it have investigated and reported their findings. It is true, of course, that with the lapse of sufficient time, graphite may develop in a few more plants.

The reports so far obtained in this survey have amply demonstrated the need for a fundamental investigation of the conditions which may produce graphitization of piping materials. A Joint E.E.I.-A.E.I.C. Subcommittee on Graphitization of Piping was established by the Edison Electric Institute and the Association of Edison Illuminating Companies. This Joint Subcommittee has made arrangements to have such a fundamental investigation carried out at Battelle Memorial Institute.

Independent investigations such as reported by the author of this paper, and in the accompanying papers by H. J. Kerr and F. Eberle and by G. V. Smith and R. F. Miller, have served to define the problem better and suggest lines of attack. The discovery by Messrs. Smith and Miller that a spheroidizing treatment at 1300 F is a preventive rather than a preliminary to graphitization is particularly noteworthy. The experiments made by the present author appear to verify this discovery. These investigations and those by power companies and other interested parties are welcomed by the Joint Subcommittee and full advantage will be taken of such findings.

From a survey of results so far reported, it would seem advisable to caution engineers not to jump at conclusions. There probably is no single answer which will account for the different types and degrees of graphitization which have been found at welded joints in both carbon-steel and carbon-moly piping. Graphite has been found also in a carbon-moly casting at a welded joint.

As the graphitization picture unfolds, one fact emerges of immediate interest to operating engineers. This is the desirability of limiting the extent and duration of temperature swings above

design temperatures. Present limitations by turbine manufacturers and the Code for Pressure Piping and Boiler Code are based upon creep considerations alone. While it is not possible with available information to set definite limits for each material, it would seem wise to keep below the following temperatures in so far as feasible until more is known on the subject:

Carbon steel, low and medium carbon	850 F
High-aluminum carbon-moly (1.5 lb Al per ton)	925 F
Low-aluminum carbon-moly (0.5 lb Al per ton)	950 F

Hence it would be advisable for power-plant operators to consider the actual range of temperatures rather than to depend upon daily average values which fail to show the extreme temperatures reached.

There is no proof that some graphite will not result under such restrictions, but there likewise is no indication that the serious type of segregated grain-boundary graphitization will result if operating temperatures do not exceed the maximums given in the table.

It will be noted that the upper limit tentatively set for the low-aluminum more-stable type of carbon moly is 25 deg higher than for the high-aluminum variety. This is based upon the fact that only one instance of graphite has been found in the low-aluminum carbon moly, and in that case the average temperature was 975 F with swings to 990 F.

The requirement of a 3 to 6 grain size in A.S.T.M. Specification A-206 involved a reduction in the aluminum added for killing purposes from about $1^1/_2$ lb per ton of steel to only $^1/_2$ lb. The use of about $^1/_2$ lb of aluminum per ton of steel fortuitously increased the stability of the carbide structure. While the specification of grain size was based upon creep tests, the change in deoxidation practice obtained thereby seems to have been beneficial from the standpoint of increased resistance to graphitization.

The conclusion of the author that the chain type of graphitization is associated with coarse-grained Widmanstätten structure is based upon heating a fine-grained high-aluminum carbon-moly material at 2600 to 2800 F to produce an exaggerated grain growth. This is similar to, although presumably higher than, the heating for upsetting given the Springdale pipe. In the opinion of the writer, the effect of this heating and the conclusions therefrom should not be interpreted as an indictment of the low-aluminum variety of carbon-moly pipe which, in the as-rolled condition, shows a coarse-grained Widmanstätten structure. As noted in the foregoing tabulation of results, only one instance of graphitization of this type of material has been reported and the service temperature in that case averaged 975 F with swings to 990 F.

H. J. Kerr.[3] Apparently three laboratories, one represented by Mr. Emerson, one represented by Messrs. Smith and Miller, and our own, have all found that 1300 to 1350 F stress relieving does not graphitize abnormal carbon-molybdenum steel. Apparently each of these laboratories has found that such treatment hides or eliminates the effect produced by welding.

If it is necessary to use a heat-treatment of 1300 to 1350 C after welding, then the fact must be faced that the material starts its life in the spheroidized condition with apparently reduced creep strength. Again, it is to be borne in mind that the Springdale pipe had graphite 12 in. from the weld, at the section which was spheroidized, due to the heat of the forging operation.

Comment on Paper by G. V. Smith and R. F. Miller (3)

H. J. Kerr.[3] The theory proposed by the authors is that the variation of the complex carbides with temperature and condition of the steel may give an explanation also as to why steel in which aluminum is not used to deoxidize has not graphitized in service.

As understood by the writer, the proposed theory is that as the lower critical is exceeded on heating, the alloy carbides are stable carbides, but when the steel is cooled below the critical, so that no martensite is present, the carbides tend to separate in a manner to give a considerable percentage of unstable carbide.

It is recognized that straight silicon-killed carbon-molybdenum steel is much more sluggish than aluminum-killed steel. When the heat wave caused by welding passes, the silicon-killed steel tends to maintain the austenite from above the critical, and in this way bring down the carbides in their more stable form to subcritical temperatures. Some of the work we have done certainly indicates a material difference between the general pearlite grains in straight silicon-killed steel and those in which high aluminum has been used when the steels are quickly cooled through the lower critical.

The authors should be more specific in their footnote comments[5] of their paper. If the piece of steel discussed is the one concerning which the writer has carried on considerable correspondence with the authors, then he cannot agree with the statement that this steel represents a deoxidation practice similar to the steel of the headers at Springdale which did not graphitize.

It may be pointed out that there are apparently many factors involved in the deoxidation of steel. When steel is made with no aluminum, or when it is made with about 2 lb of aluminum per ton, very definite characteristics are obtained. In the case of the intermediate practice, in which from $^1/_2$ to 1 lb of aluminum is used, there are other factors which affect the result, so that direct analysis cannot be made by the simple statement of the amount of aluminum used. For this and other reasons, we have found that a McQuaid-Ehn test is the best measure of the normality of the material, and that graphitization and normality apparently are related. By this test we have cases of more pronounced normality with steels which were reported deoxidized with 1 lb of aluminum than with other steels reported to be deoxidized with $^1/_2$ lb of aluminum per ton.

General Discussion

S. L. Hoyt.[4] Mr. Sabin Crocker mentioned the work that we are doing at Battelle Memorial Institute on the graphitization of steam lines. Our particular function is to study the fundamentals and to establish the causes, if possible, on a quantitative basis. Knowing the causes, it should be relatively simple to suggest practice which will minimize or avoid the hazards of segregated graphite in pipe lines. The three papers on this subject not only throw light on the causes, but also suggest two ways of circumventing them. There can be no doubt that they are a valuable and welcome contribution.

The Project Committee for the Battelle work, the Joint E.E.I.-A.E.I.C. Subcommittee on Graphitization, has authorized full co-operation with the power industry, suppliers, fabricators, and with research laboratories which are working on this problem. One of these functions consists of collecting and correlating data which have been submitted on the installation and operating conditions of steam lines of various power stations and the results of examinations of test samples taken from the welded joints of the lines. Approximately 225 individuals in 150 companies were contacted, of which about 75 companies made acknowledgment. Reports have been received covering investigations in 33 power stations and a few more remain to be heard from. In about 40

[3] Executive Assistant, The Babcock & Wilcox Company, Barberton, Ohio. Mem. A.S.M.E.

[4] Technical Advisor, Battelle Memorial Institute, Columbus, Ohio.

per cent of the stations reporting, joints were found which showed some degree of graphitization, although only three stations had joints showing continuously segregated graphite. However, quite a few more have segregated streaks of graphite or chains of disconnected nodules which may or may not be progressing toward embrittlement. Opinion seems to differ on that point, but it is reasonable to believe that if graphite has started to form, it should continue to do so until the carbide in that area is all used up. Of course, if the steel is of low carbon content, a small amount of graphite should quickly consume the carbide, and such a joint may never become dangerous. With a higher carbon content, complete embrittlement might ultimately be produced.

About 60 per cent of the plants investigating the matter reported finding no graphite. In view of the point made by Messrs. Kerr and Eberle that low-aluminum steel of normal structure in the McQuaid-Ehn test does not graphitize, or at least is highly resistant, it may be of interest to know that in this group three out of fifteen were the low-aluminum type. The data collected to date do not give a satisfactory answer on the point. For one thing, most of the steel which has been in service long enough to show much graphite is the high-aluminum type, and it will probably be a couple of years or so before satisfactory returns are made. Possibly of equal significance are the reported operating temperatures and their bearing on graphitization. Those plants reporting graphitization also reported operating temperatures in the 900's, while those plants reporting no graphitization report operating temperatures in the 800's, in deg F. We are keeping Mr. Kerr's point in mind and hope to accumulate evidence on it.

The other two papers advance the proposition that heating a welded joint to 1300 F, prior to service will eliminate graphitization at normal operating temperatures. The data we have gathered are quite inadequate for a check on this point, since the stress-relieving temperature is standard at 1200 F. In one case, however, a plant reports stress-relieving at 1300 F, but it also reports graphitization. From the point of view of this proposition, it is perhaps unfortunate that this one case is negative, but too much weight should not be given to a single report on the matter.

The point is made in these two papers that heating the steel just above the first critical point during welding, or possibly just into the first critical point, produces a structural change around the borders of the Widmanstätten areas and predisposes those places to graphitize in service. Presumably the steep temperature gradient which is produced by welding is a highly effective method of bringing about this structural change. In view of the relatively short times over which graphitization and its inhibition have been studied or observed, as compared to the far greater design life of steam lines, it is highly desirable that this suggestion be studied and checked. For example, are we dealing with a procedure (stress-relieving at 1300 F) which completely and permanently inhibits graphitization, or with one which simply retards it for a few years? The suggestion of Smith and Miller seems to be a reasonable one that heating to 1300 F converts the carbide into molybdenum carbide which is stable, but presumably it is stable only with respect to graphitization. If the change from iron to molybdenum carbide, reported by Crafts and Offenhauer, represents what is called an "equilibrium," with an equilibrium temperature above which molybdenum carbide is stable and below which iron carbide is stable, then we need to understand the effect of operating temperatures in converting the molybdenum carbide to iron carbide, since the operating temperature is thought to lie below the equilibrium temperature. If such a change takes place, the iron carbide which would form could still graphitize, although only after a lapse of time.

At this point it is desirable to refer to some work we have done at Battelle on the identification of this material as graphite. By taking electron diffraction patterns of the fractured face, such as is shown in Mr. Emerson's Fig. 1, we obtain the graphite pattern. This is practically a conclusive identification of this material as graphite. At first, however, we tried by various means to extract this phase electrolytically and thus to secure samples for chemical, X-ray, and electron-diffraction identification. Those results likewise gave evidence of graphite, but they also identified molybdenum carbide as a constituent of the steel. This technique will be used to secure evidence on the relationship between carbide composition and graphitization.

The writer believes it to be highly desirable to refrain from oversimplifying the picture of graphitization, at least at this time. After the returns are all in, we will doubtless be able to set up a very simple mechanism of graphitization in steam lines. Bearing out this thought, two cases have occurred which have the surprising and even disconcerting characteristic in common of not forming in accordance with the heat and structural effects of the welding operation. The first is the occurrence of about one-half dozen segregated streaks of graphite $^1/_2$ to $^3/_4$ in. away from the weld, or definitely well away from the heat-affected zone. The second one is a couple of stringers of segregated graphite which pass through a heat-affected zone or at about right angles to the isothermal lines. These cases are not at all understood at present, hence the writer will not attempt to "explain" them. They do suggest, however, that in spite of the nicely conceived and skillfully conducted experimentation outlined in these papers, we may not yet have the true mechanism. Apparently what we still need is the common denominator underlying the typical isothermal type of graphitization and the nonisothermal type.

H. S. Blumberg.[5] One factor considered by those conducting investigations which have for their aim either the dissolving of graphite by some treatment or a study of effect of time and temperature upon graphitization, is microscopic examination of sections. We have found that if several microspecimens are prepared from various locations around the circumference of a joint, there may be considerable difference in the amounts of graphite observable in the several sections. This is merely a statement of the fact that graphite, if present, may not be uniformly distributed, particularly as judged by examination along single planes cut through the thickness of tubes. It follows from this that evidence for an increase or decrease in the amount of graphite due to any given treatment should be based upon more than a relatively small difference in graphite in two different fields.

Mr. Emerson has already described the simple tests being commonly used by those interested in sampling joints to determine whether particular joints should be allowed to remain in service or whether graphitization has developed sufficiently to warrant removal and replacement. Our laboratory has examined samples removed from 33 joints representing 7 different power plants, from which the following observations have been made:

No graphite was found in any of the samples taken from tubing treated with less than 0.5 lb aluminum per ton. This is particularly emphasized by the fact that one material studied (0.11 lb Al per ton) had operated at an average temperature of 975 F for 35,000 hr (this being the highest operating temperature represented by any of the samples) and showed no signs of graphite.

Graphite in varying degrees was thus found only in tubes made from steel treated with appreciable amount of aluminum (about 2 lb per ton), so-called "aluminum-killed steel." However, not all joints made of this type of steel showed graphite. Advanced graphitization was found only in some of those tubes which had "coarse-grained" ferrite-pearlite structure (1–3 actual grain size) due to temperature used in upsetting tube ends before welding. To the writer's best knowledge, the only joints which have been

[5] Chief Metallurgist, M. W. Kellogg Company, Jersey City, N. J.

purposely removed from power-plant service because of advanced graphitization were in so-called coarse-grained (about 1–3 actual grain size) aluminum-killed steel (about 2 lb Al per ton). While graphite has also been found in aluminum-killed steel (about 2 lb Al per ton) with finer actual grain size (about 4–8) in the unaffected base metal near the weld, as far as is known no joints of this type have been purposely removed. In other words, in such metal it is considered that at present graphite is randomly dispersed and does not materially affect the strength, ductility, or shock resistance of the welded joint. Sampling of joints at later dates should show whether graphitization is seriously advancing.

The highest operating temperatures appeared to give most severe graphitization.

No relation was found between welding technique or position of joint axis in service and graphitization. Welding-technique factors studied were string versus weave beads and bead thickness. Axes of joints studied were horizontal and vertical.

The nature of graphitization in low-carbon steels and the manner in which it takes place are certainly little understood at the present time. Hence the present papers are of prime importance in suggesting prior treatment technique which may retard or prevent graphitization, in advancing a hypothesis to explain graphitization and in stimulating further work on this most important subject.

H. J. Kerr.[5] We have made a very considerable investigation of graphitization in power plants and other industries where carbon-molybdenum steel has been in service for a considerable length of time, without finding a single instance of graphitization of fully silicon-killed carbon-molybdenum steel, when aluminum was not used. To put this on a definite basis, the writer would state that no carbon-molybdenum steel, showing a normal McQuaid-Ehn grain size of 1 to 5 has been found graphitized. This is a vitally important point, and the request is made that, if anyone knows of such a case, it will be appreciated if that information is forthcoming as quickly as possible.

In the case of carbon-molybdenum steel in which aluminum was used in the deoxidation, a considerable amount of graphitization has taken place where the aluminum addition has been of the order of 1¾ to 2 lb. Such steels show abnormal with a McQuaid-Ehn grain size of the order of 7 to 8.

In between these two extremes, the statement of the amount of aluminum used in the deoxidation does not give a measure of the graphitization tendency, in so far as can be determined. Some steels reported to have been deoxidized with 1 lb of aluminum per ton show much more definite normality and no graphitization in service than other steels in which ½ lb of aluminum per ton has been used and which have graphitized in service. Here particularly the McQuaid-Ehn test seems to be the best measure of the susceptibility that we have found.

A. E. White.[6] These three papers are of vital interest to those using plain-carbon or alloy steel for high-temperature and possibly high-pressure service.

Although much work needs to be done to determine the cause of graphitization in plain-carbon and alloy steel, a most urgent and immediate need is to determine ways and means of rectifying graphitization without destruction of the materials.

Closure to Paper by R. W. Emerson

As a result of the very interesting and enlightening discussions on the "Graphitization of Steel Piping" several pertinent questions have arisen, some of which are perhaps due to insufficient clarification on the part of the writer.

Mr. Crocker's comments regarding the general association of the chain type of graphitization with a coarse grained Widmanstätten structure is well taken. Three possibilities are believed to exist when exploring for graphitization adjacent to welds, namely, (1) no graphite, (2) dispersed graphite, and (3) segregated graphite. Segregated graphite may be further subdivided into (*a*) chain graphite and (*b*) nodular graphite as shown in Figs. 3 and 6(*a*), respectively. If segregated graphite is found to exist, it is believed that the chain type will be found if the adjacent base metal has a coarse-grained Widmanstätten structure. It is not to be implied, however, that the presence of a coarse-grained Widmanstätten structure adjacent to a weld, such as commonly found in the current A.S.T.M. A-206 carbon-moly steel piping in the as-rolled or normalized condition, is synonymous with segregated chain-type graphitization. Limited experience with the current carbon-moly material in which a considerably smaller amount of aluminum is used in deoxidation of the steel has indicated this material regardless of grain size to be structurally more stable than the previously used (deoxidation treatment 2 lb aluminum per ton) carbon-molybdenum steel piping.

In connection with comments made by Mr. Kerr and Dr. Hoyt regarding a 1300–1350 F stress-relieving treatment, the finding of graphite at a distance of 12 in. from a weld, and the extent of inhibition of graphitization by the foregoing treatment, it may be stated with almost positive assurance that there is no presently known heat-treatment which could be said to *permanently* inhibit all graphitization in a carbon-moly steel such as that in which heavily segregated graphite has been found to exist adjacent to welds. This statement is based on the fact that a longitudinal section of pipe extending 24 in. from a weld was examined at several locations throughout that distance, and dispersed graphitization was found in all cases although the grain size and microstructure varied considerably as a result of the original hot fabricating operations.

Although general dispersed graphitization was found to have occurred in piping remote from welds, no specific mention of this fact was made originally in the paper since this type of graphitization was found to have little or no effect on the physical properties of the piping system. On the contrary, heavily segregated graphite was found to result in extremely poor ductility over a very localized region adjacent to the weld. The purpose and intent of the 1300 F stress-relieving treatment therefore is to prevent if possible the subsequent formation of *segregated* graphite. It was by no means intended that this treatment would permanently inhibit all graphitization. It appears at the present time that it will be necessary to further investigate steel-melting practices, deoxidation treatments, and the possible use of additional alloying elements in order to obtain a material in which greater assurance can be given against general graphitization.

Mr. Kerr's findings regarding the use of the McQuaid-Ehn test in determining the normality of carbon-moly steel which he has shown to be related to graphitization is believed to have considerable merit and should be given consideration as a possible test to be incorporated into A.S.T.M. Specification A-206 for carbon-molybdenum steel piping. It is to be pointed out that this relationship regarding normality and graphitization has also been observed by Austin and Fetzer.[7] They state, "In general, the results indicated that coarse-grained normal steels were stable while the fine-grained abnormal steels graphitized. Evidence has been provided to show that alumina, which may have such a profound effect on the control of grain size and abnormality, may similarly markedly lower the stability of the carbide."

[6] Director of Engineering Research, University of Michigan, Ann Arbor, Mich. Mem. A.S.M.E.

[7] "Cementite Stability and Its Relation to Grain Size, Abnormality, and Hardenability," by C. R. Austin and M. C. Fetzer, Transactions, American Society for Metals, vol. 29, 1941, pp. 339–354.

Closure to Paper by G. V. Smith and R. F. Miller

Mr. Weisberg's description of his experimental study is a valuable addition to the subject of graphitization of steel piping. We were particularly interested in the finding that graphite was produced in samples held for 936 hr at 1000 F and that stressing accelerated this graphitization.

Since writing our paper, we have also succeeded in producing graphite experimentally in a weld-heat-affected zone and incidentally also obtained a confirmation of the efficacy of our suggested preventive treatment. A brief description of a portion of our experiments may be of interest. We obtained, through the courtesy of Mr. R. W. Emerson, a section of carbon-molybdenum pipe that had been removed from the Springdale Generating Station and prepared two sections approximately $1 \times 2^1/_2 \times 4$ in. After normalizing one section at 1650 F and the other at 2000 F, we laid down on opposite sides of each of the samples a weld bead, in one case at a relatively slow rate and in the other at a relatively fast rate, so as to give on each sample a relatively narrow and a relatively wide heat-affected zone. Each sample was then cut in two, and one half of each subjected to a post-heat-treatment of four hours at 1300 F and the other half nontreated. The samples were then placed in a furnace at 975 F and held for 1000 hr. Sections were cut from each of the samples and examined metallographically for evidence of graphitization. At the low temperature end of the heat-affected zone of the steep temperature-gradient weld of the sample normalized at 1650 F and not post-treated, small dark particles were noted which, though they could not be resolved as such, were very evidently the first traces of graphite. No such particles were observed in the companion section which had received the preventive treatment, nor in the wide heat-affected zone of the same sample, nor in either of the welds of the sample normalized at 2000 F whether post-treated or not. The remaining sections were reintroduced into the 975 F furnace, held for another 1000 hr, and sections cut for further metallographic examination. By this time, 2000 hr, the graphite particles of the sample mentioned had grown sufficiently to be resolvable as such and again there was an absence of graphite in the companion post-treated sample and in all the other welds. Thus graphite was produced in the narrow weld-heat-affected zone of a sample previously normalized at 1650 F but this graphitization was prevented by a post-treatment of four hours at 1300 F. No graphite was observed in the wide weld-heat-affected zone of this pair of samples or in either of the weld-heat-affected zones of the pair previously normalized at 2000 F. These experiments are continuing and will be described in more detail subsequently.

Mr. Kerr's comments regarding deoxidation practice and the relation between graphitization and normality are interesting. It is difficult to understand the reason for a relationship between abnormality and "graphitizability," but this perhaps is to be expected in view of our lack of knowledge of either phenomenon separately. Of course, there are really two factors to be considered with respect to graphitization, namely, thermodynamic stability and reaction rate. We suspect that the apparent relationship between abnormality and graphitizability owes its existence to a greater rate of graphitization of the "abnormal" steel and does not negate the possibility of graphitization of "normal" steel. However this may be, the utility of the relationship, if found to be true, as a means of separating carbon-molybdenum steel into two classes one of which may be expected to be subject to graphitization during service, is obvious.

Mr. Kerr has also raised the question of spheroidization of the steel during preventive treatment with the attendant possible loss in creep strength. The spheroidization resulting from four hours at 1300 F, as in our experiments cited earlier, is not great, being no more extensive than perhaps that resulting from 10,000 hr at the service temperature. Mr. Kerr has apparently contemplated a much longer post-treatment time or a higher temperature than we. Moreover, according to data of Miller et al[8] a short-time treatment at 1300 F can be expected to increase rather than decrease the creep strength. Of a number of heat-treatments including simple normalizing, a treatment of five hours at 1300 F after normalizing resulted in maximum creep resistance in the standard creep test. The beneficence of this treatment is attributed to the development of a "fine groundmass precipitate, probably a molybdenum-rich carbide."

We wish to correct Mr. Kerr's impressions regarding our hypothesis of the reason for localized graphitization. Briefly, we postulated that the austenite which forms on heating just above the lower critical transforms to or yields, under conditions of relatively rapid cooling (as occurs adjacent to a weld), a carbide which is unstable with respect to graphite at the serivce temperature. It is by postheating below the critical, not above, that we thought to prevent localized graphitization. It appears to us that under some circumstances, treatment immediately above the critical might not be efficacious for preventing graphitization, as for example should the steel be subsequently fast-cooled. In such a case it would seem that the conditions might again be set for graphitization. Perhaps this is the reason for the occurrence of graphitization in the sample cited by Dr. Hoyt in which a plant has reported graphitization after stress-relieving at 1300 F; it may be that the lower critical was exceeded owing to inexact temperature control. We doubt, incidentally, that in this case there was localized graphitization; and in this connection it might further be emphasized that the important thing to avoid is localized graphitization, and not so much random graphitization; we doubt that any treatment will prevent all graphitization in this material. Contrary to Dr. Hoyt's opinion, we do not believe that only the carbide in the vicinity of a graphite particle will be converted to graphite, and that accordingly "if the steel is of low carbon content, a small amount of graphite should quickly consume the carbide, and such a joint may never become dangerous." Actually, it seems certain that if, in the Springdale Station pipe, only the carbide in the immediate vicinity of the region where failure subsequently occurred had graphitized, there would not have been sufficient graphite to form the near-continuous network that was the cause of failure. In other words, carbon had migrated from the remainder of the sample. Our suggested preventive treatment was presented with the hope that it might prevent localized graphitization, but not necessarily all graphitization.

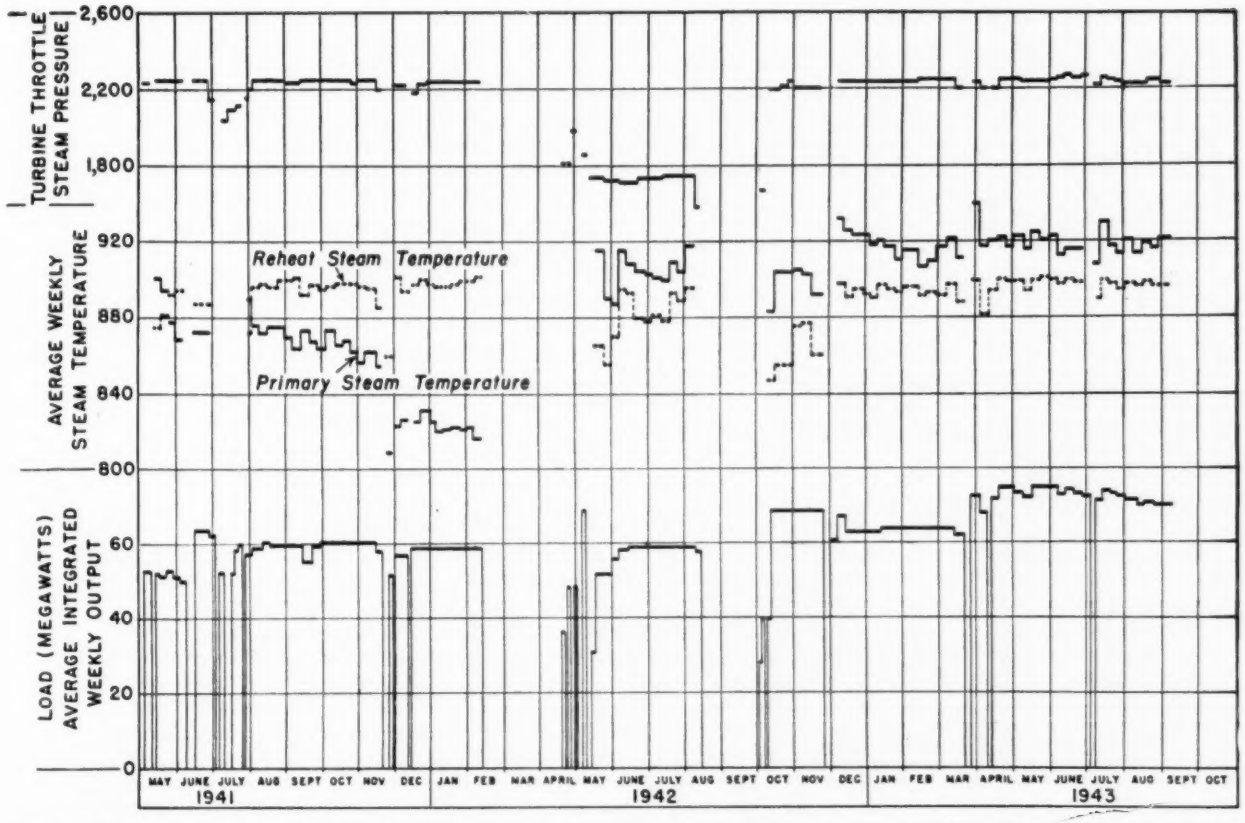

FIG. 1 OPERATION OF UNIT 3, TWIN BRANCH STATION, OF THE INDIANA & MICHIGAN ELECTRIC COMPANY, OPERATING SUBSIDIARY OF THE AMERICAN GAS & ELECTRIC COMPANY, FROM MAY, 1941, TO SEPTEMBER, 1943

Operating History of the 2500-Psi Twin Branch Plant

BY PHILIP SPORN[1] AND E. G. BAILEY,[2] NEW YORK, N. Y.

The experience gained in the operation of the 2500-psi steam-electric generating unit, projected more than 6 years ago for the Twin Branch Station of the Indiana & Michigan Electric Company, from the date it was placed in operation, March, 1941, to August 31, 1943, is outlined in this paper. During the early months of operation many lessons were learned and steps taken to correct difficulties which arose. Alterations were completed in spite of wartime handicaps, and since April, 1943, the unit has been operating at the design values of capacity, pressure, and temperature. Even prior to that time, however, i.e., December, 1942, the boiler had been operated at or had been in condition to operate at full design values. In considerable detail, the authors describe the work of alteration carried out during the three operating periods discussed, and present performance data recorded during these periods. They believe that the operating experience of the last 2 years has verified the judgment of those responsible for undertaking this distinctive development in power generation, and that 2500-psi natural-circulation boilers, 2300-psi steam turbines, with their related equipment, can be made to give a power plant that is technically and commercially sound.

MORE than 6 years ago a 2500-psi steam-electric generating unit was projected for installation at the Twin Branch Plant of the Indiana & Michigan Electric Company. After much study, thought, and intensive effort, the project was placed in operation in March, 1941. The story of that design and construction is fully covered, as many know, by a series of articles which appeared in the October 18, 1941, issue of *Electrical World*. It is not proposed to repeat that story but

rather to supplement it by giving an account of our experiences gathered over the subsequent 2-year period of operation.

During that time many lessons have been learned and solutions found to many old and newly created problems. These solutions were, of course, often delayed in execution because of wartime conditions. However, this did not cause any diversion from the main objective. The work went on, alterations were completed, and the unit has been operating at the design values of capacity, pressure, and temperatures since April, 1943. The boiler, however, has been operating at, or has been in a condition to operate at, full design values since December, 1942.

Fig. 1 gives a graphic history of the operation of this high-pressure unit. It will be noted that the total time which has elapsed since the unit was first placed on the line in March, 1941, naturally divides itself into three periods. The first period started with May 5, 1941, the date the unit was placed back on the line after preliminary adjustments and inspections, and ended with February 13, 1942. The arrangements during this period are shown in Figs. 2 and 3. The second period started on April 20, 1942, and ended August 14, 1942, and had the arrangement shown in Fig. 4. The third period started October 1, 1942, with the arrangement shown in Fig. 7, and after changes to circulation and very minor changes to surface, as shown in Fig. 8, has continued up to the present.

In that entire period two main outage intervals were experienced during which substantial changes were made in one or more parts of the boiler. Both of these periods, however, were scheduled months in advance of the time when the unit was actually taken out. In other words, the difficulties encountered were such that they could have been endured. There was a period of some 3 months when the unit was operated at a pressure of approximately 1750 psi. But since the changes that were completed on October 1, 1942, the unit has had no major difficulty, and for a period of a year the unit, in so far as the boiler is concerned, has been in a condition to operate at full design values of capacity, pressure, and temperatures, and has actually operated at these values for a period of over 8 months. This record, it is believed, speaks for itself.

The faith of the authors in the soundness of natural circulation for this design pressure was completely substantiated at the very start by measurement of circulation as the boiler was first brought to operating pressure. As a matter of fact, circulation tests showed circulation values which exceeded calculated performance. Because the subject of circulation in high-pressure boilers has been a source of technical controversy, a more detailed account of this phase is covered in a separate companion paper.[3] With the increase in boiler output, it became apparent that temperature and heat distribution among the various portions of total heat-absorbing surface were to be the real problems.

With 940 F steam temperature and 900 F reheat temperature, 43 per cent of the heat value in Btu absorbed per pound of steam at the maximum design load of 550,000 lb per hr is used for superheat and reheat; whereas, with 1300 psi and 950 F, only 27 per cent is used for superheat; and with 400 psi and 700 F, only 14 per cent is used. Because of this, it was necessary to install superheater and reheater surface in zones of higher gas temperature than is usual on boilers operating at lower pressure levels.

Adjustments and Changes

Fig. 2 shows a cross-sectional arrangement of the boiler as originally placed in service in March, 1941. The furnace front wall and the first and second division walls were $3^1/_4$-in. partial-stud tubes on 6-in. centers. The furnace side walls were 4-in. partial-stud tubes on 6-in. centers. These walls comprise the entire steam-generating surface. The partial-stud tubes have a bare face to the furnace, a cross section of which is shown in Fig. 6. The side walls of the first open pass and the side walls and rear wall of the second open pass were reheater surface as was 25 per cent of the width of the convection pass. Seventy-five per cent of the width of the convection pass plus seven groups of platen tubes across the width of the second open pass were superheating surface. A spray-type attemperator located in the connecting pipe between the convection superheater and the platens provided superheat control and dampers at the economizer outlet provided reheat control.

The first column in Table 1, shows the heat absorption during the initial period of operation. At 52,000-kw output, the superheat- and reheat-surface absorption rates exceeded the design expectations. In order to keep the final steam temperatures down to design levels, it was necessary to employ more than double the calculated full-load attemperation. A change

in surface distribution was therefore indicated as a general solution of the difficulty. In order, however, to be able to obtain operating data and experience at high ratings with the high-ash Indiana coal to aid in deciding upon the necessary permanent corrective steps and to permit practical operation until such time as the material could be fabricated and made ready to install, it was decided to make relatively quick temporary alterations to the unit.

Fig. 3 shows these temporary alterations. The reheater tubes in the first and second open-pass side walls were studded and gunnited with bafflemix to reduce the absorption and to aid in retaining slag on the first open-pass walls. Lightweight concrete was installed in one half the lanes of the upper three banks of tubes in the convection reheater to reduce absorption. The capacity of two of the attemperator nozzles was increased to permit a greater range of superheat control. Telescopic soot blowers and a water-cooled drip ledge were installed in the second open pass to aid in handling the slag accumulation in this zone. Armor plates were placed over the reheater tubes in the sloping floor at the bottom of the second open pass to prevent their damage by large pieces of falling slag. A tertiary-air duct was added at the top of the first open pass to permit a greater degree of regulation of the excess-air conditions throughout the furnace and open passes.

These changes were completed by June 15, 1941. With these changes made, it was possible to operate the unit up to maximum rating by overattemperation and to maintain the excess air on the low side; and this afforded the opportunity to obtain test data and operating experience at high loads. The unit output, however, averaged about 60,000 kw. Continuous output at higher loads was impractical because of excessive slag accumulation in the second open pass, and the flame cutting through between some of the tubes of the second division wall due to low excess-air conditions. Typical distribution of heat absorption during this period is shown in the three columns of Table 1, under operating period 1, Fig. 3. The absorption by the reheater surface steadily increased during this period and it was necessary to lower the primary-steam temperature, and hence the temperature entering the reheater, in order to hold the temperature entering the low-pressure turbine at the design level.

During this operating period, tests at high load showed that the total circulating flow was 5,100,000 lb per hr rather than 3,600,000 lb per hr expected during the design of the unit. Due to this additional circulation and the endwise flow of the water in the drum some water-level instability was encountered at low gage-glass levels and occasional "shots" of carry-over occurred because of unbalanced water levels between the two ends of the drum. It was decided to raise the gage glasses, cyclone separators, and normal water level 2 in., during the coming outage scheduled for permanent alterations, in order to correct this condition.

Fig. 4 shows the alterations made to the unit during a 2-month outage beginning in February, 1942. Every other tube for the first 7 ft from either side wall was removed from the first division wall and placed over the reheater tubes in the first open pass to reduce the reheater absorption and to provide a stable covering in this zone. These were on 12-in. centers and so were made sinuous to provide equal covering for the close-spaced reheater tubes. Openings were thus left between the tubes on 12-in. centers in the first division wall for the full height for 7 ft from either side wall. The second division wall was changed to 4-in. tubes on 6-in. centers (from $3^1/_4$-in. tubes on 6-in. centers), full-studded on the first open-pass side and with flat studs between the tubes on the second open-pass side. This was done to prevent flame from cutting through the wall and to eliminate refractory on the second open-pass side from the slag standpoint. The screen tubes at the top of the first open pass were changed to provide an open path for the gases. The original single-row superheater-platen tubes were regrouped into smaller, i.e., more compact, double-row platens, in order to reduce the superheating surface and to provide room for installing two retractable soot blowers as well as to facilitate lancing.

The reheater tubes in the rear wall and sloping floor of the second open pass were covered over with a new waterwall of $3^1/_4$-in. tubes on 6-in. centers flat-studded between the tubes in the vertical portion and covered with Bailey blocks on the sloping floor. This was done to reduce the reheater absorption and to withstand the impact of pieces of falling slag. The upper 24 ft of the reheater tubes in the side wall of the second open pass were replaced with bare close-spaced Croloy 2 tubes and the studs and bafflemix were removed from the tubes in the lower portion. The concrete was removed from the convection reheater and additional soot blowers were added as shown in Fig. 4. All these steps were part of a co-ordinated program to give better balance of heat-absorption distribution and to give each section of surface the necessary mechanical and metallurgical protection or tolerance.

Shortly after the unit was returned to service on April 20, 1942, two tubes in the first division wall failed on two occasions when the load was raised to 480,000 lb per hr and the seventh and eighth burners were placed in service.

The first failure was in the form of a crack in the tube, the leakage being such that an orderly unloading of the unit was permissible. The second failure, however, was due to a sudden opening up of the tube resulting in an instantaneous shutdown of the boiler. The automatic protective devices provided, coupled with the thorough training program to which the operating staff had been schooled, and the detailed manner in which preparations were made for such an eventuality, made possible a perfect handling of the situation. Turbines and all auxiliaries were shut down in proper sequence and the boiler was bottled up so that the drum was not subjected to any undue thermal stress. As a matter of record, no ill effects of any kind were encountered subsequent to the repair of the tube and the restarting of the boiler. These failures were located about 10 ft from the roof of the furnace on the first wide-spaced tube on either side of the solid part of the division wall. Observation showed the flame to be short-circuiting through the lanes at this elevation, and these tubes were completely enveloped by flame.

An investigation of these failures led to the conclusion that they were caused by thermally induced stresses well above the yield point, produced by extremely high absorption rates across the tube wall approximately $^1/_2$ in. thick. This is covered more fully in a second companion paper.[4] Based on this analysis a decision was made that, for a permanent solution of this trouble, these lanes should be closed off, and the wall again made solid by additional tubes. As a temporary stop-gap and to permit the unit to stay on the line until convenient to take out for permanent repairs, these tubes were covered with stud plates and chrome ore and the load was limited to six-burner operation. It was also decided to operate temporarily at approximately 1750 psi, in order to take advantage of reduced-pressure stress. This, it was known, would be very slight but it was felt that the need of the capacity made available by the unit was so pressing that this reduction in pressure was desirable even though it gave but a small additional margin of safety. In addition, boiler

[4] "Distribution of Heat Absorption and Factors Affecting the Performance of the Twin Branch 2500-Psi, 940 F Boiler With Reheat to 900 F," by F. G. Ely and L. B. Schueler. Presented at the Annual meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

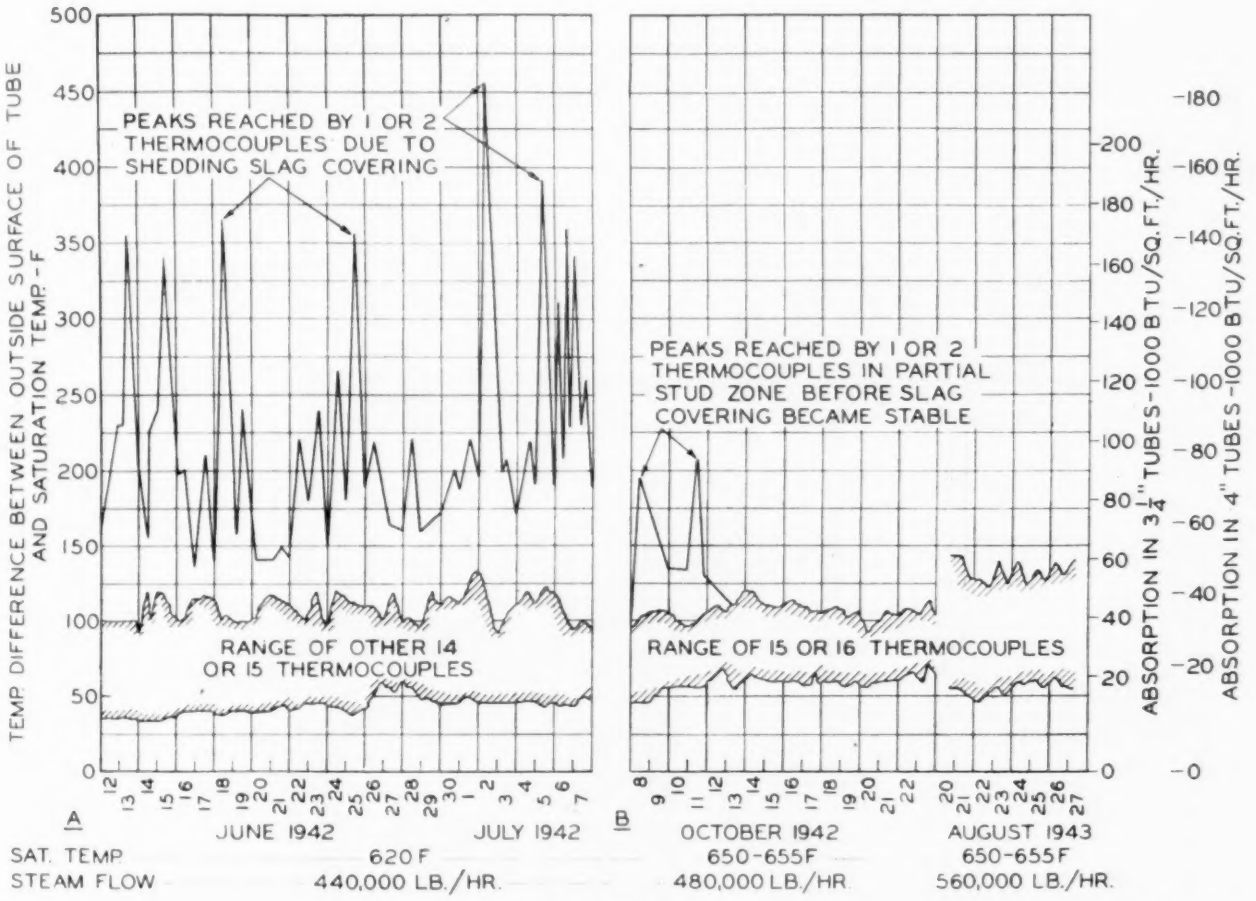

FIG. 5 LOG OF FURNACE-TUBE-WALL TEMPERATURE DIFFERENTIALS

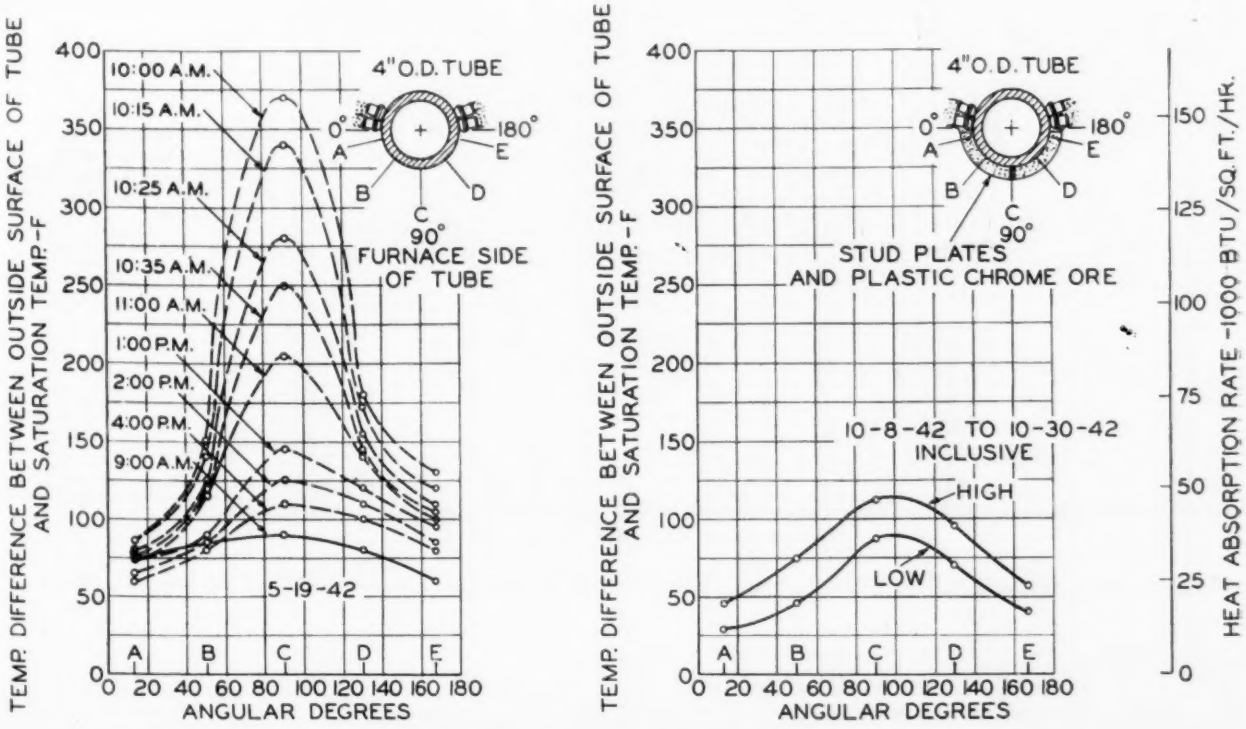

FIG. 6 COMPARISON OF TUBE TEMPERATURES BETWEEN PARTIAL- AND FULL-STUD CONSTRUCTION

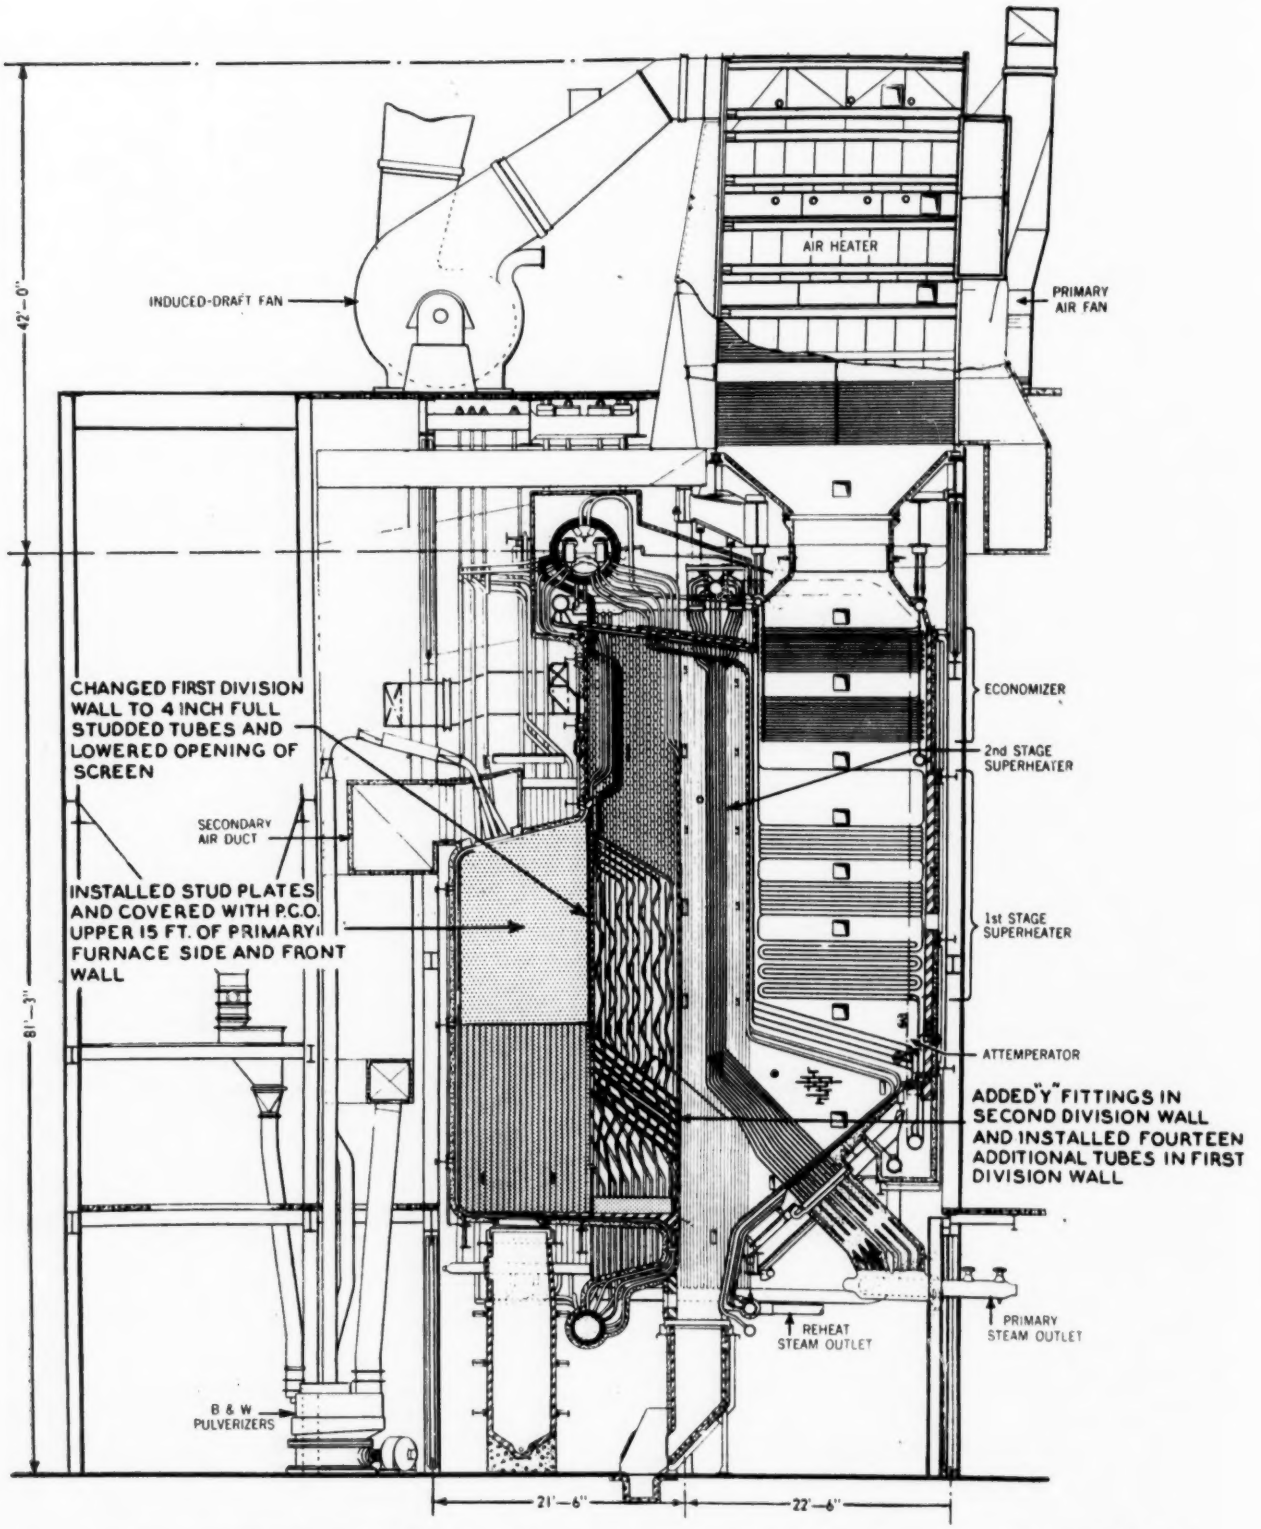

FIG. 7 ARRANGEMENT OF BOILER OF UNIT 3, TWIN BRANCH STATION, AS OPERATED FROM OCTOBER 1, TO NOVEMBER 25, 1942

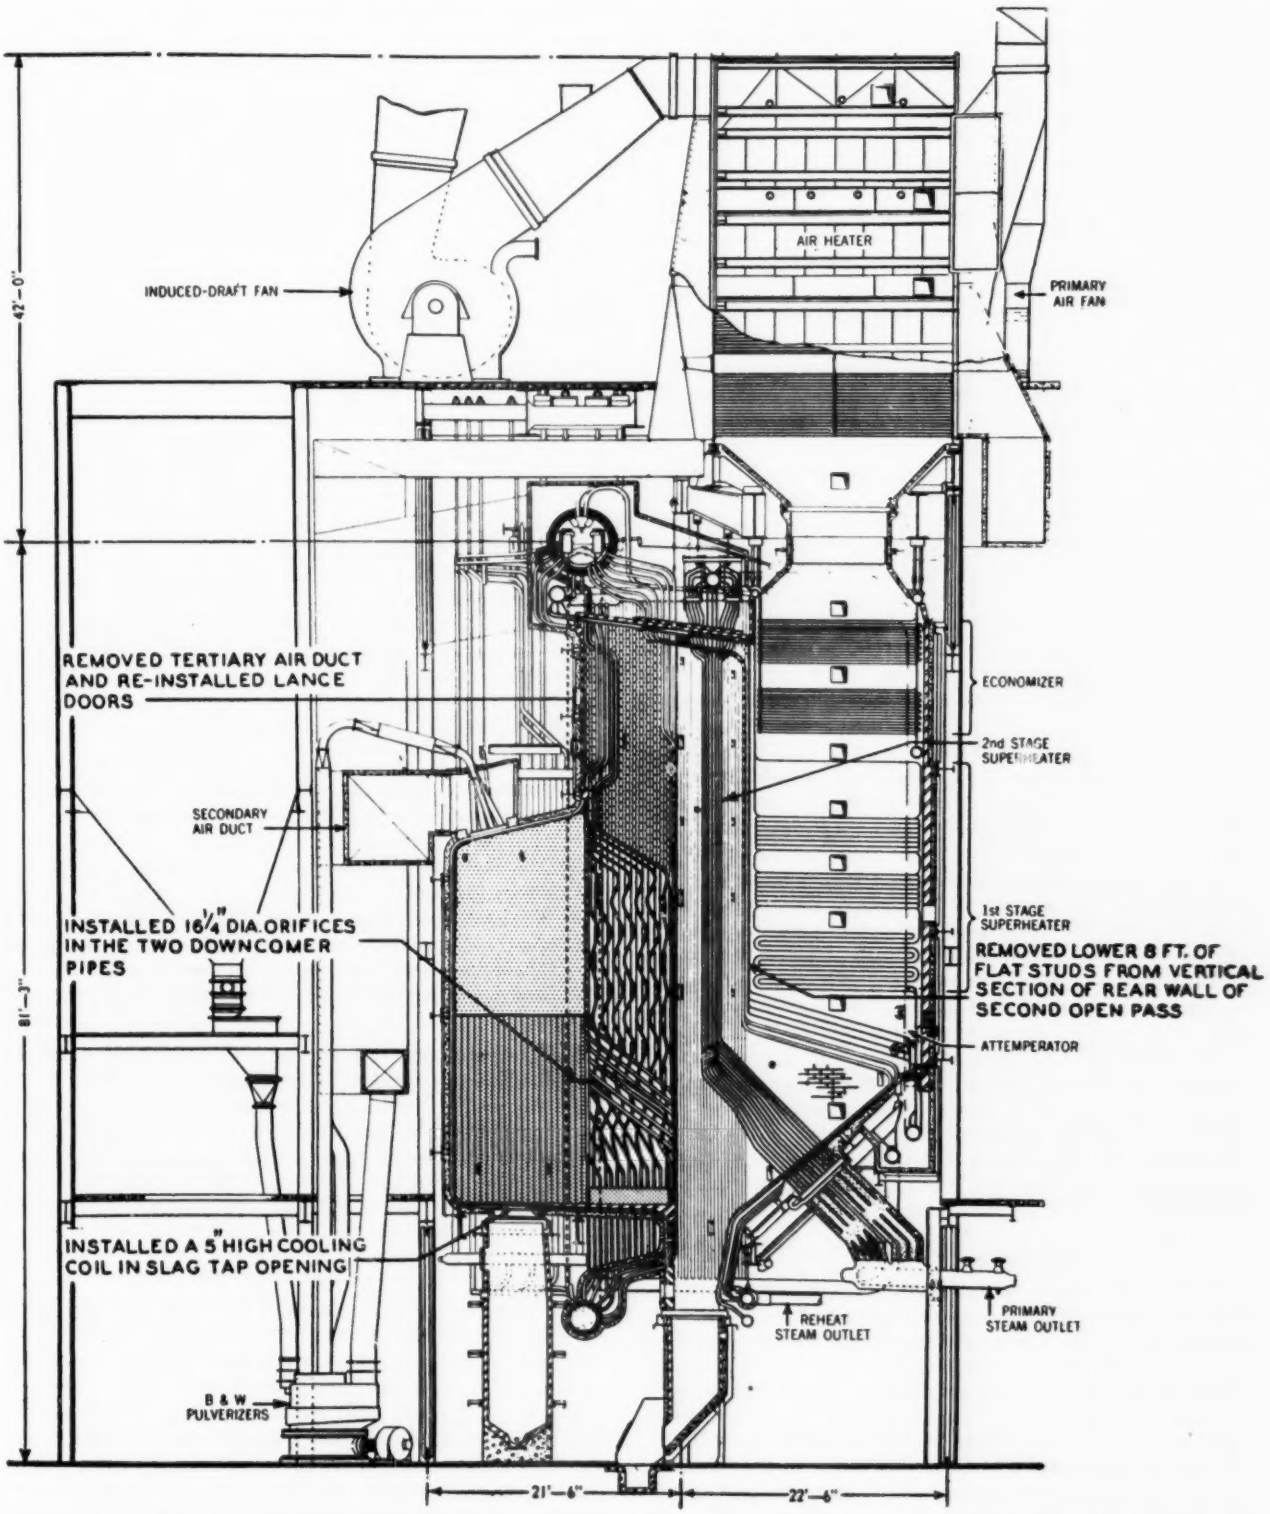

FIG. 8 ARRANGEMENT OF BOILER OF UNIT 3, TWIN BRANCH STATION, AS OPERATED SINCE DECEMBER 1, 1942

operation was governed by tube-temperature indications, some of which were recorded continuously and others of which were merely indicated.

These temperature readings were obtained through some 57 specially designed thermocouples which had been installed in the furnace face of the partial-stud and full-stud tubes throughout the furnace and 16 of these couples were connected to a recorder.

Fig. 5(*A*) shows a typical record of these couples obtained in June, 1942, with the arrangement of Fig. 4. Fig. 5(*B*) shows a similar record with full-stud tubes in the upper part of the primary furnace with the arrangement of Fig. 7. The bulk of the couples, under Fig. 4 conditions, would record from 40 to 125 F above saturation temperature, indicating absorption rates from 30,000 to 50,000 Btu per hr per sq ft, whereas different couples on the partial-stud tubes would register peaks of 350 to 450 F above saturation temperature indicating localized absorption rates as high as 200,000 Btu per hr per sq ft, due to the slag covering peeling away from the tubes. As shown by Messrs. Ely and Schueler,[4] at 200,000 Btu per sq ft per hr heat transfer the stresses at the inner fiber of a $3^1/_4$-in. × 0.5-in. carbon-moly tube (0.5 per cent Mo) approach the short-time ultimate strength at 2350 psi with a saturated temperature of 660 F. At this point temperature accounts for 88 per cent of the total stress. The right-hand chart, Fig. 5(*B*), shows the temperature record after the tubes were covered in accordance with the layout shown in Fig. 7, which will be described. The average absorption rates were about the same, but all the peaks were eliminated.

Fig. 6 shows an interesting phenomenon in connection with the thermocouple data. Five couples were located around the furnace half of a tube at approximately the same elevation. The chart at the left shows the temperature changes on a partial-stud tube when the slag peeled. The center of the furnace face rose from 90 F above saturation to 370 F suddenly, whereas, the couples on the 50-deg points rose from 80 F to only 175 F indicating that the slag did not completely peel at the sides of the tubes. These temperatures gradually returned to normal as a new slag coating built over the tube. The chart at the right shows the temperature distribution around a full-stud tube, but here no sharp peaks are in evidence.

The alterations indicated in Fig. 4 were quite successful in reducing the superheat and reheat to the design levels as shown in operating period 2 in Table 1. With proper excess-air conditions the superheat and reheat were somewhat on the low side, and slag troubles were eliminated, it being possible to keep the second open pass clean with the retractable soot blowers and supplemented by some hand-lancing.

Further Alterations Made

On the other hand, the rating of the unit was definitely restricted. Hence when the first opportunity, determined by system capacity and load conditions, presented itself after the material needed for the next change had been fabricated, the unit was shut down and the changes which started with the shutdown of August 14 were initiated. Fig. 7 shows the alterations which were made during this period. The upper 15 ft of the furnace side walls and front wall were covered with stud plates and chrome ore to eliminate the temperature peaks caused by shedding slag. The first division wall was changed to 4-in. full-studded tubes on 6-in. centers, and the wall made solid by bringing 14 tubes over from the second division wall. The screen opening from the furnace was also lowered 7 ft, in order to provide longer gas travel and to give a wider range for free-running slag.

These changes were successful in eliminating the high localized absorption rates and permitted slag-tapping at a load as low as 300,000 lb per hr. The increased steam-generating circuits increased the circulation rate to 5,500,000 lb per hr, which produced some water-level instability at low levels at ratings above 500,000 lb of steam per hr and the water level would become as much as 3 in. to 4 in. different between the two ends of the drum with unbalanced firing conditions. These factors combined to make the permissible water-level range between water-level instability and carry-over too small for trouble-free operation above a load of 500,000 lb per hr.

As shown in Fig. 8, this trouble was corrected during Thanksgiving, 1942, by installing a $16^1/_4$-in-diam orifice in each of the two 28-in. downcomers, which reduced the circulation to 5,000,000 lb per hr at full load and increased the resistance in the downcomers sufficiently to bring the water level at the two ends of the drum within $^1/_2$ in. of each other, regardless of firing conditions. There has not been a case of water-level instability or shots of carry-over since then. At the same time a 5-in-high cooling coil was installed around the slag-tap hole to retain the slag level over the floor to about 6 in. at the hole. Also, the lower 8 ft of the flat studs were removed from the waterwall at the rear of the second open pass. These changes resulted in the proper balance of superheat and reheat, as shown by the data under operating period 3 of Table 1.

The analysis of the results of the extensive testing of the boiler during these operating periods given in Table 1 brought out several reasons why the actual results from heat-absorbing surfaces for water-heating, steam-generating, superheating, and reheating portions were at variance with the original design. These were as follows:

1 Incomplete evaluation of the long-term insulating effect of the slag from these Indiana coals on the bare tubes of the primary furnace.

2 The fact that combustion is not entirely completed in the primary furnace.

3 The gas-temperature measurements on other units on which the design absorption rates were based were somewhat lower than they should have been based on later information obtained.

4 The use of Eastman's gas specific heats rather than those of Justi.

For these reasons, the heat absorbed by the primary-furnace surface where the steam is generated was considerably less than the design value; whereas, the heat absorbed by the first open-pass and the second open-pass surfaces where a large part of the superheating and reheating is done, was considerably greater than the design values. Thus the total superheater and reheater absorption were originally much greater than called for by the design conditions.

Feedwater Chemistry

The problems in the boiler-feedwater chemistry anticipated by some did not materialize. The feedwater treatment and boiler-water conditions that are maintained are comparable with our 1500-psi boilers. In the matter of steam purity, the conductivity of steam from the boiler averages 0.8 micromho. This is equivalent to solids carry-over of about 0.5 ppm. Tests on evaporated-steam samples substantiate this value. A slow building up of stage pressures takes place on the high-pressure turbine. Whenever these pressures approach the established limitations, the condition is corrected by dropping the primary-steam temperature by attemperation for a period of several hours. Turbine-supervisory instruments, the wide range and complete control of steam temperature makes it possible to carry out this operation within a period of 2 to 4 hr while maintaining an output in excess of 65,000 kw.

Turbine

In view of the difficulties which many users of 1500-psi topping turbines encountered during the period 1937 to 1940, one might have with some possible justification anticipated blading failures on a 2500-psi turbine. It is true this would have been based upon a somewhat superficial reasoning. As a matter of fact, those responsible for the design of this project and the turbine design had by that time so thoroughly integrated the experience encountered on the Logan and the Windsor turbines as to feel confident that a first-stage bucket having a length of only 0.75 in. and utilizing construction similar to that employed in the rebuilt first stages of the Logan and Windsor turbines would give no difficulties of any kind. Experience has fully borne this out.

Only one major problem developed in the operation of the high-pressure turbine and this was caused by vibration of the turbine rotor in its bearings. This condition appeared in the initial operating period of the unit and was apparently corrected by altering the oil flow to the bearings. Part-load operation, entailed by the temporary derating of the boiler, precluded operation at full loads to establish definitely that the correction was adequate up to full load. When the boiler design was ultimately modified so that full steam capacity became available and the turbine could be run at its full-load rating, there was a recurrent vibration of the shaft within the bearings. Further studies were made and the difficulty diagnosed as due to oil whip and that was caused by inadequate loading of the upper halves of the bearings. It was ultimately corrected by the addition of jack bolts. These jack bolts served artificially to load the halves of the bearings at all times, and no further trouble has since been experienced from bearing vibration.

The value of turbine supervisory equipment was again demonstrated following the proved worth of these devices in the Windsor installation. While troubles were being experienced due to bearing vibration, these instruments were used as an operating guide, and their record aided materially in the final solution of the problem. It is heartening to note that these supervisory instruments, quite novel a few years ago, are receiving increasingly favorable attention from power-plant designers and operators.

There were several minor troubles which occurred on both high- and low-pressure turbines. However, these were not the consequence of using high pressure and high temperature. These difficulties could just as well have been experienced at lower pressures and temperatures. To provide greater operating convenience, the initial-pressure regulator was redesigned to function as a pressure governor. This pressure governor responds to steam pressure ahead of the turbine stop valve, and is used for base-load operation, thus automatically loading the turbine in accordance with boiler output. This governor is provided with a motor-operated spring adjustment so that, for large load changes, the pressure may be manually compensated by the operators.

Electrical

Electrical storms on the 27,600-v system being supplied from Twin Branch have dropped auxiliaries off the line on several occasions but without any serious consequence to the unit. This was due primarily to the impedance relationships of the various windings of the main power transformer bank of this unit. This is a 4-winding bank and one of the windings supplies a 2300-v auxiliary bus. The reactances between the 4 windings were, however, so arranged that short-circuits on the 27,600-v system caused a greater drop in the 2300-v auxiliary-bus voltage than that which occurred on the 27,600-v bus itself. This meant that short-circuits on the 27,600-v system of only moderate severity reduced the 2300-v bus voltage very seriously. The difficulty has been taken care of for the present by feeding the 2300-v auxiliary bus from another transformer taking its supply from the 27,600-v bus. The final solution has been worked out in connection with unit No. 4 at Twin Branch, now in process of completion.

Boiler Feed Pumps

Operation of the high-pressure boiler feed pumps has reached a point of reliability comparing favorably with that of pumps in plants of much lower pressure. However, a number of corrections had to be carried out before this availability was achieved. There are three Ingersoll Rand boiler feed pumps installed at Twin Branch. They are 5-in. pumps having 8 stages direct-connected to 2500-hp 3600-rpm motors. Normally one pump is used to carry the full load of the plant. These pumps have forged-steel barrel-type casings and the inner-casing assembly can be removed as a unit.

The first and most difficult problem encountered was due to vibration of the outboard and discharge end of the pump shaft and bearing. This vibration caused disturbances of packing, excessive shaft-sleeve wear, scoring of bearings, and wear of main oil gear drive. This vibration was eliminated by adjustments to balancing-drum clearances, better shaft alignment, and rotor balance.

In the early stages of operation the packing life was short and the shaft-sleeve wear excessive. To break down the high pressure ahead of the packing, a double step-type labyrinth is used, the leakage from these labyrinths being returned through a common header to the 8th-stage heater at 150 psi pressure. With the water temperature at 340 F rather large quantities of water are required to remove the heat generated by rubbing friction. The short life of the packing was attributed to the combination of the high pressure in the labyrinth chamber and the high temperature, and the subsequent flashing in the packing gland. The choice of 150 psi pressure in the labyrinth was made to give the best thermal efficiency. This difficulty was entirely cured and packing life has been greatly extended by dropping the labyrinth leak-off pressure to a value between 90 and 110 psi. Under these conditions packing life is now just as satisfactory as with 1500-psi-pressure pumps.

A certain amount of erosion, as a result of high pressure, was experienced due to leakage past the separating diaphragms between stages. This has been minimized by the use of stainless steel on the sealing surfaces. Excessive wear of shaft sleeves, balancing drums, and labyrinth parts has been materially reduced by substitution of parts made from more suitable alloy material.

Two motors were initially furnished for the three pumps. The bedplates of the pumps were designed to make possible rapid shifting of motors from one pump to another. However, the early difficulties with the boiler feed pumps and the time-consuming job of pump and motor alignment dictated the advisability of purchasing a third motor. Significant, however, is the fact that there has been no loss of plant capacity due to failure of a boiler feed pump.

Feedwater Heaters

There are two high-pressure feedwater heaters on the discharge of the high-pressure boiler feed pumps. Although these heaters were the subject of some concern prior to installation, their behavior has been entirely satisfactory. There has been no outage due to leakage. Some depositing of solids, mostly on the water side of the heaters, takes place over a period of time. Piping provisions have been added and a method established chemically to clean these heaters. This work can be performed

while the unit is in operation. However, to date, there has been no occasion to apply this procedure. The good performance of the heaters is doubtless due to sound design, and to the carefully established starting procedure which avoids quick temperature changes. In starting up the shell side of the heaters is heated up gradually by auxiliary steam so that, when the turbine comes on the line, the heaters are ready for service.

Operation and Performance

Operating and maintenance problems resulting from operation at high pressure have been relatively few, in fact less than on any of the 1500-psi plants of most recent construction on the American Gas and Electric Company systems. There has been no difficulty with any of the high-pressure piping or valves. Some slight leakage is being experienced with the boiler-drum safety valves due to warping of seats and disks. Corrective measures are still in the experimental stage. This also holds true of the boiler-drum gage glasses. The high pressure apparently causes some assembly distortion and that, coupled with other factors, is resulting in considerable leakage and shattering of glass, thus requiring frequent and specialized maintenance attention.

An examination of Fig. 1 indicates that barring the two scheduled intervals utilized for making the major changes previously described, the availability of the unit compares favorably with most power installations operating at even as low a value as one third the pressure of Twin Branch. As a matter of fact, this unit is now one of if not the most troublefree installations on the American Gas and Electric Company systems. Except for a small deficiency in primary steam temperatures, the boiler is meeting all expectations of those who planned and designed the unit as to capacity, reliability, efficiency, and all-round performance. In this connection there are given in Table 2 the results of two efficiency tests which were conducted in May, 1943. Included also in this tabulation are the expected results. Here a mere comparison of expected with actual test performance renders its own commentary.

TABLE 2 BOILER NO. 3 EFFICIENCY TESTS

Date Time of day	Expected performance	May 12, 1943 8 a.m.–5 p.m.	May 14, 1943 8 a.m.–5 p.m.
Coal fired per hr, lb	71000	64921	65013
Steam flow to turbine, lb per hr	550000	556250	560440
Steam flow through reheater, lb per hr	440000	466520	470040
Heat value of coal as fired, Btu	10000	11126	11248
Efficiency of boiler unit, per cent	85.63	86.81	87.04
Boiler drum pressure, psig	2440	2334	2343
Superheated-steam-line pressure, psig	2335	2261	2271
Reheater-inlet pressure, psig	420	424	428
Reheater-outlet pressure, psig	376	400	405
Final primary-steam temperature, F	940	930	928
Reheat-inlet steam temperature, F	545	554	550
Final reheat-outlet steam temperature, F	900	893	900
Economizer-inlet feed temperature, F	487	476	473
(HVT) gas temperature entering convection section, F	2020	1870	1869
Average gas temperature entering air heater, F	690	712	712
Average gas temperature leaving air heater, F	347	407	396
Average air temperature entering forced-draft fan, F	80	101	95
Total air entering first open pass, per cent	...	115.0	114.9
Total air leaving air heater, per cent	133	126.2	126.9
Total draft loss, in. H_2O	11.3	11.0	11.4
Total secondary-air resistance, in. H_2O	9.3	8.1	8.7

In the matter of thermal performance, test values, whether obtained over a period of a day or a period of several days, have never been given, as they have no reason to be given, any particularly heavy weight from an operating standpoint. Rather, what is significant is the continued performance taken over a yearly or similar period. Here it is regretted that performance over a full year at full rating is not as yet available. However, in Table 3 there is given a summary of operating results covering the period beginning March 26 to August 31, 1943. This period begins with the date when the final adjustment to the bearings of the high-pressure turbine was completed, the effect of which made possible full-load operation of the unit. It is significant to note (1) that there were only two short-duration outages in this interval, both scheduled, to take care of matters clearly explained in Table 3; (2) that in spite of these outages the unit with a maximum rating of 76,500 kw averaged during this interval for the period that it was running close to 72,700 kw per hr with a performance of 10,035 Btu per kwhr output to feeders. This corresponds to a thermal efficiency of 34 per cent. This was accomplished by some interesting operating factors, i.e., capacity factor, 91.9 per cent, output factor, 95 per cent; availability factor of unit, 96.7 per cent.

The figures of 95 per cent as a desirable and necessary availability factor in high-grade steam-plant design and performance and 10,000 Btu per kwhr as a thermal-performance figure for a modern steam plant have been held up for a number of years as an ideal to attempt to reach, but one which it was perhaps unreasonable to expect to attain fully under present conditions. It would appear from the foregoing figures that, as to performance, the figure has been very closely attained, and as to availability the figure has perhaps been exceeded, in the Twin Branch 2500-psi job.

TABLE 3 OPERATING DATA UNIT NO. 3, AFTER PROVIDING JACK-BOLT ARRANGEMENT[a] ON BEARINGS 1 AND 2, COVERING PERIOD FROM 4 A.M. MARCH 26, TO MIDNIGHT AUGUST 31, 1943

Total hours in period	3812
Total hours operated	3686.88
Total generation, kwhr	267,997,000
Generation per hour, kw	72,689
Auxiliary power, kwhr	16,744,611
Total output, kwhr	251,306,389
Total fuel consumed, lb	233,941,000
Heat value of coal as fired, Btu	10,778
Output, Btu per kwhr	10,035
Thermal efficiency, per cent	34.0
Capacity factor, per cent	91.9
Output factor, per cent	95.0
Availability of the unit, per cent	96.7

Outages:	No. hours off
Friday, April 9, unit No. 3 was removed from service for leak check test on low-pressure condenser, and acid washing high-pressure and cross-over heaters feedwater side, and inspection of induced-draft fans. Unit was returned to service 10 p.m. Sunday, April 11, 1943	53.04
Unit No. 3 out of service 72.08 hr as per schedule for inspection of boiler, changes to electrical connections to accommodate unit No. 4, and general inspection of unit and auxiliaries during period July 2, to July 6, 1943	72.08
Total time off during this period	125.12

[a] Jack-bolt arrangement was provided on bearings 1 and 2 during shutdown from 8:47 p.m., March 19, to 4 a.m., March 26, 1943. This change permitted full-load operation of unit.

The authors believe that the operating experience of the past 2 years has verified the judgment of those responsible for undertaking this distinctive development in power generation. Without going into the merits or demerits of other thermal cycles or equipment, Twin Branch experience has shown that 2500-psi natural-circulation boilers and 2300-psi steam turbines, with their related equipment, can be made to give a power plant that is technically and commercially sound.

Discussion

W. H. Armacost.[5] The authors of the three papers, covering the Twin Branch Plant, are to be congratulated for their able and frank description of the operating history, heat absorption, per-

[5] Vice-President, Combustion Engineering Company, Inc., New York, N. Y. Mem. A.S.M.E.

formance, and the test results of the 500,000-lb-capacity natural-circulation boiler applied to the 2500-psi steam-electric generating unit of that station. These papers, together with those published previously on this installation, will be referred to frequently.

Pioneering in the field of such a high pressure, particularly with a very large steam-generating unit and with natural circulation is not a simple extension of well-known scientific laws. It is therefore to be expected that some of the initial design features of such a unit might require modification, but it is distinctly to the credit of the manufacturer and user that they co-operated not only to produce an efficient unit of high availability but that they also co-operated in presenting to their fellow engineers the detailed procedure which was followed in accomplishing these results. Building this unit represents a great achievement, particularly when one considers the controversial opinions advanced at the time the unit was planned.

Referring to the description of the tube-metal temperatures which are illustrated in Figs. 5 and 6 of the paper by Messrs. Sporn and Bailey, it will be noted that furnace side-tube temperatures as high as 1070 F, or 450 deg F above saturated temperature, were recorded even though a circulating rate of 10 water to 1 steam existed within the tubes, and that these high temperatures were reduced by covering the tubes to reduce the absorption approximately 50,000 Btu per sq ft per hr.

Our experience also indicates that variations in cleanliness of the furnace wall tubes produce severe and rapid variations in furnace tube temperatures, but, of course, the tube thickness is also an important factor.

It is interesting to compare the data mentioned with similar information taken at the Montaup Electric Company on the 650,000-lb-capacity 2000-psi controlled forced-circulation boiler where only bare tubes of $1^1/_4$ in. OD, 0.165 in. minimum thickness are present in the furnace, and with only a 5 water to 1 steam circulation ratio. The highest temperature reported under normal operation was 750 F, which is only 135 F above saturation temperature. Fig. 9 of this discussion shows the effect of lancing a portion of the furnace wall, which is normally coated with about $^3/_4$ in. of slag in a zone where the flame temperature might approach 3000 F. The hot face of the tubes was only approximately 50 deg F higher than fluid temperature in the tubes under normal condition of operation with pulverized-coal-firing, but the temperature indicated by all thermocouples rose about 100 deg F, and in some cases to a peak of 170 F, when the slag was removed from the area being studied. The increase due to higher rate of heat absorption would be even greater with thicker tubes, in which case the hot-face temperature might exceed safe limits; but, with tubes of 0.165 in. thickness, it is obvious that a very high rate of heat absorption can be tolerated or even encouraged without reaching a condition that could be called "overheating," provided of course, there is adequate circulation of water to the heated surface of the tubes.

On this unit, it is possible to determine accurately the water flow to the furnace circuits by the measurement of pressure differential across the calibrated orifices, and to check the total flow calculated by this method against total flow determined from pitot tubes in the downtakes. Results by these two methods have checked within a few per cent. It is known that no steam is trapped in the downtakes because the water temperature is below saturation temperature, and calorimeters were used as a further check.

There have been tube failures in two different furnace circuits at Montaup Electric Company since it was started up in August, 1942. These were repaired by cutting out and welding in new sections of tube. One of these occurred several weeks after starting up, and the other several months later. These tube failures were due to dirt and foreign material, such as oxide scale, resulting from field welds in the boiler circuits, and piping. Accordingly it was decided to wash the boiler with acid.

The circulating pumps are operating very satisfactorily on this boiler. Some trouble was experienced originally, but after providing a few thousandths of an inch additional clearance in the glands, all appreciable wear stopped.

There have been no pressure-part or mechanical changes made on this boiler since it was erected, except the drum internals and no further changes are contemplated.

Figs. 10, 11, and 12 of this discussion show the results of recent informal tests run with both coal- and oil-firing to determine operating characteristics of the Montaup unit. On each chart the lines represent expected performance with coal-firing and the points indicated by C are the corresponding measured data. The points indicated by O are the data with oil-firing.

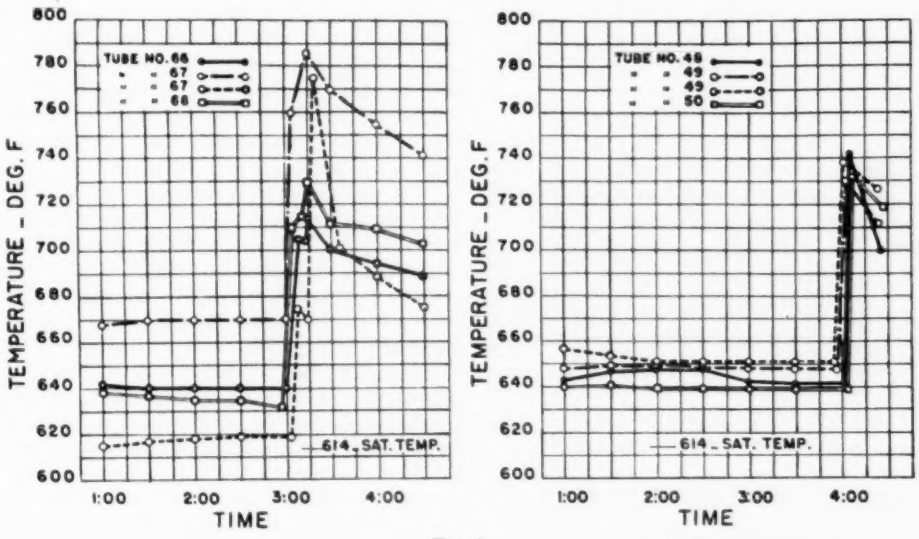

FIG. 9

Referring to the steam temperature leaving the superheater, this was under control by means of the by-pass damper, which was about 40 per cent open at maximum load with either fuel; so the steam temperature could have been increased or decreased at will. At the 450,000-lb per hr load, the by-pass damper was completely closed with oil-, and about 5 per cent open with coal-firing.

The steam temperature to the resuperheater is purposely maintained a little lower than predicted because the temperature increase in the reheater is a little greater than expected.

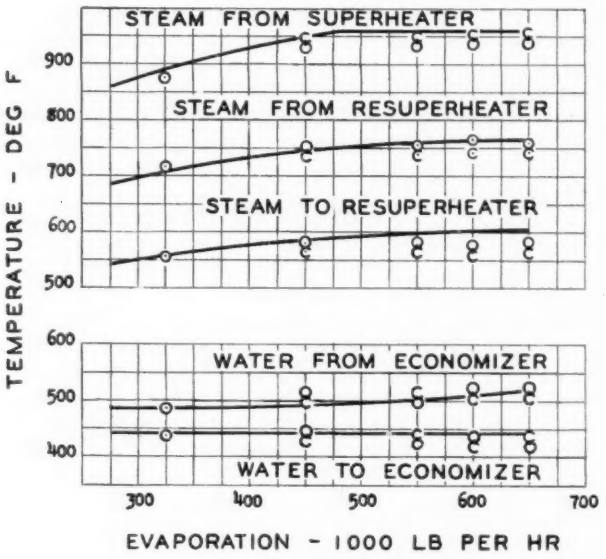

FIG. 10

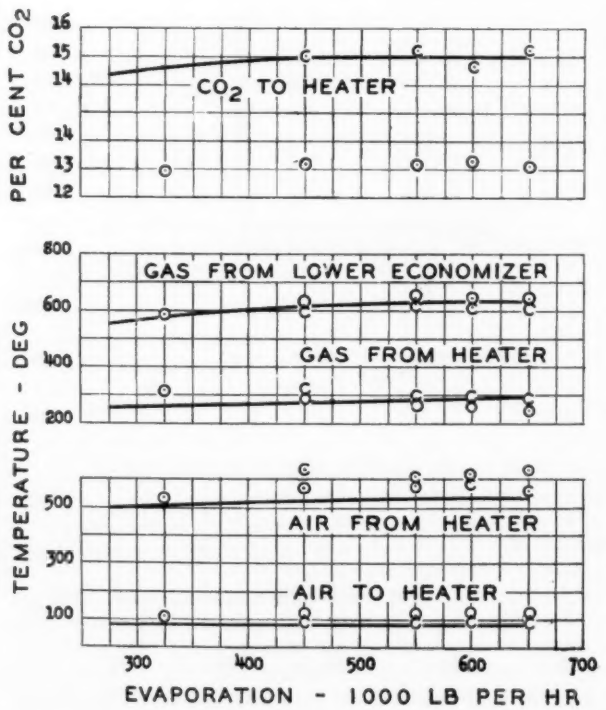

FIG. 11

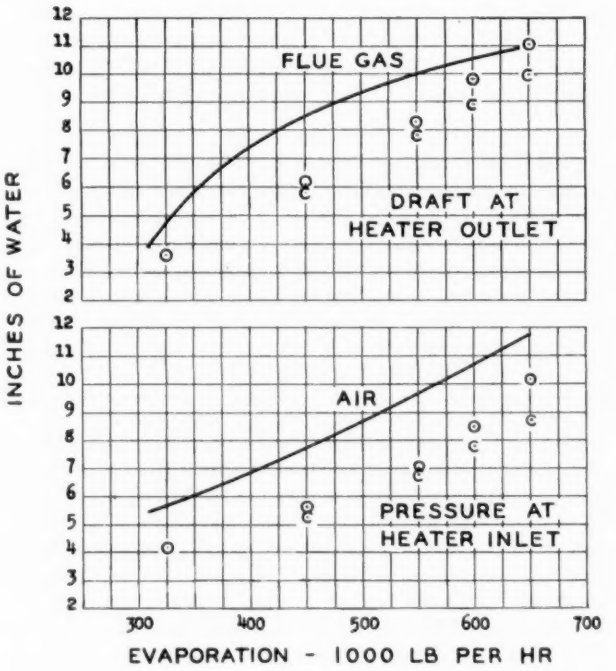

FIG. 12

C. W. BELL, SR.[6] The design of the boiler apparently provided decidedly too much superheating surface and we suspect somewhat less than the ideal amount of normal boiler surface, since we note that the average gas temperatures appear to be somewhat high under final conditions.

The particular point in the analysis of operation, which we feel was not fully explained, has to do with the statement that heat-absorption rates are estimated to have reached 200,000 Btu per hr per sq ft.

The writer has observed in a large number of power plants and on a correspondingly large number of tube failures, that tubes will bulge and sometimes split in a manner such as was experienced at Twin Branch only when the tube becomes dry or at least very nearly dry. This can occur after some critical rate of steam production is reached. In other words, it is our impression that the steam-release rate was so high at some point lower down in the failed tube that the section which failed was attempting to serve as a superheater and, consequently, the heat-transfer rate was decidedly lower than the maximum obtained with a fully wetted internal surface.

We would suggest that thermocouples embedded close to the inside wall, in other words, set in counterbored holes, would shed considerable light on conditions inside the tube at various steaming rates.

One of the most interesting developments exemplified in this boiler we feel is the clean-cut external downcomers for feeding water to the lower ends of all groups of heating-surface tubes. We have felt for many years that this plan should have been applied to boilers of earlier design, since we have observed cases where it was definitely possible for circulation to reverse under certain conditions. The Twin Branch design could not possibly do this. The design chosen demonstrates nicely the effectiveness of circulation where no interference exists, and the error in required size was definitely on the safe side.

---

[6] Pennsylvania Power & Light Company, Hazleton, Pa. Mem. A.S.M.E.

I. E. Moultrop.[7] About 20 years ago the first commercial high-pressure installation went into service at the Edgar Station of the Boston Edison Company. The pressure was 1200 psi, the temperature was 750 F, and the turbine had a capacity of 3000 kw. To step up the pressure by 1200 lb and the temperature only by 200 F in 20 years does not seem like rapid progress yet much development has been done. Merely increasing the pressure was no great problem in itself; other industries had been using similar or higher pressures for some time. However, increasing the boiler pressure did create new problems such as the circulation within the boiler, a most interesting study, and one for which the complete answer perhaps has not yet been found. The steam temperature has increased more slowly, only a few degrees at a step, while power-plant engineers wait for the metallurgist to find better heat-resisting metals. It is believed that the intensive research going on for military needs will be quite valuable after the war. Also the experience acquired in building superchargers and the so-called gas turbines will be of great value.

The frank discussion of operating troubles encountered and construction changes made is most interesting and timely. They are relatively small when one realizes that no natural-circulation boiler had ever been built for these extreme conditions, and the builder is to be congratulated for the excellent results of its engineering. The splendid control of steam temperature is remarkable. Formerly it was quite difficult and usually there was practically no control of the temperature, a situation which gave the turbine builders much concern.

The paper could well have given more space to the control room and method of operation. A few years ago it would have been unthinkable to attempt to operate a boiler from a distant point. The laws of Massachusetts forbid it. Yet here is an extremely large boiler, successfully being operated from an operating room removed from the boiler and with nobody around the boiler. The fact that this is both practical and successful is proved by the report of tube failures where the situation was handled perfectly in all cases. A reliable indicator of the water level in the boiler drum and a CO_2 recorder which gives immediate gas analysis of the flue gases are two of the outstanding instruments on the very large gage board in the control room.

The American Gas & Electric Service Corporation has rendered a great service to the world in showing that a power plant can be built to give reliable service and show an efficiency exceeding the internal-combustion engine.

In closing it should be pointed out that because this installation has been successful it does not follow that all future power plants should be designed on similar lines. The high-pressure and high-temperature station has a higher initial cost and requires greater operating skill. It is most useful where the system load factor is high. Fuel efficiency should go hand in hand with dollar efficiency.

G. B. Warren.[8] The public utilities of this country are producing about 6 times as much power now as they did during a corresponding period in the first world war. They are doing this on but twice as much coal per month. In other words, they are doing this at an efficiency of power production such that the average fuel consumption per unit of output is but one third as great as it was 25 years ago.

Such an achievement has only been possible because first one public-utility group and then another, assisted, to be sure, by the equipment manufacturers, have had the initiative to pioneer and the courage to take the risk required to make the next step in this forward march. The present result is a great tribute to the strength and power of our American way of doing things. The continued reduction in the price of electric power is evidence enough that these savings have been passed on to the consumers.

The recently announced higher powers and lower fuel consumptions of the power plants for our combatant naval vessels have come directly from the step-by-step progress of the power companies in this country.

It is true that we may be approaching the end of this progress in the steam cycle itself, but there is still probably enough in it to make considerable additional progress in the efficiency of the best stations; and the average coal consumption per kilowatthour in this country, low as it is, is still 60 per cent above that of the Twin Branch Plant.

We should not get too complacent, however. We still get out but $^1/_3$ the power inherently in a pound of coal in our best power plants, from $^1/_6$ to $^1/_4$ in our ships, and less than $^1/_{10}$ in our railway locomotives.

Additional superposed stations, more general use of higher pressures, higher temperatures, resuperheating, the mercury steam cycle, the gas turbine, and perhaps even the combination of the gas turbine and the steam or mercury cycle will permit still further progress.

The authors of the present paper can well feel proud of the part they personally have played and the part their respective organizations have played in this progress, not only in the particular achievement reported on here, but in a whole host of previous achievements in which they have both been outstanding.

The difficulties reported on the high-pressure section of the turbine, annoying as they were to the owners, have been overcome and were in reality minor in character and not in any way inherent in turbines for these steam conditions. The shaft of this turbine was designed to be smaller in diameter than had ever before been attempted for a turbine of this output, in order to reduce the packing losses at the high pressures involved. Such slender shaft machines it turned out are sensitive to looseness in the fit of the bearings in their pedestals and under such conditions are apt to vibrate when at full speed at a frequency which is about $^1/_2$ the running speed. The high temperature of the turbine casing at each end adjacent to the turbine bearings caused the bearing casings to expand and let the oil-cooled bearings loosen in the pedestals. The low weight of the turbine rotor in proportion to the work it was doing was insufficient to keep it steady. Jack bolts of 45 deg were put in as stated in the paper. When these were tightened, the vibration was eliminated immediately, thus indicating the correctness of the diagnosis. Several new bearing designs have been worked out, any one of which should preclude such difficulties on future machines to which they are applied.

Authors' Closure

It was anticipated that regardless of the efforts and skill employed during the engineering and design stages of the unit, difficulties were bound to appear. We had, however, complete faith in the soundness of our decision to proceed with a natural-circulation boiler.

The use of 4-in-diam tubes with approximately $^1/_2$-in. wall thickness more than satisfied the circulation requirements although the heavy wall thickness resulted in high furnace side-tube temperatures. This difficulty was completely solved by use of stud plates and plastic chrome ore. The corrected arrangement of surface giving temperature distribution as shown in Fig. 6 is comparable with the data presented by Mr. Armacost in his discussion of our paper. The larger tubes solved the problem of adequate natural circulation and with application of studding

[7] Consulting Engineer, Belmont, Mass. Mem. A.S.M.E.

[8] Turbine Engineering Division, General Electric Company, Schenectady, N. Y. Mem. A.S.M.E.

give heat-absorption rates and corresponding metal temperatures comparable to the results being obtained with the small and thin tubes of the forced-circulation boiler at Montaup described by Mr. Armacost.

The authors believe that the analysis of tube failures, given in detail in the accompanying paper by Messrs. Ely and Schueler, answers Mr. Bell's query as to the manner and cause of the tube failure. It is our conclusion, substantiated by facts, that this failure was produced entirely by thermally induced stresses and that there was more than adequate circulation in the tube at time of failure.

The answer to Mr. Moultrop's comment that more space should be given to control room and method of operation can be found in the series of papers on Twin Branch published in the October 18, 1941, issue of *Electrical World*.

The authors share with Mr. Warren the belief that avenues of progress are still open in the field of efficient generation of power, and that the results obtained to date offer no cause for complacency. They hope that their experience in carrying through the Twin Branch 2500-psi development will stimulate others to initiate developments to improve upon and to surpass Twin Branch.

Natural-Circulation Test Results on the 2500-Psi Twin Branch Boiler

By W. H. ROWAND[1] AND T. B. ALLARDICE,[2] NEW YORK, N. Y.

An essential requirement of the 2500-psi boiler of the Indiana & Michigan Electric Company (American Gas & Electric Service Corporation) at the Twin Branch Station was the provision of positive circulation in all heat-absorbing or steam-generating areas of the unit. The history and details of design and operation of the Twin Branch unit are given in companion papers.[3] The present paper discusses the design of a system incorporating outside downcomers feeding a lower drum, with direct supply lines to all generating circuits, and cyclone separators in the steam drum, providing centrifugal separation of steam from circulating water. Tests were conducted on a full-diameter, half-length model of this arrangement at Ohio State University. The results of studies, tests, and other considerations are discussed in this paper, as well as operating results obtained. The conclusion is reached that the provision of natural circulation in boilers at 2500-psi operating pressure has ceased to exist as a problem.

AT the time the decision was reached to build a 2500-psi natural-circulation boiler for a capacity of 550,000 lb of steam per hr at Twin Branch, the question of natural circulation for such a high pressure was thoroughly considered. After full study, the conclusion was reached that it was a sound and practical application, provided all the factors inherent in determining successful circulation were properly developed and taken advantage of. Among members of the engineering profession, the normal interest and speculation as to the ability to carry through, evidenced when boiler pressures substantially above any previously attained commercially for large-sized operating units have been proposed, was accentuated in this case by the proposal to operate on natural circulation. The reasons for this speculation are understandable since, as shown in Fig. 1, which illustrates the variation with pressure of the density of steam and of water at saturation temperature, the density differential between water and steam is only 28.4 at 2400 psi, whereas at 300 psi, this differential is 52, and at 1400 psi, it is 39.8.

The ability to circulate is a complex function of this density differential, so in order to utilize the differential that is available, it is of the utmost importance to prevent any steam being entrapped in the circulating water in the downcomers. Fig. 2

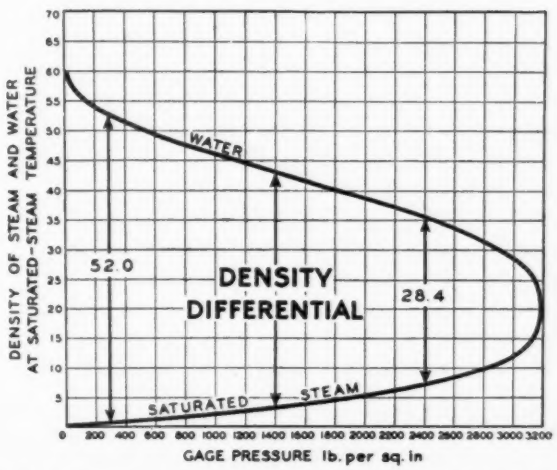

FIG. 1 VARIATION WITH PRESSURE OF DENSITY OF STEAM AND OF WATER AT SATURATION TEMPERATURE

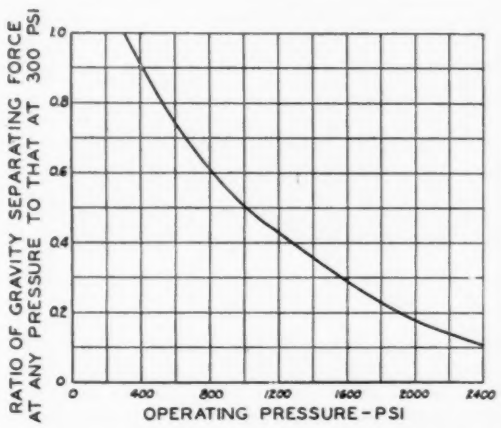

FIG. 2 GRAVITY SEPARATING FORCE ON STEAM BUBBLES IN WATER

shows the gravity separating force on steam bubbles in water at various pressures expressed as a ratio to the separating force at 300 psi. At 2400 psi, this separating force of gravity is only 10 per cent of that at 300 psi, and only 29 per cent of that at 1400 psi; therefore it is apparent that the difficulty in obtaining circulating water free of steam for the downcomers increases manyfold at the 2400-psi pressure level.

The engineers of the American Gas and Electric Service Corporation were convinced that, due to the conditions previously mentioned (Figs. 1 and 2) the over-all design should be one that assured positive circulation in all heat-absorbing or steam-generating areas of the unit. Previous experience with units of considerably lower operating pressures had shown that tube failures will result in any area of a boiler unit where sufficient circulation is not provided for in the initial design.

The design proposed by The Babcock & Wilcox Company with outside downcomers of ample capacity, feeding a lower drum,

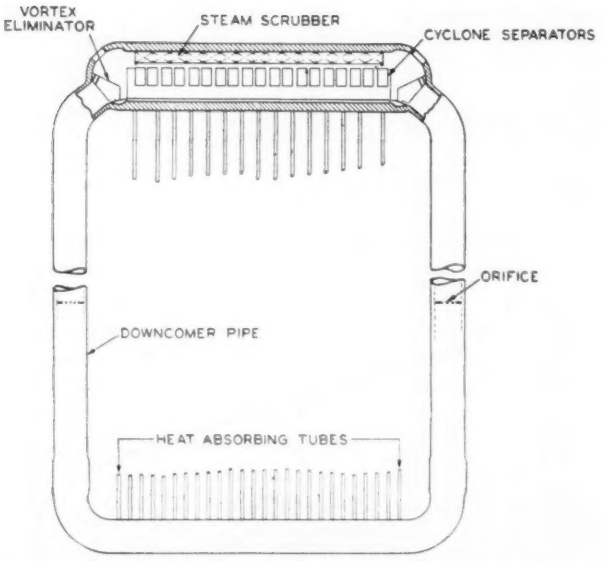

FIG. 3 FUNDAMENTALS OF CIRCULATION IN THE TWIN BRANCH BOILER

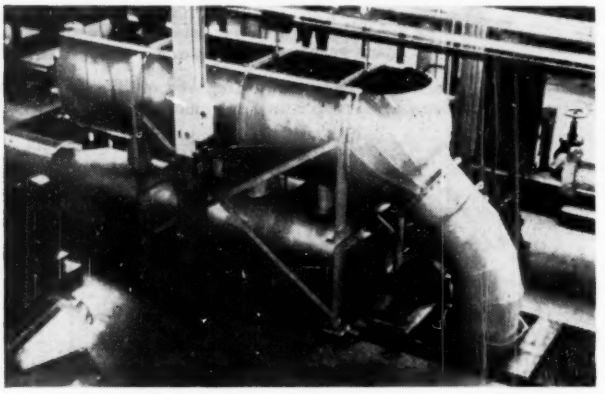

FIG. 4 FULL-DIAMETER, HALF-LENGTH MODEL OF DRUM AND DOWNCOMER PIPE FOR TEST PURPOSES

with direct supply lines to all generating circuits, and with the application of cyclone separators in the steam drum which provide a centrifugal separating force several times greater than that of gravity indicated a satisfactory unit for the conditions specified. A simplified circulation diagram of the unit is shown in Fig. 3.

It will be noted that the fundamental circulation scheme is reduced here to the simplest imaginable arrangement. It consists of a 28-in-diam downcomer pipe from either end of the 54-in-diam drum. These pipes are carried down outside the boiler setting in order to keep the resistance losses at a minimum and to prevent the generation of any steam in the downcomers. Recognizing the effect of endwise flow of the circulating water along the drum on producing vortexes at the entrance of the downcomer pipe and on water-level stability due to the hydraulic-gradient phenomenon, a full-diameter half-length model of the drum and downcomer pipe, as shown in Fig. 4, was built and tested with water at Ohio State University in order to provide the best means for preventing vortexes entering the downcomers, and to determine the range of stable operating water levels with what was considered an ample excess of circulating-water flow above the design flow of 3,600,000 lb per hr.

The actual result of all the studies, investigations, considera-

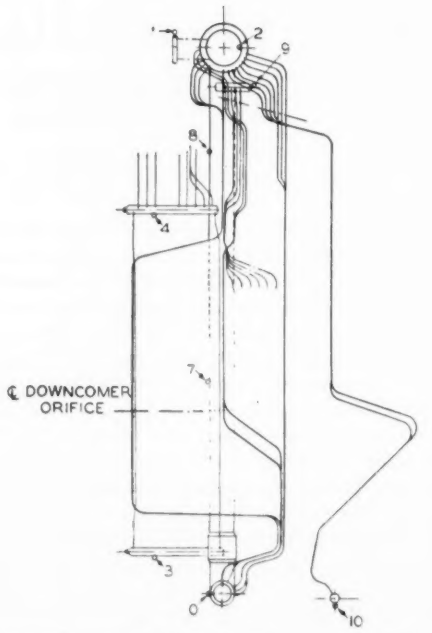

FIG. 5 STATIC-PRESSURE CONNECTIONS FOR CIRCULATION TESTS

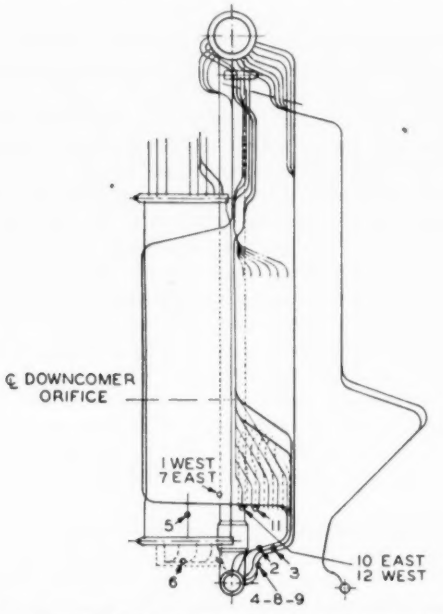

FIG. 6 PITOT-TUBE LOCATIONS FOR CIRCULATION TESTS

tions, and design decisions, as given in this paper, substantiates the judgment of those responsible for the final installation.

ARRANGEMENT OF BOILER AND TEST EQUIPMENT

During the construction of the boiler, pressure taps for measuring differential heads across the various circuits and the fluid density in the downcomers, and pitot tubes for measuring the flow in the various circuits and in the downcomers were installed. The locations of the pressure taps are shown in Fig. 5. Fig. 6 shows the locations of the pitot tubes.

When the unit was first placed into service, the steam-generating circuits were (1) the furnace front wall; (2) the first division wall and (3) the second division wall, which were

$3^1/_4$-in. partial-stud tubes on 6-in. centers; and (4) and (5) the furnace side walls which were 4-in. partial-stud tubes on 6-in. centers. The side walls of the first open pass and the side walls and rear wall of the second open pass constituted reheater surface.

During 1942, alterations[3(e)] were made on the unit in order to reduce the reheater and superheater absorptions, and to prevent the gases from cutting through between the tubes of the first and second division walls. During these alterations, the upper 15 ft of the furnace front and side walls were changed to full-stud construction, the first and second division walls were changed to 4-in. full-stud tubes, $3^1/_4$-in. sinuous tubes on 12-in. centers were placed in front of the reheater in the first open-pass side walls and a waterwall of $3^1/_4$-in. tubes on 6-in. centers was placed in front of the reheater surface forming the rear wall of the second open pass and the sloping floor at the bottom of the second open pass. A comparison of the circulation test results with both of these arrangements of heating surface will be given.

Test Results

As a matter of interest, the first time pressure was raised on the boiler, the total circulating flow in the boiler was measured at various pressures from 1100 psi to 2400 psi at a steam output of 135,000 lb per hr. The results from these tests which show the actual effect of operating pressure on the circulating flow are shown in Fig. 7, where the circulating flow expressed as a percentage of that at 1100 psi is plotted against pressure. The test data are represented by the circles and the reference curves show the ratio of the density of water at saturation temperature to that at 1100 psi; also the ratio of the density differential between water and steam at saturation temperature to that at 1100 psi. This is experimental verification of the previous statement that the circulating flow is a complex function of this density differential. This type of relationship between circulation and pressure should hold up to pressures approaching the critical provided that the downcomer circulating water is kept free of entrapped steam.

Fig. 8 shows the circulating flow determined by tests over the steam-output range for the various circuits and also the total circulation in the downcomers for the original and the final arrangements of heating surfaces. In the circulation calculations during the design stages of the boiler, a factor of safety was used in evaluating the average density over the height of the heat-absorbing risers. As shown by the results, this factor of safety was too large since the total circulating flow on the original arrangement was 5,100,000 lb per hr rather than the design value of 3,600,000 lb per hr. Due to this additional circulation, some water-level instability, as evidenced by a slow surging in the gage glass, was encountered when the gage-glass water level was lowered to a point approaching the bottom of the glass, which was 9 in. below the drum center line. When the alterations to the heating surfaces were made, the cyclone separators and the gage glasses were raised 2 in. which placed normal water level 1 in. below the center line of the drum rather than 3 in. below in order to provide additional flow area for the water along the drum.

Because of the larger-diameter tubes and the additional circulation circuits which were added during the alterations, the total circulating flow was increased to 5,500,000 lb per hr after the alterations were made. This caused some water-level instability with the gage-glass level about 4 in. below the drum center line, and the flow resistance in the downcomers was so small that unbalancing the rate of firing across the width of the boiler by cutting out burners would cause a difference of water

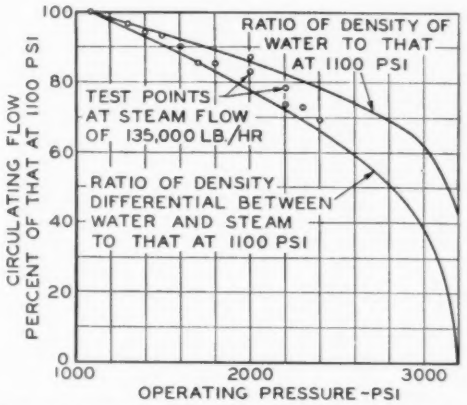

Fig. 7 Effect of Pressure on Circulating Flow

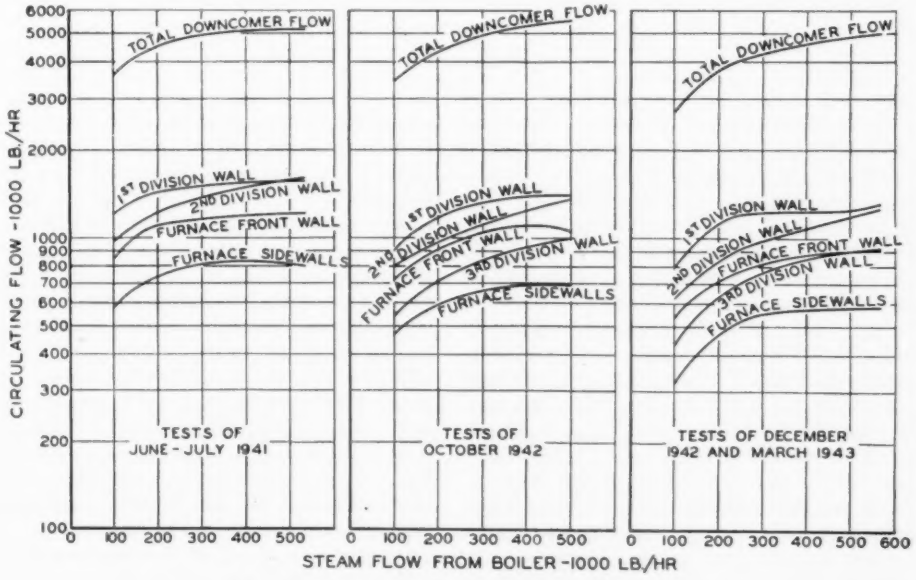

Fig. 8 Circulating Flow in Various Circuits

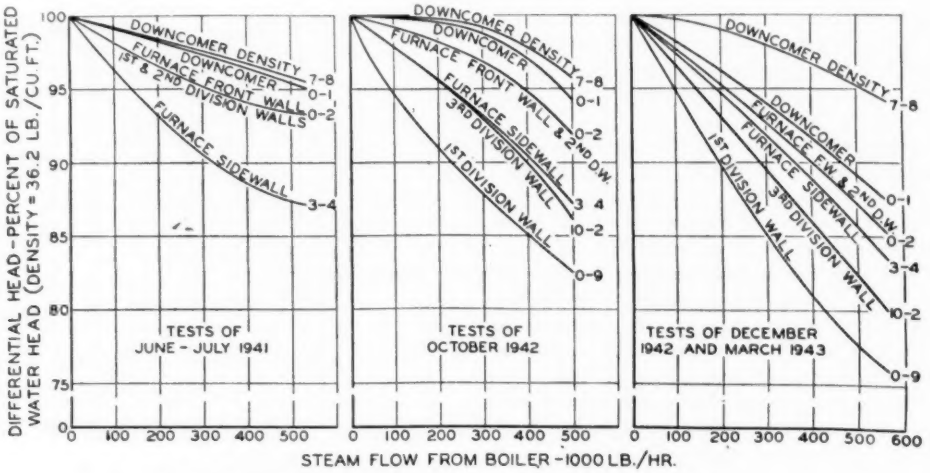

FIG. 9 DIFFERENTIAL HEADS OF VARIOUS CIRCUITS OF BOILER

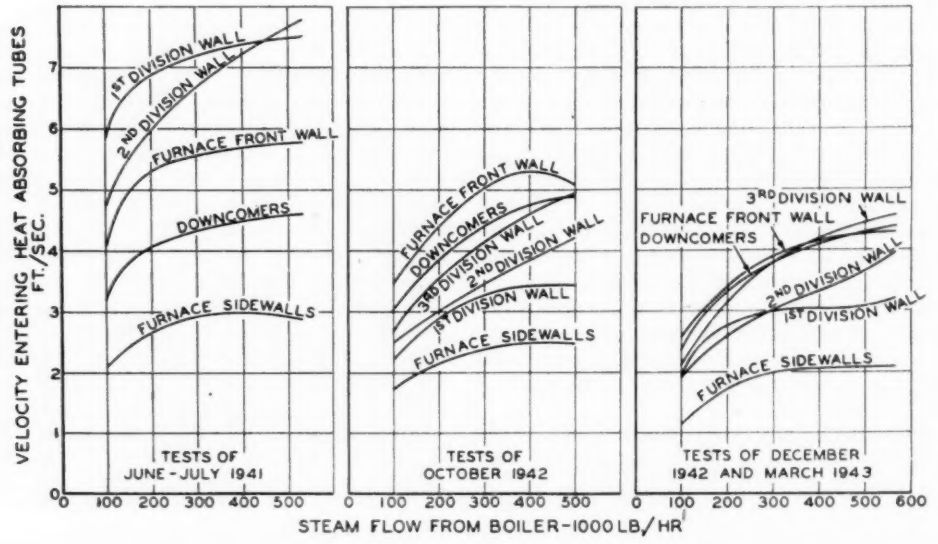

FIG. 10 VELOCITY ENTERING HEAT-ABSORBING SECTIONS OF VARIOUS CIRCUITS

level between the two ends of the drum of as much as 3 to 4 in. These two factors made the permissible water-level range between water-level instability and carry-over too small for trouble-free operation above a load of 500,000 lb per hr.

In order to correct this condition, an orifice with a $16^1/_4$-in-diam opening was placed in each downcomer during November, 1942. The results of this change are shown at the right in Fig. 8. The circulating flow was reduced to 5,000,000 lb per hr at 560,000 lb steam flow, and the downcomer resistance was increased to 2.5 ft of standard water. This change has resulted in completely satisfactory operating conditions with no water-level instability or carry-over occurring within the 12-in. visible range of the gage glass, and neither condition has occurred since this change even with load changes from 500,000 down to 350,000 lb and back again in 3 or 4 min. Water levels at the two ends of drum are always within $^1/_2$ in. of each other regardless of firing conditions.

Fig. 9 shows the differential-head test results on the various circuits in the boiler over the range of steam output. The numbers refer to those shown in Fig. 5. This is expressed in percentage of the head produced by water at saturation temperature (density equals 36.2 lb per cu ft) with no flow. The distance between normal water level and the center line of the lower drum is 68.45 ft which equals a differential head of 39.7 ft of standard water. In the case of the downcomer, the difference between the differential head and 100 per cent is a measure of the reduction of density below that of saturated water due to steam entrapment plus the resistance loss in the downcomer. The downcomer density at maximum load is about 95 per cent of that of saturated water which indicates very little steam entrapment in the circulating water even at this high pressure level and substantiates the original faith put in the ability of the cyclone separators to separate the steam and the water. The difference between the downcomer density curve and the downcomer differential-head curve is a measure of the resistance loss in the downcomers. The addition of the orifices increased the resistance loss from $1^1/_2$ per cent up to 6.2 per cent at maximum load. In the case of the heat-absorbing circuits, the differential head is equal to the sum of the average density in the circuit plus the resistance loss. The difference between the downcomer differential head and that of the furnace front wall is a measure of the resistance loss across the cyclone separators, which is only 2.6 per cent, or about 1 ft of standard water at maximum load.

DRUM PRESS.-PSI	2310	2280	2300
ORIFICES	NONE	16¼" IN EACH DOWNCOMER	

Fig. 10 shows the velocity of the circulating water in the downcomers and entering the various heat-absorbing circuits before generating any steam. The reduction in velocity between the original design and that after the alterations to the heating surfaces is the result of the larger-diameter tubes and the additional circuits. The velocities after installing the orifices range from about 2 fps to 4.5 fps entering the tubes at maximum load. It is worthy of note that the velocities increase as the rating of the boiler increases.

Table 1 gives the pertinent circulation test data for the individual circuits of the boiler, as well as a comparison of the results at 500,000 lb per hr steam flow before and after installing the orifices in the downcomers. It also tabulates these data at a load of 562,000 lb of steam per hr after the installation of the orifices. The orifices reduced the total circulating flow and the average velocity entering the tubes approximately 10 per cent at 500,000 lb steam flow and decreased the mixture steam ratio (which is a reciprocal of per cent steam by weight) leaving the tubes from 9.4 to 8.3 on the average, which means an increase in the percentage of steam by weight from 10.6 per cent to 12.1 per cent. The average percentage of steam by volume leaving the tubes increased from 39.8 per cent to 43 per cent. At the overload of 562,000 lb per hr, the average mixture steam ratio is 7.2, and on the highest-duty tubes is 5.7, corresponding to percentage of steam by weight of 13.9 per cent, and 17.5 per cent, respectively. The percentage of steam by volume on the average is 47.1 per cent and leaving the highest-duty tubes is 53.6 per cent. These values indicate a large excess of circulation and a large margin of safety in so far as any possible tube distress is concerned.

Conclusions

Since the tubes were changed to full-stud construction, the thermocouples at full load consistently show a range in temperature of the outside face of the tubes of 725 F to 785 F, which, with a saturation temperature of 655 F, indicates local absorption rates from 30,000 to 55,000 Btu per hr per sq ft.

Before this unit was placed in service, considerable public discussion had taken place in respect to excessive carry-over of boiler-water salts in the steam at this high pressure level, based upon theories advanced about steam solubility and the partial-pressure phenomenon. Actual operating experience on this boiler, however, has proved that the purity of the steam is as good as or better than the majority of the units operating at pressures of 1400 psi and below. The conductivity of the steam is consistently about 0.8 micromhos, indicating solids carry-over of about 0.5 ppm and an evaporated-steam sample showed 0.57 ppm. In the matter of turbine-blade deposits, the operating history is also as good as, or better than, the majority of the units operating at pressures of 1250 psi and below. A slow building up of stage pressure is experienced on the high-pressure machine, and this is corrected every few months by dropping the primary-steam temperature to about 750 F for 2 or 3 hr. There has been no indication of building-up in the low-pressure turbine. This experience is based upon feedwater treatment and boiler-water conditions which have been no different than in most 1400-psi boilers.

The authors believe that the successful operation of this unit at the intended operating pressure since May, 1941, and the results of the extensive testing of the boiler, give clear evidence for the conclusion that natural circulation is entirely practical and provides the necessary margin of safety for boiler-design pressures up to 2500 psi, provided that all factors inherent in the determination of successful circulation with steam generation at this pressure are considered and properly developed in the design of the unit. It may be stated that, properly handled, the problem of providing adequate natural circulation in boilers operating at pressures up to 2500 psi has ceased to exist.

Distribution of Heat Absorption and Factors Affecting Performance of Twin Branch 2500-Psi Boiler

By F. G. ELY[1] and L. B. SCHUELER,[2] NEW YORK, N. Y.

This is one of three papers,[3] describing various phases of the 2500-psi 940 F boiler with reheat to 900 F, installed in 1941, at the Twin Branch Station of the Indiana & Michigan Electric Company (American Gas & Electric Service Corporation). Details are given of the major design changes which were made from the inception of operation, and which upon completion, have permitted full rating and specified superheat and reheat temperatures to be possible for the past year. These changes were based upon extensive tests to determine heat-absorption rates and distribution of heat throughout the unit. The occurrence of failure of two tubes in the first division wall is made the subject of analysis, leading to the application of stud plates welded to tube faces with refractory packed between plates. Performance curves are given, and the conclusion is reached that further investigative work is needed to evaluate the detailed factors which combine to achieve the results.

THE Twin Branch high-pressure unit represents an unusual combination of design conditions for a steam-generating unit to produce steam at 2500 psi, 940 F and with steam reheating at intermediate pressure to 900 F. Such design requires considerable experience and skill in proportioning of surfaces which superheat the steam and those generating surfaces which precede the superheater in the setting. This is generally a critical feature of any unit because it involves a decrease in cycle efficiency if the superheat is low, or hazard to the safety of operation if superheat is sufficiently high to reach the temperature limitations imposed by available metals and alloys for pressure-part construction.

Design Considerations

The original Twin Branch design was carried out with the aid of the then current methods for determination of heat-transfer characteristics of the various cooling surfaces and with supporting data gained from actual field observations on a unit of similar arrangement operating with different fuels and with similar fuel on a short test run.

In a unit designed for these final steam requirements, it is impracticable, when firing low-ash-fusion coal, to do all of the superheating and reheating in the familiar convection-type equipment. Some limit of gas temperature entering the closely spaced tubes of a convection bank must be observed, and the amount of heat available from the gases, at 2000 F, for example, is insufficient to supply the requirements of the steam, even with perfect counterflow convection heat exchange. Furthermore, the rapidly diminishing rates of heat exchange, as the gases are cooled, would necessitate an uneconomically large extent of heating surface. In order to reach a practical balance of heat distribution to water and steam in the unit it therefore was necessary to advance the steam-heating components forward into the higher-temperature zones where heat was available and where higher exchange rates could be obtained, but with due consideration being given to the behavior and influence of fuel ash and slag.

For the design conditions obtaining at Twin Branch and with full advantage being taken of stage heat recovery in feedwater, it is shown in Fig. 1 that nearly one half of the heat absorbed in the generating unit must be by steam-cooled surfaces and that the ultimate margins of temperature between the steam and the safe metal limits are largely consumed by steam-film and tube-wall gradients. Furthermore, a careful arrangement of surfaces was necessary to maintain steam and metal temperatures as nearly uniform as possible in the parallel circuits of the various superheater and reheater sections. This called for proper location of the sections with respect to heat source, provision for uniform distribution of steam flow to the parallel circuits, and provision for mixing the partially superheated steam in a common chamber between sections to equalize any unbalance before final superheating, all within reasonable limits of pressure drop. Also, the design requirement for maintaining full superheat and reheat temperature over a substantial portion of the load range further complicated the problem since the radiant-surface characteristic is generally such that maximum metal temperatures are encountered at low flow, while the convection surface usually follows the reverse trend. In addition, there was the requirement of an adequate supply of auxiliary steam to protect the radiant-reheater sections during starting of the unit.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Initial Operating Conditions

Initial operation of the Twin Branch boiler gave immediate indication that the heat absorbed by steam, particularly in the reheater, was too great. The full temperatures of superheat and reheat were attained at approximately 70 per cent load, using all of the gas by-pass and attemperator control capacity available. This condition initiated a comprehensive field investigation which at times turned this large commercial unit into a field laboratory, but at the same time without appreciable interference with normal operation. Some of these investigations and the resulting design alterations are reported herewith.

In the original arrangement, the reheater surface included exposure of the side-wall area of the first and second open passes, as well as the roof and rear wall of the second open pass, and the sloping floor of the cavity under the convection pass. The final-stage superheater likewise had a greater area of exposed surface by extended arrangement of the platen tubes instead of the grouping as now disposed.

Temporary alterations were made immediately, consisting of applying a gunnited refractory coating to the side-wall reheater tubes, covering one half of the surface of the reheater hopper slope, closing alternate gas lanes in the primary-reheater convection bank with refractory concrete, and increasing the capacity of the attemperator spray nozzles. These changes permitted operation up to 80 per cent of full capacity without exceeding safe tube and steam temperature; some advantage being gained by running with lowered excess air and by overattemperation in the superheat cycle to produce steam temperatures lower than design level in order to lower the temperature of steam returned to the reheat cycle, since the reheater proved to be the most critical portion of the heating surface.

The unit was operated for several months in this condition for the purpose of gaining experience, pending delivery of materials for the projected rearrangement of surfaces.

Test Investigations

Tests were run to obtain data on heat-absorption rates and distribution of heat throughout the unit, and particularly in the furnace and open passes where high gas temperatures prevailed and where important increments of steam-heating surface were present. Several tests were run using water-cooled high-velocity-thermocouple and gas-sampling tubes for complete traverse of the gas stream at successive sections of the unit, from which data the corresponding increments of heat absorption could be calculated. Daily routine test readings were taken of the flow and temperature rise in each section of the superheater and reheater systems, using each section as an independent calorimeter. These data afforded a valuable basis for determining the extent to which final reproportioning of surfaces would be necessary. The circumstance that all of the steam-generating surface of the boiler was in the primary furnace and open passes provided a unique comparative means of measuring and evaluating heat-absorption rates by two independent methods.

Significant data from these test investigations are shown in Figs. 2 to 5, inclusive. The evaluation of heating surfaces is based upon projected areas of exposed wall and platen arrangements, but with inclusion of the complete circumferential areas of spaced tubes in the furnace-outlet screen and in the convection screen and tube banks. In the case of Fig. 2, the gas temperatures were obtained from special test traverses with the high-velocity thermocouple. In Figs. 3 to 5, inclusive, the plotted points represent "daily-test" values of heat-absorption rate of the different components of steam-heating surface, determined by the calorimeter method, and in Fig. 5, comparative points are shown for the eight special tests, calculated on the gas-heat basis.

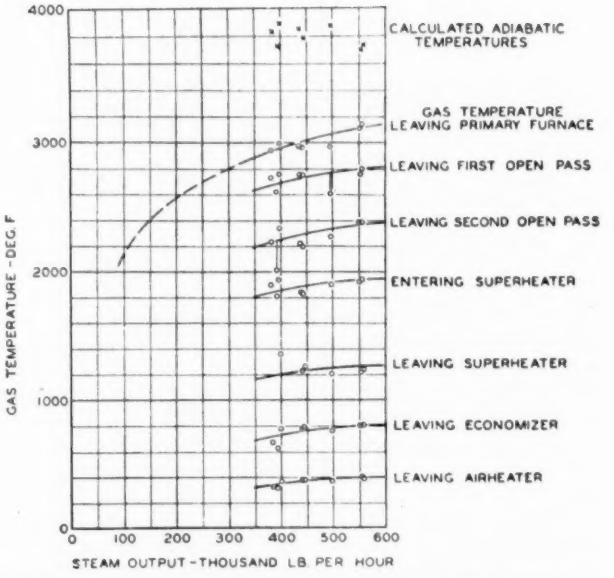

Fig. 2 Gas Temperatures at Various Sections of Boiler Unit as Measured by High-Velocity-Thermocouple Traverse

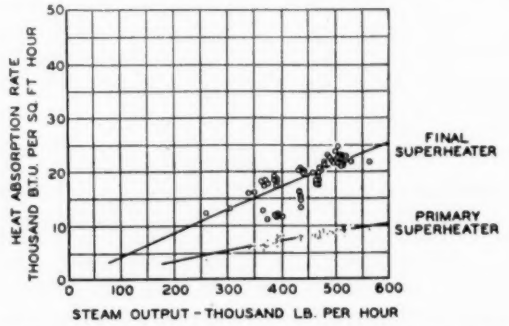

Fig. 3 Heat-Absorption Rates of Primary and Final Superheater

It will be noted from Figs. 3, 4, and 5 that individual absorption rates at a given load show considerable variation in day-to-day operation. Cumulative data to the outlet of the second open pass indicate that these variations are to some extent self-compensating, as evidenced by the greater uniformity of points shown in Fig. 5. Gas-flow control in the convection sections, and attemperator control of superheated steam provide the necessary supplementary compensation for production of uniform final steam temperature.

The cumulative absorption rates at the second open-pass outlet show a close agreement between daily calorimeter test and high-velocity-thermocouple test methods. It is difficult to carry a similar comparison forward to the primary-furnace and open-pass individual sections of the unit. However, some confirmation of the HVT test values is afforded by other means of testing that were applied.

Fig. 6 shows the absorption rate of a portable water-cooled thermal probe inserted for a distance of 5 ft through an inspection door in the lower part of the primary furnace. When the probe was first inserted a high absorption rate was obtained, which diminished to a value of approximately 48,000 Btu per sq ft per hr as slag accumulated on the probe surface to a condition of equilibrium thickness. Slag was then removed, the probe was reinserted in the furnace and was kept clean by repeated scraping for a short interval of time in order to measure

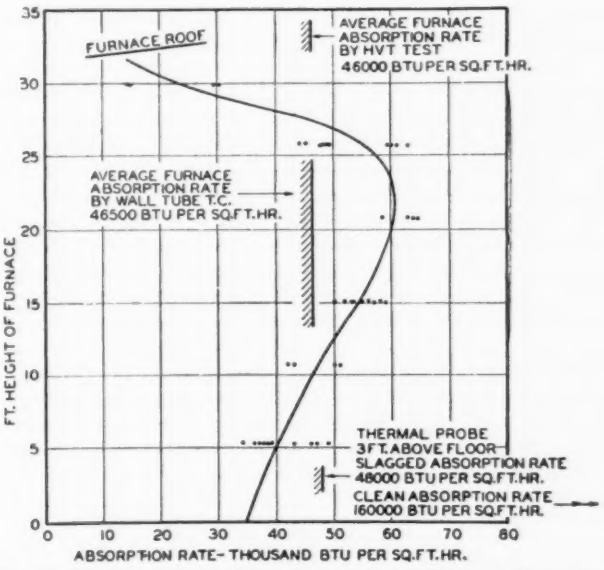

FIG. 7 DISTRIBUTION OF HEAT ABSORPTION IN PRIMARY FURNACE, AS INDICATED BY WALL-TUBE THERMOCOUPLES AND OTHER TESTS AT 570,000 LB PER HR STEAM-OUTPUT RATE

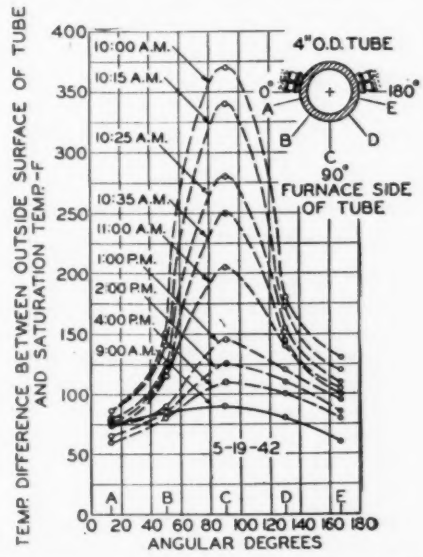

FIG. 8 DISTRIBUTION OF TEMPERATURE IN FURNACE-WALL TUBE, SHOWING EFFECT OF SLAG REMOVAL FROM BARE TUBE SURFACE

the comparative clean absorption rate under identical furnace conditions. This was found to be approximately 160,000 Btu per sq ft per hr. The relation of slagged to clean absorption rate was 30 per cent.

Fig. 7 represents a plot of equivalent heat-absorption rates as calculated from furnace wall-tube temperature data obtained from special thermocouples installed at 21 distributed points of the front-wall and side-wall furnace tubes. By utilizing the temperature differential between tube-surface temperature and saturation temperature, and assuming negligible inner surface resistance to heat flow (which condition has been convincingly demonstrated for tubes with positive circulation), it has been possible to calculate equivalent values of local heat-absorption rates which reveal an interesting pattern of the distribution of heat in the furnace. The average of 46,500 Btu per sq ft per hr compares rather closely with the value of 46,000 for the over-all

furnace, as determined by gas-temperature test methods, and the value of 48,000 shown by the slagged thermal probe.

An example of the influence of slag on local heat-absorption rates and metal temperature of bare furnace wall tubes is shown in Fig. 8. This plot represents a series of readings taken from thermocouples installed at five points around the circumference of a tube in the left side wall of the primary furnace, at elevation 15 ft above the furnace floor. It will be noted from Fig. 7 that this is near the zone of maximum heat intensity. Shortly after 9 a.m. a sudden increase in tube temperature was observed, and inspection showed that the fused slag coating on the tubes in this area had peeled or crept away, leaving tube surfaces exposed directly to furnace radiation. The sudden increase of 280 deg is equivalent to a gain in heat-absorption rate from approximately 40,000 Btu per sq ft per hr at 9 a.m. to 160,000 Btu per sq ft per hr at the 10 a.m. reading for the local area affected by loss of slag protection. In the course of the next 6 hr, the tube returned to lower temperatures as the slag coating was restored by the normal process of accumulation in the furnace.

Analysis of Tube Failures

One practical significance of this occurrence becomes evident in considering the causes which led to the failure of two tubes[3(a)] in the upper portion of the first division wall. These failures were located on the furnace face of the tubes and occurred during the period when alternate tubes were omitted from this portion of the wall, allowing furnace gases to short-circuit into the upper part of the first open pass.

Fig. 9 shows the calculated pressure stress and the combined pressure and thermal stresses for a Twin Branch primary-furnace division-wall tube of $3^1/_4$ in. OD and 0.500 in. thickness, plotted as a function of heat-absorption rate. The ultimate, yield, and proportional-limit stresses for the material involved are also shown. The pressure and thermal stresses shown are those which obtain in the form of tension at the inner fiber of the tube. It is indicated that absorption rates of the order of 75,000 Btu per sq ft per hr may result in combined stresses in excess of the yield point of the tube involved.

It was established that slag peeling in certain portions of the primary furnace, particularly where both radiation and convection heat exchange were imposed on the tube, could result in absorption rates as high as 200,000 Btu per sq ft per hr. A gradual increase in absorption rates to such a level would probably be less harmful than a sudden increase, since the full temperature stress would not be realized due to creep permitting considerable "relaxation." However, with sudden peeling of slag, and exposure, it is probable that the full elastic properties of the material were retained long enough to develop the full elastic stresses so that the yield stress was exceeded.

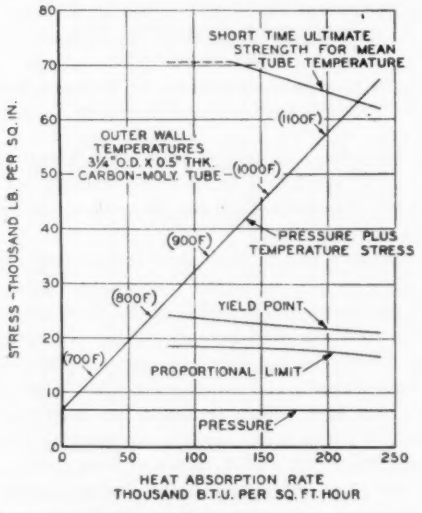

Fig. 9 Calculated Tube-Wall Stress at Various Rates of Heat Absorption

Although analysis indicates that the ultimate stress was probably never reached, as a consequence of thermal stress, the fact that failures did occur can probably be explained by the results of careful laboratory examination of the failed tubes. These showed that the areas surrounding the failures were bulged and the microstructure indicated that the outer portion had been subjected to temperatures as high as 1600 F and the inner wall had been appreciably higher than saturation temperature. Examination also showed oxide deposit inside the tube in a small area around the ruptured zone, and measurements showed that appreciable thinning of the original wall was produced at the immediate line of rupture. The conditions surrounding the failures, that of internal-corrosion attack, blistering, and apparent rupture due to hoop stress in excess of the ultimate strength, could not be logically ascribed to inadequate circulation as is sometimes the case for such occurrences since later tests established the adequacy of circulation in these circuits.

Existing instrumentation in the form of a hydrogen recorder, for continuous sampling and analysis of feedwater and saturated steam, gave positive evidence of the corrosion phase involved in these tube failures. In one case this record showed a progressive rise of hydrogen evolution in the boiler to high levels during a

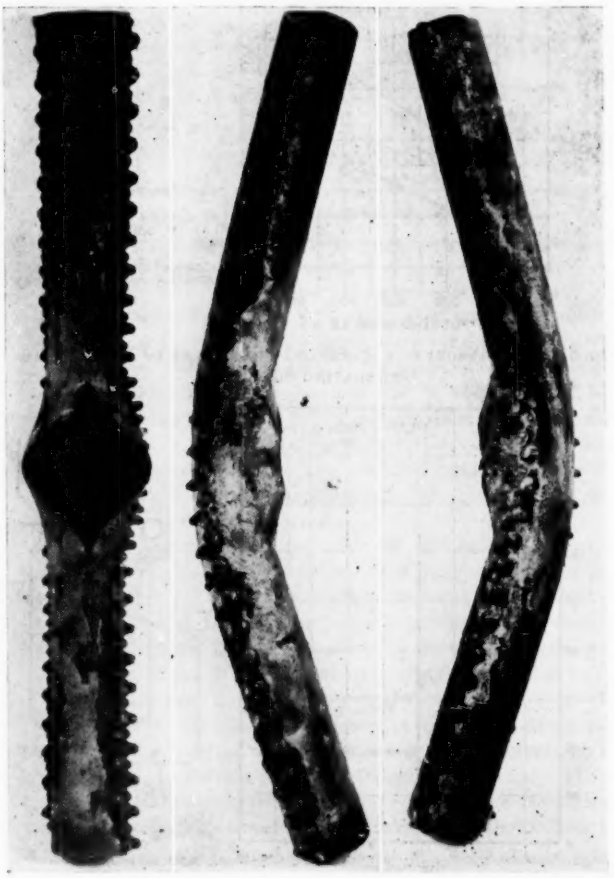

Fig. 10 General Appearance of Ruptured Tube, Showing Three External Views

period of two and one half hours immediately preceding the rupture.

A probable logical sequence of conditions leading to ultimate rupture of the tubes has been established as follows:

1 Peeling off of slag exposing the bare tube to concentrated radiant and convection heat transfer, resulting in sudden thermal stress and normal pressure stress, combining to exceed the yield point at the inner fiber of the tube.

2 Slight permanent "stretch" of inner fibers, producing a small blister in which formation of a steam film leads to corrosion attack which produces an oxide layer in the affected area.

3 Recurrent or continued exposure of this zone, producing overheating and further blistering of the area with ultimate rupture due primarily to pressure stress in excess of the ultimate strength at the temperature attained.

The foregoing record of hydrogen evolution indicates that this sequence probably was completed within the $2^1/_2$-hr period described.

The appearance of one of the ruptured tubes is shown in Fig. 10. A closer view at the point of rupture is shown in Fig. 11. Initial failure occurred in a length of approximately $2^1/_2$ in. and developed further as a tear for a total length of 7 in. along the tube.

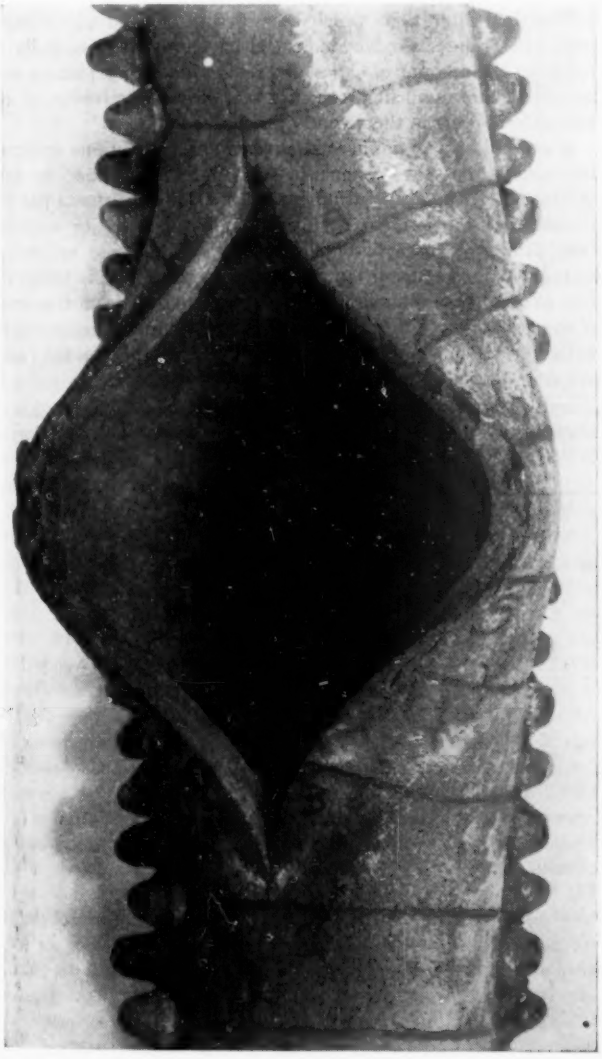

FIG. 11 CLOSE-UP VIEW OF RUPTURED TUBE, SHOWING APPEARANCE OF FRACTURE

The presence of oxide scale on a small area of the inner surface, as well as a measurable thinning of the tube wall and enlargement of tube circumference, indicated the existence of an initial blister. Characteristics of the main fracture, however, are those of an elastic failure, and the presence of numerous small cracks close to the line of rupture indicate that parting of the metal occurred first in the outer surface of the tube as a result of hoop stresses exceeding the ultimate strength of the metal at the temperature attained. The absence of knife-edge fracture would seem to exclude the probability of general overheating such as would be expected under conditions of low water or restricted circulation.

There are three likely alternatives for overcoming the difficulty described. These are as follows:

1 The use of smaller-diameter tubes with corresponding decrease in thickness in accordance with Boiler Code rules. This would produce lower thermal stress at a given heat-absorption rate, but at the expense of circulation efficiency.

2 The use of thinner wall tubes of the same diameter provided sanction of Boiler Code authorities could be obtained.

3 Application of a protective covering to the existing tubes which would prevent direct exposure of bare tubing in case of slag peeling, but would withstand action of temperature and slag conditions prevailing.

The first two of the foregoing alternatives were impractical, since the Twin Branch unit was already built and operating and could not be spared for any such major alterations if they had been considered preferable. Alternative 3 was the only one seriously considered as satisfactory and practical. The application of stud plates welded to the tube face at intervals with refractory material packed between plates had given satisfactory performance on numerous other installations under severe operating conditions. Furthermore, experiments with thermocouples on adjacent bare and covered tubes in the primary furnace of another unit[4] had demonstrated the effectiveness of the stud-plate construction as a protection against ex-

[4] "Studies of Heat Transmission Through Boiler Tubing at Pressures From 500 to 3300 Pounds," by W. F. Davidson, P. H. Hardie, C. G. R. Humphreys, A. A. Markson, A. R. Mumford, and T. Ravese, Trans. A.S.M.E., vol. 65, August, 1943; see discussion by F. G. Ely, pp. 580–581.

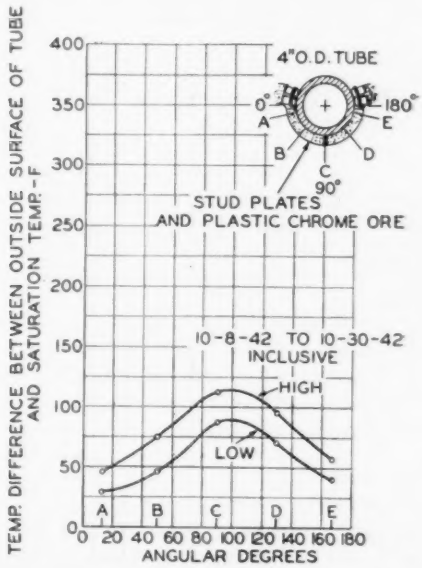

FIG. 12 DISTRIBUTION OF TEMPERATURE IN FURNACE-WALL TUBE FOLLOWING APPLICATION OF STUD PLATES AND CHROME ORE

cessive localized change in heat-absorption rates across the tube wall.

As a part of the final alterations of the unit, stud plates were applied to the upper 15 ft of primary-furnace-wall tubes to provide protection of the pressure parts against this capricious behavior of slag in the hotter zones. A comparative pattern of tube-temperature distribution at the same location after installing stud plates is shown in Fig. 12. It is apparent that the temperature differential between the outer tube surface and saturation is as great as for the slag-covered bare tube of Fig. 8, indicating that normal heat-transfer rates are substantially equal for the two types of surface. However, there has been a consistent absence of sudden temperature changes as a result of greater permanency of the protective tube covering.

Slag Characteristics

Slag is without question the greatest single factor causing variation and disturbance in the performance of the absorbing surfaces. The extent and thickness of coverage are affected by composition of the coal ash, by segregation effects within the furnace, by excess air and the nature of the furnace atmosphere, and of course by change in temperature of slag particles and gases in their passage through the unit.

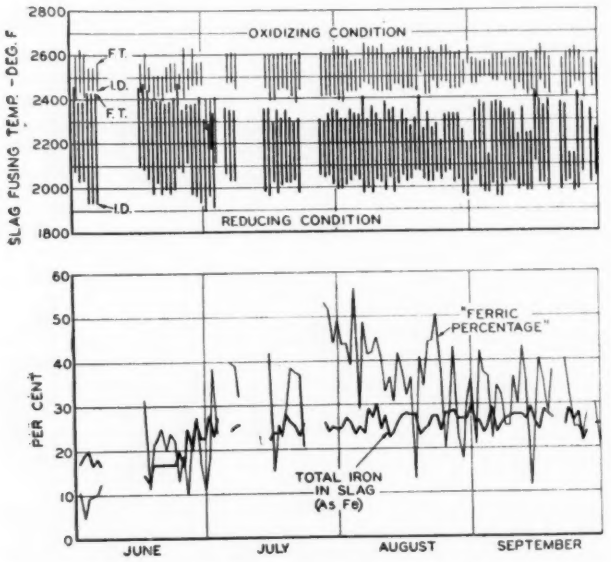

Fig. 13 Properties of Slag From Furnace Tap, Daily Samples

Samples of slag, collected daily from the tap stream, have shown appreciable variations in fusing characteristics and in the state of oxidation of the iron content, as shown in Fig. 13. Other samples collected from different portions of the unit show significant diversities of composition and fusing-temperature range as plotted in Fig. 14. It is apparent that the effect of iron, which in its ferrous form acts as a dominant fluxing agent, is materially altered both by segregation of quantity and state of oxidation, in passage through the unit.

A proper evaluation of these influences is of great importance to the balancing of heat-absorbing surfaces. Adequate range of temperature control, and means for removal of slag from critical zones are important to continuous operation of the unit within narrow limits of steam temperature, and permissible rates of steam-temperature change.

Final Alterations and Performance

The final alterations which have permitted continuous base-load operation since November, 1942, consisted principally of reducing the amount of exposed surface in final superheater and in intermediate and final reheater sections and provision of retractable blowers in the second open pass.

A general survey of thermal performance conditions existing throughout the unit is shown in Fig. 15, as determined by test of May 14, 1943, at an output rate of 570,000 lb of steam per hr. Considering the unit to be divided into seven major sections (viz., primary furnace; first open pass; second open pass, and so on, as indicated), the upper curve shows the values of gas temperature at exit from each section and was determined from traverses of the gas stream, using the shielded high-velocity thermocouple, with corrections made to the basis of the multiple-shielded high-velocity thermocouple[5] (MHVT).

[5] "Gas Temperature Measurement and the High-Velocity Thermocouple," by H. F. Mullikin, *Temperature*, Reinhold Publishing Corporation, New York, N. Y., 1941, pp. 775–804.

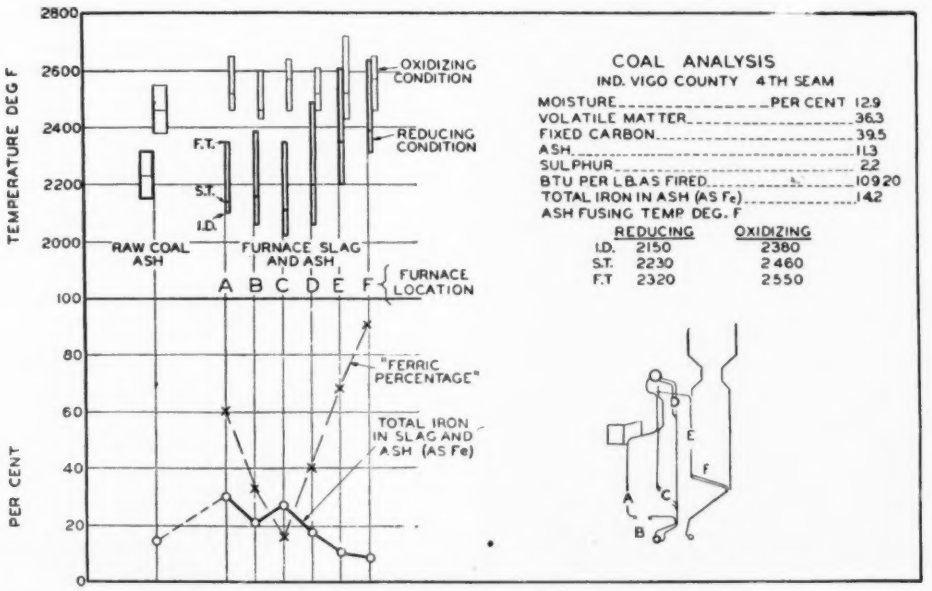

Fig. 14 Properties of Slag From Various Locations in Furnace

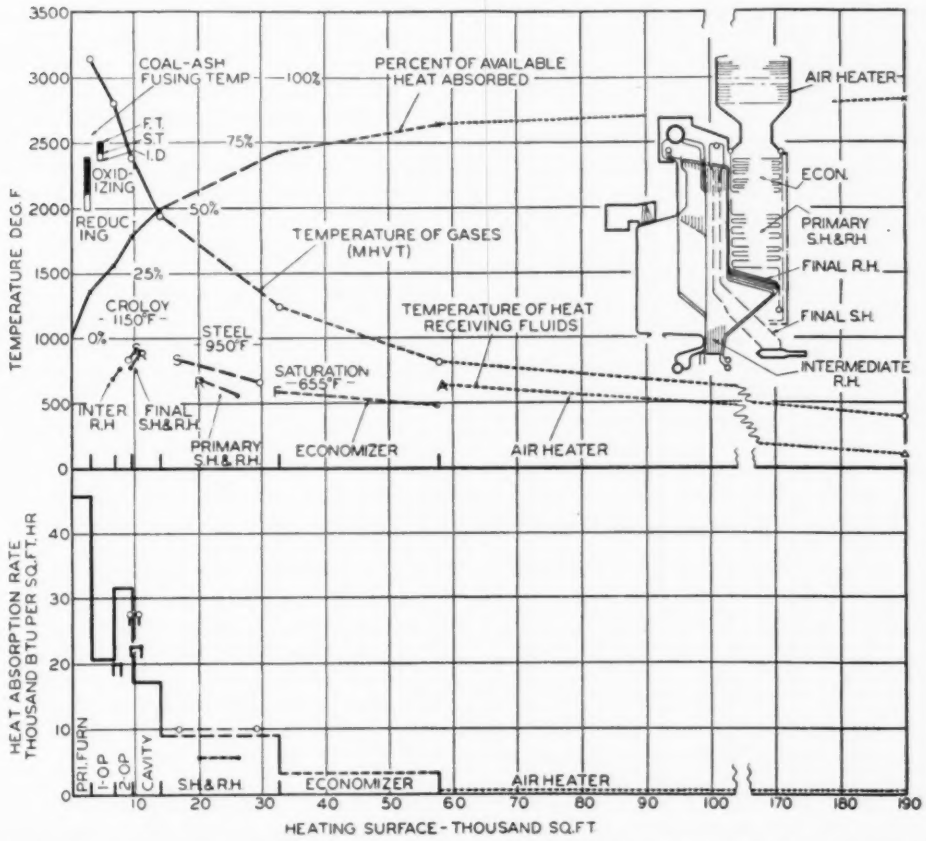

FIG. 15 GENERAL SURVEY OF THERMAL PERFORMANCE CONDITIONS AT 570,000 LB PER HR STEAM-OUTPUT RATE

In relation to this curve of gas temperature, there are shown for each section of the unit the corresponding temperatures of the heat-receiving fluids in the air heater, economizer, superheater, and reheater, and the respective limiting metal temperatures. The difference in temperature between gases and receiving fluids is a basic measure of the available potential for transfer of useful heat.

On the lower portion of the chart is a plot of heat-absorption rates, calculated by familiar methods for each individual section, from the data on gas weight, specific heat, and temperature drop in that section. The area under this curve is proportional to the total quantity of heat absorbed per hour, and it is clearly indicated that those sections of the unit, which are located in the higher temperature zones, account for a major part of the total absorption, and are functioning at high specific rates.

It is somewhat difficult to show in simple graphic form the different categories of heating surface which co-exist in individual sections of the unit. For example: The second open pass contains water-cooled generating tubes in the front and rear division walls, reheater tubes forming the side walls, and superheater tubes in platen grouping, which extend from top to bottom of the pass and also across the cavity section. Some liberties have therefore been taken to represent those portions of the steam-heating circuits individually, at their approximate location in the temperature field. Heat-absorption rates shown for these circuits have been measured independently of the gas-temperature method by calculation based upon steam-flow rate and temperature gain. The indicated rates are quite consistent with those shown for the total surface of the section.

Heat-absorption rates of the primary furnace and first open pass are based upon the assumption that combustion is completed before the gases leave the primary furnace. Recent data obtained from sampling of the gas stream at the furnace outlet and first open-pass outlet by means of water-cooled fly-ash samplers, indicate that a certain proportion of solid carbon is present at the exit of the furnace and is consumed in passage through the first open pass. Quantitative determinations in terms of hourly heat equivalents are extremely difficult to make; however, it is estimated that this item may justify a revision of approximately 5000 Btu per sq ft per hr decrease in the furnace absorption rate, and a corresponding increase of 4000 Btu per sq ft in the first open pass, as compared to the values shown in Fig. 15.

SUMMARY AND CONCLUSIONS

Sustained operation at full load since March, 1943, adequately confirms the fact that the functional design features of the various component parts of the Twin Branch unit have been substantially fulfilled. In brief, these are represented by the following:

1 A primary furnace with high heat-release and absorption rates, forming a chamber for effective combustion and the collection and removal of slag over a wide load range.

2 The first open pass, comprising an open channel in which gases and slag can be cooled through the critical "sticky" ash range but with much lower absorption rate.

3 The second open pass consisting of an open channel with widely spaced superheater platens in which surfaces are kept reasonably clean by mechanical blowers supplemented by some hand-lancing with resulting high absorption rate, thus reducing the gases and ash particles to a safe level before entrance to the convection passes.

4 The convection passes in which closely spaced tubes are utilized to accomplish the remaining work and in which mechanical blowers are fully effective for cleaning.

It is brought out more fully in one of the companion papers[3(a)] that the Twin Branch 2500-psi boiler, after undergoing some major design alterations, based upon the investigations and studies reported herein, has been in a position to operate for the past year at full rating and specified design superheat and reheat temperatures, and with continuity of performance hardly exceeded by any known 1500-psi boiler unit.

From the standpoint of broad boiler-design principles the following conclusions are clear from the Twin Branch experience: Boiler design in the high-temperature portion of a unit of the type under discussion is still far from being a precise and formulated science. It is not surprising that this should be true in view of difficulties in measurement of high gas temperatures and quantitative determination of the insulating effects of ash and slag. It is also clear that no single "bull's-eye" test can be expected to establish a complete criterion of performance, and that the range of day-to-day variation in operating condition must be adequately explored and appreciated in order to provide satisfactory margins of control.

In more conventional installations, where only steam-generating surfaces are involved at the forward part of the setting, self-compensating influences tend to iron out the variations which accompany change in fuel, excess air, and even change of human factors, so that the exacting tolerances of superheater and turbine are easier to meet. Nevertheless, there are many such installations subject to chronic or occasional operating hardship due to unbalanced distribution, abrupt shedding of ash and slag from heat-absorbing surfaces or limitation of operating range and stability.

In the Twin Branch unit the performance of "calorimeter sections" provided a direct yardstick measurement for proceeding with confidence upon final major alterations. Unusual opportunity was afforded for comparative measurements by other methods applicable to all types of units, and establishment of calibration criteria which permitted a more complete accounting of the absolute heat content of the gases. The authors feel that the work at Twin Branch has contributed material progress to that practical accomplishment.

Further investigative work is needed to evaluate the detailed factors which combine to produce an over-all result. The comprehensive program, sponsored by the Special Research Committee of the A.S.M.E. for resolving this problem is an important step leading to the design of better boilers.

Discussion

M. K. Drewry.[6] That more heat is actually absorbed in the superheater and reheater of the Twin Branch boiler unit than in the boiler, as shown by analysis of Fig. 1 of the paper, is significant in this consideration of heat-absorption distribution and steam temperature control.

More than normal slag insulation of tubes before the reheater and superheater reduces the pounds of steam generated and simultaneously increases the total Btu for superheating and reheating. Thus a powerful combination of two vital circumstances works toward high steam temperatures. The paper is replete with data showing unusually wide heat-absorption variations as far back as the primary superheater. It is thus logical that base-load operation, with uniform coal, greatly facilitates operation.

For steam conditions approaching those at Twin Branch, superheaters disposed in the furnace and in the boiler passes, both alongside enough water-tube surfaces so that superheating and evaporating heat-absorption will always vary proportionally, seem more practical for normal load and coal variations.

The paper does the power-generation industry a real service in evaluating the wide variations in furnace heat-absorption rates that may occur in actual practice. Its authors deserve commendation for their clear and complete presentation.

H. F. Mullikin.[7] The extensive gas-temperature measurements on this unit, as shown in Fig. 2 of the paper, are of interest. In spite of the considerable variation in furnace conditions due to different excess-air values, varied slag-fusion temperatures, etc., the gas temperatures are very uniform. The maximum variation of primary-furnace-outlet gas temperature from the mean-line value of 3070 F at 500,000 lb per hr steam flow (shown in Fig. 2) appears to be only 100 F which is a difference of 100/3070 or 3.3 per cent based on the Fahrenheit scale. Referred to room temperature the difference would be but slightly larger.

If the results are transformed to the heat-transfer basis of Fig. 5, the maximum difference of 5000 Btu per sq ft hr from the mean-line value of 48,000 Btu per sq ft hr at 500,000 lb per hr steam flow is 5000/48,000 or a little over 10 per cent.

It would appear that heat-absorption rates in a furnace vary considerably more than do furnace-outlet temperatures. A possible explanation might be that excess-air variations affect calculated heat-absorption rates more than they affect measured furnace-outlet gas temperatures.

W. T. Reid.[8] Further application of the method of determining furnace efficiencies by use of the high-velocity thermocouple, as reported by the authors, is encouraging in extending the use of this tool in furnace testing. Earlier reports on its application were received with some skepticism because of the many difficulties experienced in the past in maintaining rare-metal thermocouples at high temperatures in an atmosphere that at times may be strongly reducing. That the authors continue to use the instrument is proof enough that the inherent problems in its design have been solved. The unusually close agreement between heat-absorption rates in the primary furnace, computed by the temperature gradient through wall tubes, as measured with embedded thermocouples, and by the high-velocity thermocouple should be of extreme interest to anyone contemplating further study of the flow of heat in furnaces. The ability to use such data to modify the unit described with resulting improvement in its performance characteristics is encouraging.

Although obviously this paper is not a description of experimental methods, some questions as to technique are indicated.

With reference to Fig. 7 of the paper, the authors state that the wall-tube thermocouples were installed at 21 points distributed between the front and side walls. Inasmuch as there is considerable variation in the rate of heat transfer from point to point within the furnace, it would be interesting to know the actual positions in which these relatively few thermocouples were placed so that they were capable of averaging the heat absorption in the entire cavity; statistically it would appear that many more temperature points would have been required to give concordant results.

Also, the use of the thermal probe near the bottom of the furnace, as shown in Fig. 6, is less readily acceptable as a measure of the average rate of heat absorption in the primary furnace. It is suggested that the observed absorption of 48,000 Btu per sq ft per hr at a point 3 ft above the floor was approximately the minimum rate that could have been obtained with the probe in the primary furnace, and that, if the probe had been inserted at a higher position in the furnace, a greater rate of absorption would have been found. Fig. 7 supports such a belief. The many factors affecting the heat absorbed by the probe, including its position where it could "see" the walls of the first open pass and possibly the cold tap hole, and the fact that it projects into the gas stream, increasing the proportion of heat transferred by conduction as compared to the wall tubes, would indicate that the observed close correlation between it and the other methods occurred purely by chance. If the probe was used at other positions, also, it would be interesting to learn how its heat-transfer rate compared with that of the embedded thermocouples.

This paper includes interesting observations on the effect of slag deposits upon the rate of heat transfer, well exemplified by Figs. 6 and 8. For comparison purposes it would be desirable to know both the thickness of slag on the probe and on the wall tubes, the probe when slagged showing 30 per cent of the heat transfer when it was clean, whereas 24 per cent was found with the wall tube of Fig. 8. In addition, knowing the thickness of the two slag deposits, if the conditions in the furnace remained constant over the slagging period, it would have been possible to compute the over-all conductivity factor for this coal-ash slag. At present no such data are known to be available in the literature.

The authors' remarks relative to the importance of slag in affecting the performance of heat-absorbing surfaces are well taken. Our knowledge of the fundamental properties of coal-ash slags is increasing but slowly because of the complexity of the systems involved, but data already available can be used to good advantage in explaining actions hitherto considered obscure. However, it has been found that knowledge of the composition of slag is absolutely essential for any real understanding of its behavior at high temperatures, and it is hoped that the authors will include in their closure the complete analysis of the ash of Fig. 14, as well as that of the samples of slag taken from various positions in the unit. The reported change in iron content is most interesting in showing the pronounced segregation in this furnace; but the other constituents, particularly silica and lime, are also important in any comparison with other units burning coal having different ash characteristics.

The authors' statement that iron in the ferrous form is a dominant fluxing agent is correct, but in the ferric state it is equally effective at the higher temperatures where the slag is a true liquid. Thus the sole effect of a decrease in ferric percentage caused by reducing conditions is to lower the temperature where the slag is converted from a liquid to a plastic material during slow cooling, that is, the range of temperature where the slag behaves as a liquid is greater under reducing conditions than when the atmosphere is oxidizing. At higher temperatures, change in ferric percentage has little or no effect upon the flow properties of the slag.

Authors' Closure

Mr. Drewry's comment, indicating the desirability of intermingling the generating and superheating surfaces, so that variations in heat absorption, caused by change of slag characteristics, would be proportional between the two classes of surface, is of basic interest and deserves consideration in furnace design. To some extent this feature was embodied in the Twin Branch unit where the first open pass contained both generating and reheating surface, and the second open pass contained generating, superheating, and reheating surface, arranged to form the individual walls of the section. Slag formation on these areas was not always similar, and it is doubted that important compensation was realized.

To carry the principle of surface dispersion farther, to the point of installing alternate generating and superheating tubes in a single wall, would entail difficult structural problems in providing for unequal expansion and for possible warping of superheater elements. Individual tubes, offset from the wall, are likely to acquire different degrees of slagging and to exert an opposing influence upon the slagging of near-by surfaces.

In view of the great difference of inner-boundary resistance between evaporating and steam-cooled tubes, it would not be practical to operate superheater surface at the high values of absorption rate which are normal for the primary furnace of a slag-tap unit, and local shedding of slag would probably be disastrous. Furthermore, such exposed superheater surface in a primary furnace would require a starting and initial operating procedure of long duration to prevent overheating of tubes until they acquired their normal protective coating of slag.

For the case of a dry-ash furnace having lower normal absorption rates and operating below the fusing-temperature range of the ash, it would seem that no natural equilibrium thickness could be expected, although some compensating effect might be obtained as a result of circumstance or of deliberate wall-cleaning practices. Direct experience with a dry-bottom unit, having radiant superheater surface in one wall, indicates that load variations result in considerable unbalance in ash coverage of the generating and superheating surfaces, and consequent rapid fluctuations in steam temperature of considerable magnitude, which are difficult to predict and control and require considerable operating attention in the way of burner adjustments and wall-cleaning. The need for positive means of controlling steam-temperature fluctuations still appears to be an important requirement, particularly for extremely high-temperature designs where tolerances between steam and allowable metal temperature limits are small.

Dr. Mullikin's remarks are appreciated in that they call attention to the phenomenon of apparent consistency in furnace-outlet-temperature values in spite of variations in excess air, and heat-absorption rates. This also has been observed in tests of gas- and oil-fired water-cooled furnaces in which the slagging influence was at a minimum, and where a large increase of excess air, admitted at the burners, caused little or no corresponding decrease in measured furnace-outlet-gas temperature, although the calculated heat-absorption rates were definitely lowered.

Both temperature and heat-absorption-rate criteria are significant in the performance of the unit and must be in functional agreement; which of course it is our endeavor to comprehend. The authors question his use of the Fahrenheit zero as a proper basis for comparing the percentage variation in temperature with percentage variation of furnace heat-absorption rates.

If it be accepted that heat exchange is dependent upon temperature difference between source and receiver, one might consider 2320 F ash fluid temperature, Fig. 14, as an approximate wall-surface temperature and a more suitable base for comparison. Disregarding, for simplicity, the fourth-power function or the existence of a radiating source temperature above that of the exit gases, this 100-deg variation in furnace-exit temperature represents 13 per cent of the range between 2320 F and 3070 F, which seems more nearly commensurate with the 10 per cent variation in calculated absorption rates.

The techniques of boiler-testing, thus far developed, are limited for quantitative data to a rather coarse breakdown of the unit into a few major components. Thus the primary furnace as a

whole has been treated as one component, for want of adequate means of segregating its several discrete wall sections or portions of a single wall.

As Mr. Reid points out, the general agreement of values, shown by the thermal probe and by the wall-tube thermocouples, with the over-all average furnace-absorption rate is largely fortuitous, but probably carries the implication that, in a furnace which has acquired an equilibrium coating of molten slag, the distribution is likely to be more uniform than for the case of partly slagged and partly clean surfaces.

Some improvement has been made in field use of the rare-metal high-velocity thermocouple, notably by running frequent calibration checks, in a portable electric furnace, against a newly made chromel-alumel couple serving as the standard. By this means, any progressive contamination error of the rare-metal couple can be detected and appropriate corrections made to the traverse readings obtained. When the accumulated error reaches a prescribed limit of 40 deg, it is customary to crop off several inches of the affected wires and to weld a new junction in the uncontaminated portion, which then will serve for several days of active testing, with calibration checks again being made as described.

Furnace-tube thermocouples were placed in five tubes, located at the center of each side wall and at the center and quarter-points of the front wall. In each tube, one thermocouple was placed at elevations 5, 15, and 25 ft above the furnace floor. Six additional thermocouples were located at intermediate elevations of the left side-wall and left front-wall tubes. In Fig. 7 of the paper, two sets of readings from all thermocouples are shown by the plotted points.

These measurements were taken and are submitted more for their collateral and qualitative interest than as absolute checks on the over-all furnace test. It is to be hoped that means will eventually be developed for more accurate quantitative appraisal of thermal distribution.

Effective thickness of slag on the furnace wall tubes is difficult to gage during operation, partly because of the limited number of inspection doors available for observation, and partly because of the variation in thickness around or along a single tube. This has been observed during shutdown to be from $^1/_8$ to $^3/_4$ in. Slag thickness on the thermal probe when withdrawn from the furnace, as shown in Fig. 7, was found to be quite uniform along the length of the probe and varied from $^1/_8$ to $^1/_4$ in. of fused slag over a layer of granular ash approximately $^1/_{32}$ in. thick.

TABLE 1 ANALYSIS OF COAL-ASH SAMPLE

	Coal ash, per cent	Ash from superheater tubes (sample F), per cent
Silica, SiO_2	38.8	42.9
Total iron, as Fe_2O_3	20.0	13.6
Alumina, Al_2O_3	25.3	28.5
Titanium oxide, TiO_2	1.1	1.4
Calcium oxide, CaO	6.7	5.2
Magnesium oxide, MgO	0.8	Trace
Total sulphur, as SO_3	4.3	0.5
Undetermined	3.0	7.9
	100.0	100.0

Complete analysis of the coal-ash sample, shown in Fig. 14, has been made in response to Mr. Reid's inquiry and is given in Table 1 of this closure. Unfortunately, none of the slag samples is now available for similar analysis, excepting that of sample F which is also shown in the table.

Summary of Reports on Physical Conditions Reported by Eight Operating Companies

By A. R. MUMFORD,[1] NEW YORK, N. Y.

IN order to narrow the field of its investigations, the Research Committee on Furnace Performance Factors solicited and obtained physical data on the furnaces of representative boiler units from eight operating companies. The data cover twenty-three units, representing about forty boilers. The capacity of these units ranges from 250,000 lb per hr to 1,000,000 lb per hr at pressures from 275 psi to 2500 psi, and total temperatures from 700 F to 960 F. These data will be analyzed by the committee, and promising lines of investigation explored in an attempt to evaluate the importance of the geometry of a furnace as a factor in its performance. The investigation will be broadened to include additional units as the line of investigation becomes sharper.

In this committee summary, where reference to a company is made, it will be by a key numeral. Similarly, units are designated by letters following the numerals. Some of the data submitted to the Committee will not be available for general distribution.

Results of Preliminary Analyses of Data

In the preliminary analyses made in the short time the data have been available, some comparisons offer points of interest. For instance, the length of the path of the flame before making contact with the convection surface at the point of discharge from the furnace varies from 108 ft in unit 7C to 33 ft in unit 8A. This length may need some more careful definition than is given it at present because of the presence, in some furnace designs, of isolated screens of widely spaced tubes which, while having more convection heat absorption than waterwall tubes, do not have as large a convective proportion as does the surface usually referred to as the boiler. At the higher pressures, these isolated screens may, with the cooling surfaces of the walls, constitute the entire evaporative surface. If sizable volumes are available for further combustion after the gases and products of combustion pass through such screens, there is some doubt as to whether or not such screens properly constitute a furnace boundary.

In the instances considered in the summary, the entrance to the main evaporative section, or, at high pressures, the entrance to the last screen before the convection superheater has been considered a boundary of the furnace. In setting up a comparison of the several furnaces, the ratio of the bounding-surface area of a sphere to its volume was considered as unity. The surface of a sphere of equal volume was computed for each furnace, and the ratio of the actual surface to this minimum enclosing surface was computed as the spherical ratio. The larger this ratio is the less the cross-sectional area of the furnace and the greater its length in the direction of flame travel. Such a factor as the suggested spherical ratio may have significance when considering the advisability of cooling the ash carried in suspension in the products of combustion below the temperature at which it is plastic and adheres to convective evaporating or superheating surface. For the units reported the spherical ratio varied from 0.765 in unit 5A to 3.263 in unit 4C. A value below unity is obviously impossible if the furnace is completely water-cooled and is possible only when exposed refractory is present. When the spherical ratio is plotted against the reported length of flame travel, a straight line can be drawn through the points with a slope showing that doubling the spherical ratio approximately triples the flame travel. Such a slope agrees with one derived from arbitrary selections of cross sections and lengths. A high spherical ratio should give more complete burning out of solid carbon and less trouble from slagging over of the free areas in convective zones, other factors being equal.

Sufficient time has not been available to study the reported conditions with particular reference to the physical properties of the ash, which, of course, varies with the different units and with time. If it is possible, later, to compare furnaces of different spherical ratios when fired with coals having ash with the same physical characteristics, it may be feasible to relate the necessary spherical ratio to the physical properties of the ash of the available coal.

A small number of the units reported data on the amounts of steam used for blowing ash from the heat-absorbing surfaces. When this amount of steam, computed on the basis of the amount of fuel burned, was plotted against the liquid temperature of the ash, a fair degree of proportionality was found except in the case of one unit which was far out of line. This unit was the furnace of a mercury boiler and was, of course, not comparable to the steam boilers because of the temperature of the heat-absorbing surfaces. When the units were examined with respect to the spherical ratio and the steam used for blowing, it was found that the steam used was proportional to the spherical ratio in company 5, which also reported only minor variation in the ash-softening, melting, and liquid temperatures of the ash. The proportion was not evident in the data reported by company 8 which used air as well as steam for blowing and no factor was available to put the two fluids on a common basis.

Flame Temperatures

At this time, data on flame temperatures along the path of travel were available from only one company for two units, 7A and 7C. Unit 7A showed a smooth curve, convex downward, when plotted against surface passed over or flame travel. However, unit 7C showed an equally smooth curve, but it was convex upward. Both units were of the same capacity with the same furnace volume. Unit 7A had a spherical ratio of 1.393 against 2.669 for unit 7C. Unit 7A operated at 425 psi and 850 F, while 7C operated at 1350 psi and 925 F. If this difference in the characteristic of the temperature versus surface passed over is confirmed by other examples, the reason for it will be an interesting and important investigation. If, in a furnace having a convex upward curve, we can control the curvature, we should

Contributed by Special Research Committee on Furnace Performance Factors with the co-operation of the Fuels, Power, and Heat-Transfer Divisions and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

be able to deposit ash in a nonplastic form where we require it.

An interesting sidelight on design features was indicated when the Btu absorbed per square foot of free area at the entrance to the superheater was plotted against the Btu fired divided by the same divisor. Although the data covered quite a range of temperatures and pressures, with consequent variation in the proportion of heat for superheating, the Btu fired was to proportional the Btu absorbed with little scatter of the points. It would seem, therefore, that the furnace was expected to properly prepare the products of combustion for passage through the superheater, and did.

A majority of the units reported have apparently adopted the practice of reducing sharply or completely dropping the load at regular intervals presumably as a deslagging operation. In many cases this was a daily occurrence.

Initial Stages of Operation

Each company was asked to report in a general way on any difficulties they experienced during the initial stages of operation, and the steps taken to correct the difficulties. In the following paragraphs some of these reports are high-spotted:

Company 1 reported that no hand-cleaning of furnaces was required, and that the only tube failures experienced were due to construction faults rather than design faults. Some minor baffle changes were required to reduce the relative amount of fuel fired in the radiant-superheater furnace.

Company 2 reported that steam-temperature fluctuations on swinging load were minimized by using steam jets to clean evaporating-wall surface on rising superheat and radiant-superheater walls on falling superheat.

Company 3 reported that the service period of stoker-fired boilers was increased two to two and a half times and hand-lancing during service hours eliminated by coal-washing at the mine. This company found that it could eliminate hand-lancing and reduce requirements for mechanical blowing in pulverized-fuel furnaces by proper spacing of convection surfaces and control of heat-release rates.

Company 4 reported one unit almost entirely self-cleaning, and one which had a temperature versus surface-passed-over characteristic which caused the deposition of ash in an unexpected inaccessible place.

Company 5 reported no difficulties with coals having ash-softening temperatures of 2500 F or more, but at high steaming rates plugging began with coals having an ash-fusion temperature of 2300 F. By careful control of secondary air, this company reported its ability to vary the effectiveness with which the furnace volume was used.

Company 6 reported that the only tube failure was caused by steam cutting, and that no measurable tube wastage has occurred. Some erosion which was experienced in the upper portion of the primary furnace was attributed to local zones of high heat release.

Company 7 reported successful cracking-off of furnace slag by dropping load. This company found it necessary to keep the furnace slag at a minimum to avoid high superheat. Hand-lancing is required at boiler and superheater entrance.

Company 8 reported performance may be good or bad on identical units in different plants, depending upon fuel and operating conditions. Variation in ash-fusion temperature did not seriously affect slag-tapping but unbalanced the superheat characteristic of the unit, because low fusion temperatures thinned down the deposit on evaporative walls and increased furnace heat transmission.

This summary and preliminary analysis should not be closed without asking for opinions and suggestions from those who have read the reports and summary. The committee is arranging for co-operative work on the physical properties of ash and on the development of instruments for making furnace measurements. The committee hopes to obtain more data from additional companies.

Furnace Design and Development of Steam-Generating Units Burning Central Illinois Coal

By JOHN R. MICHEL,[1] CHICAGO, ILL.

IN 1929 a paper was presented at the Third National Fuels meeting held in Philadelphia on the subject "Effect of Fouling on Boiler Efficiency."[2] In that paper the difficulties experienced in endeavoring to secure designed capacity and efficiency from the fuel-burning and steam-generating equipment installed at Crawford Station were discussed. The paper is cited and remarks relative to stoker-fired installations are made to emphasize the fact that problems pertaining to furnace performance and slag fouling of heat-absorbing surfaces are not incident to pulverized-fuel firing but have been matters of serious concern, especially to those burning low-grade fuels, for many years.

At Crawford Station slag fouling of steam-generating tube banks and plugging of superheaters forced periodic water lancing of these sections so that gas lanes could be kept open and reasonable ratings and operating efficiencies maintained. Notwithstanding the adoption of this procedure to augment the cleaning accomplished by regular operation of mechanical blowing equipment, it was necessary to remove the boilers from service at 35-day intervals for hand rodding and repairs.

Since radical changes in design necessary to overcome slag-fouling difficulties could not be accomplished economically in this installation an improvement in the fuel supplied was investigated. Extensive tests indicated that the use of washed Central Illinois coal would permit increased boiler service periods and improve boiler performance. Evaluation of increased station capacity and other resultant advantages justified installation of a washer at the mine for preparation of Crawford Station's coal. At present with the station burning washed Central Illinois coal and with mass blowers installed to remove the slag which now deposits, 75-to-80-day boiler-service periods are attained with no hand cleaning or water lancing necessary during service periods.

During the later part of the foregoing developments in 1937, a 30,000-kw topping unit was installed in another Chicago station. The boiler complement of this unit consists of two 375,000-lb per hr, 1275-psi, 910 F, pulverized-fuel-fired steam-generating units, data on which are submitted on data sheets 1, 2, 3, and 4.

It will be noted from the proximate fuel analyses and ash characteristics given that all pulverized-fuel installations reported on use normal Central Illinois coal. Although this coal has many unfavorable characteristics it is not advisable to provide a better grade of fuel for Chicago stations because of economic considerations. At Crawford Station, however, furnace conditions and resultant steam-generator performance made necessary the use of washed Central Illinois coal in order to obtain designed station capacity. In later pulverized-coal installations, provisions made in furnace design overcame slagging difficulties to the extent that normal Central Illinois coal could be satisfactorily used.

Central Illinois coal has a few characteristics which adapt it to being burned in pulverized form. It is a free-burning coal, high in volatile, and as a result ignites easily and burns thoroughly with little combustible remaining in the fly ash or furnace slag. Likewise, its low ash-fusion temperature permits ready tapping in installations with wet-bottom furnaces. Objectionable features arising from its high moisture content, high a h content, low ash-fusion temperature, high sulphur content, and low grindability far outweigh any advantages. Low ash-fusion temperature coupled with high ash content are reasons for severe slagging of heat-absorbing surfaces. The slagging difficulty is accentuated when this fuel is burned in pulverized form due to a fundamental weakness of pulverized-fuel firing, that is, in the conventional pulverized-fuel-fired installations nearly 50 per cent of the ash in the coal passes from the furnace as fly ash.

In designing the previously mentioned 375,000-lb per hr pulverized-fuel-fired steam-generating units, slag-fouling problems were recognized as being outstanding among the difficulties to be overcome in the design of the furnaces and the units. In this installation slag screens were provided between the primary and secondary furnaces, wide tube spacings were provided in the steam-generating banks of tubes, telescoping deslagging units were provided in the steam-generating banks and superheaters, and provision for hand-lancing the steam-generating banks and lower superheaters were made in addition to the usual complement of mechanical blowers for the remainder of the unit.

In operation of this installation a constant cleaning program was found necessary to maintain the boiler units in proper operating condition. The full time of three boiler cleaners on each watch is required; that of two men, one for each boiler, is required for air-lancing the steam-generating tube banks and that of the third man is required for operation of the mechanical blowing equipment on both boilers and intermittent air-lancing of the superheaters. With this arrangement six months' operation of the boiler units is obtained before outage for regular inspection, maintenance, and cleaning is necessary.

With the foregoing experience on the 375,000-lb per hr units, several requirements were stipulated in the design of three 425,000-lb per hr, 1325-psi, 935 F, steam-generating units for a 50,000-kw topping unit to be installed in another Chicago station. Among these were lower unit furnace heat release, wide spacing of steam-generating tubes and consequent lower entering-gas velocity to the tube banks, wide spacing of superheater tubes with entering-gas temperatures of approximately 1900 F, and provision in the design for hand-lancing doors so disposed that all heat-absorbing surfaces of the boiler unit could be cleaned while in service.

To overcome difficulties experienced with telescoping deslagging units used in the previous installation, mass blowers were applied where possible and rotating retractable elements were used above the steam-generating tube bank and in the superheater. Operation of these boiler units since January, 1942, has indicated that steps taken to eliminate difficulties due to slag fouling of heat-absorbing surfaces were ample, since operation of the mechanical

Contributed by Special Research Committee on Furnace Performance Factors with the co-operation of the Fuels, Power, and Heat-Transfer Divisions and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

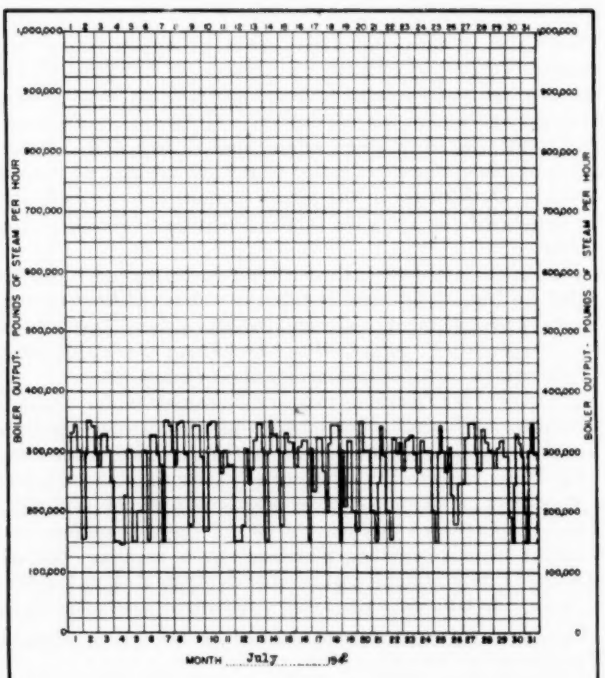
blowers twice daily maintains the boiler units in clean operating condition.

Data relative to this installation, comparable to that given for the 375,000 lb per hr unit installed in 1937, are given on data sheets 1A, 2A, 3A, and 4A.

With some experience from the early operation of the foregoing 425,000-lb per hr units, the design of two 750,000-lb per hr, 1325-psi, 935 F, steam-generating units for a 147,000-kw condensing turbine generator unit was developed. Similar requirements relative to furnace heat release, tube spacings, entering gas temperatures and gas velocities, to that of the 425,000-lb per hr units installed in 1941 were stipulated. In the 750,000-lb per hr installations, however, tube banks of the steam-generating sections and superheaters were so disposed that only retractible mass blowers were necessary for the mechanical blower installation.

Although the 750,000-lb per hr units have not been in regular service supplying steam to the unit for which they were designed, they have been used to supply steam to other 1200-psi, 900 F equipment in the station. Part of this operation was with full designed heat release in their furnaces, full steam flow not being attained because feedwater at design temperature was not available from installed equipment. Indications from this operation are that no hand lancing will be required in their regular operation.

Similar data to that given for other units mentioned in this paper are shown for the 750,000-lb per hr units on data sheets 1b, 2b, 3b, and 4b.



The furnace designs developed in the installations discussed have resulted mainly from an endeavor to overcome slagging difficulties associated with the use of Central Illinois coal in high-capacity installations. The fundamental governing factors in attaining installations which perform satisfactorily with this fuel were low furnace heat release, relatively low entering-gas velocities to convection tube banks, furnace gas temperature below the softening temperature of the ash where gases enter the convection banks, proper disposal of heat-absorbing surfaces to allow adequate installation of mechanical blowing equipment, and provision of hand-lancing doors so arranged that all heat-absorbing surfaces can be manually cleaned in the event of failure of the mechanical blowing equipment.

The foregoing design provisions necessarily require a steam-generating installation that is somewhat higher in first cost. Experience, however, has proved these provisions necessary in pulverized-fuel installations burning Central Illinois coal. Until new methods of firing or methods of slag control are developed, which definitely are proved to be effective in avoiding slagging difficulties, the foregoing principles as applied to furnace and unit design should be adhered to, especially in installations burning Central Illinois coal.

Pulverized-Coal-Fired Boiler Furnaces, Public Service Electric and Gas Co., New Jersey

By H. WEISBERG,[1] NEWARK, N. J.

This paper presents statistical information on pulverized-fuel furnaces installed on the Public Service Electric and Gas Company, New Jersey, System. Reasons are given for the selection of the various designs described and actual operating conditions are discussed. It is indicated that there is a need for more rational design data, and a program of research is suggested.

EXPERIENCE with large pulverized-coal-fired steam-generating units on the Public Service Electric and Gas Company System extends over a period of eleven years. That these units represent a distinct advance over boilers of earlier design, which were stoker-fired, is particularly evident under present heavy load conditions with the poorer quality of coal available. The purpose of this paper is to present a description of the furnaces of the pulverized-coal units as well as information on operating conditions and difficulties encountered in operation, for the benefit of the Research Committee on Furnace Performance Factors, designers, and prospective purchasers of this type of equipment.

There are now installed on this System ten units which may be grouped into four principal designs, indicated by Figs. 1 to 4 respectively, and briefly described as follows:

1 A straight tube, cross-drum unit (700 lb, 850 F), Boiler No. 11, Burlington Station, equipped with turbulent-type circular burners firing a water-screened, dry-bottom furnace.

2 Two bent-tube units (1350 lb, 950 F), Boilers Nos. 25 and 26, Essex Station, with a two-stage furnace arrangement, slag-tap ash removal and rectangular burners.

3 Six bent-tube units (1350 lb, 950 F), Boilers Nos. 12, 13, 14, and 15, Burlington Station, and Nos. 51 and 52, Marion Station, similar to design 2, but including refinements developed as a result of operating experience with design 2.

4 A mercury unit (140 lb, 980 F) at Kearny Station having an eight-sided dry-bottom furnace with a rectangular burner in each wall directed toward the center of the furnace.

Data pertinent to comparison of furnace performance are given in Table 1, including detailed description of the units, typical coals burned,[2] fuel-burning rates, and a summary of the cleaning schedules.[3] The fuel-burning rates recorded are based on actual maximum outputs for not less than four hours during a normal operating day rather than on design or rated capacities. Typical load curves are shown in Figs. 5 to 8 inclusive.

[1] Mechanical Engineer, Electric Engineering Department, Public Service Electric and Gas Company. Mem. A.S.M.E.

[2] Additional information on coals burned is included in Appendix A.

[3] For detail cleaning schedule see Appendix B.

Contributed by Special Research Committee on Furnace-Performance Factors with the co-operation of the Fuels, Power, and Heat-Transfer Divisions and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not of the Society.

DISCUSSION OF DESIGN FEATURES

The predominating factor in the performance of large pulverized-coal-fired furnaces is the formation of slag and ash on the walls and convection surfaces. The pattern of slag deposits on the walls varies not only with the design of furnace and burners, but with the quality of coal burned, the amount of cleaning which is done, load variations, and time the unit has been in service. Performance of identical furnace arrangements in different plants is good or bad depending upon the fuel burned and the operating conditions. Design is essentially empirical and is usually determined as a result of operating troubles with earlier units. A start on a rational approach for predicting slag accumulation is suggested by Bailey,[4] but much work remains to be done before performance of any new design can be predicted accurately in advance of actual operation.

The original pulverized-coal-fired furnaces in this country were adapted from stoker-fired installations of that time and had practically no water-cooled wall surface. Output was limited by inability of the refractory walls to withstand the high combustion temperatures and by large slag formations on the walls and bottoms of the furnaces, which could not be removed while the boilers were in operation. In connection with the first pulverized-coal unit installed on this System at Burlington Station during 1932, design 1, an attempt was made to water-cool a large portion of the furnace to minimize these difficulties. The unit has given excellent service, but maintenance of such refractory walls as were included is a definite limitation to output and continuous operation. This applies also to the refractory ash hopper. In design 2, which was placed in operation in 1938 and subsequent installations all refractory surface was eliminated.

Prior to the installation of design 2, an investigation of many units in the East and Middle West seemed to indicate that the bent-tube type boiler was less subject to slagging of the convection surfaces than the straight-tube type. For this reason a bent-tube boiler was specified. While it is not at all certain that there has been any less slagging of the convection surfaces in this design than in the original straight-tube boiler, there probably has been no greater tendency to slag. From the standpoint of adequate circulation at the higher pressure (1475 lb on the drum) this type of boiler turned out to be a fortunate choice.

In connection with the latter design, furnace-wall blowers were first developed and have since been applied on all installations. Without some form of regular cleaning, slag gradually accumulates on the walls starting around the burners and building up toward the furnace exit. Gas temperatures leaving the furnace increase, eventually causing slagging of the convection surfaces unless the formation of slag on the walls is checked. With the blowers, the accumulation above the elevation where the slag is fluid may be blown off periodically, resulting in more stable operation. Of course the same effect may be obtained

by hand-lancing or reducing load regularly so that the slag will chill and drop off. All three methods are used as required, but the wall blowers appear to do the most satisfactory job with a minimum of labor and loss of output.

Wet ash removal was chosen for the boilers of designs 2 and 3 as this arrangement resulted in a more economical layout for the steam conditions, taking into consideration the wide variety of coals to be burned. The variation in fusion temperatures of the coals actually burned in these units at Burlington in one typical month, namely, 2130 F to 2640 F (Table 1) without any appreciable difference in the amount of cleaning required, indicates that this objective has been realized. With the slag-tap type of unit, however, variation in the fusion temperature of the ash changes the thickness of slag on the walls of the hot portions of the furnace and this presents somewhat of a problem with superheat control. Operating experience with the dry-bottom furnaces indicates that this arrangement may also perform satisfactorily from the slagging standpoint with a variety of coals, providing the burners are carefully designed, combustion rates are held down, and the furnace walls are kept free of slag accumulation.

Design 3 is practically the same as design 2, the principal difference being the elimination of the large ash hopper under the secondary furnace. The hopper was found to be a source of air leakage and required extra maintenance on account of heat radiation from the secondary furnace.

The mercury unit furnace, design 4, was dictated by the requirements of the mercury cycle. The temperature of the cooling medium in the lower mercury-cooled walls is in the order of 1100 F, so that the tube wall temperatures run about 1250 F. This condition made a low-heat-release dry-bottom design desirable. Special attention was paid to keeping flame away from the sides of the furnace by placing a burner in each wall directed toward the center of the furnace. Here again blowers were installed to remove slag from the walls. Keeping the furnace walls clean has a double purpose in this unit, as it was found that the insulating effect of the slag on the walls, in addition to causing the convection bank to slag over, actually impaired circulation of the mercury in the wall tubes sufficiently to result in damage to the convection bank which is fed by these tubes.

Comparison of Furnace Surfaces

The fuel-burning rates indicated in Table 1 represent the actual maximum rates at which the units are operated. The limits are steam temperature, mercury-vapor temperature, or just plain conservatism rather than furnace capacity. Ten or fifteen per cent higher output has been obtained on each of the units described, but these rates are not regularly maintained and therefore detailed information on them is not reported. Short duration tests at the higher outputs are meaningless as there is insufficient time for slag conditions to become stabilized. It is suggested that research is needed to determine the limitations of various furnace designs. This may be accomplished by analyzing reports on existing installations, by field tests, or by calculating methods yet to be developed.

Heat released or fuel burned per sq ft of water-cooled furnace surface has been used by some as an indication of the tendency to slag the convection surfaces. It is of interest to note the higher hourly fuel-burning rate per sq ft of radiant water-cooled furnace surface indicated by design 1, Boiler No. 11, Burlington, viz., 159,500 Btu per sq ft as compared to rates in the order of 100,000 Btu per sq ft for the more recent designs. As previously stated neither of these rates represents a furnace limitation. The higher rate is obtained in design 1 without an excessive amount of cleaning and with coal at least as difficult to burn as any fired on the other units. The primary reason for eliminating the brickwork on the more recent designs, which increases the water-cooled surface and reduces the fuel-burning rate per sq ft, was to reduce outage for brickwork repairs. It is quite likely that the furnace volume and consequently wall surface could have been reduced in the newer designs without encountering any difficulty. For the higher-pressure installations, however, it may be that extra furnace wall surface can be installed more economically than an equivalent amount of convection surface, particularly if long field welded tubes without intermediate headers are utilized. The high input per unit width of furnace up to 31,500,000 Btu per ft in the higher-pressure boiler designs 2 and 3 as compared to 19,900,000 Btu per ft in the older lower-pressure design, reflects the trend toward narrower furnaces.

Comparing the fuel-burning rates per sq ft of total radiant plus convection surface preceding the superheater, there is a much closer agreement between the units reported, viz., 63,820 to 74,040 Btu per sq ft. Regular steam blowing of the convection bank and superheater seems to be essential to maintain this rate without slag accumulation in the superheater, especially for the more closely spaced tubes.

In connection with design 2, the tubes in the first section of the superheater were originally spaced with an 0.8-in-wide free-gas opening between tubes. The close spacing was dictated by economy considerations. The burning rate per sq ft of free-gas area in this section was over 5,000,000 Btu per sq ft as indicated by the figures shown in Table 1 for Boiler No. 25, Essex Station. It was found that slag accumulated between tubes with this spacing even with an excessive amount of soot-blower operation. When every other superheater tube in this section was removed, thus increasing the spacing to 4.1 in. and reducing the burning rate to 2,452,000 Btu per sq ft of free-gas area, as indicated for Boiler No. 26, this difficulty was eliminated.

All water-cooled surfaces are calculated on the basis of projected wall area at tube center lines without adjustment for differences in construction such as tangent tubes, block-covered tubes, and stud or fin tubes. Hottel factors are applied to spaced wall and ash hopper screen surfaces while total gas-side tube surface is used in calculating convection surfaces. The floor surface of wet-bottom furnaces is neglected entirely because of the insulating effect of the chrome ore and slag. Radiation from the furnace to the convection bank is allowed for in arriving at the "furnace surface" by adding the cross-sectional area of the furnace at the furnace exit to the sum of the wall surfaces. A similar allowance is made for the total "furnace surface and convection bank to superheater" by adding the cross-sectional area of the gas pass at the superheater entrance, including by-pass, to the sum of the surfaces to that point. Furnace volume includes total combustion space above ash hopper water- or mercury-cooled surface to convection section of boiler. Although not theoretically correct, for the sake of simplification, burning rates are based on the higher heat value of the fuel with no allowance for heat added with the preheated air.

Value of Slag Screen

In connection with design 2, the slag screen between the primary and secondary furnaces was omitted on one of the boilers during the initial operation to determine its value. Fig. 9 shows comparative gas temperatures entering the superheater as determined by high-velocity thermocouples. These temperatures indicate that the additional surface of the slag screen is well utilized. For a gas temperature of 2000 F entering the superheater 20 per cent more output is obtained by the addition of the screen which represents 17 per cent additional furnace surface. The screen apparently raises the average heat-absorption rate of the furnace. The cost of the screen surface compared to an equal amount of additional wall surface is probably low as the projected area of both sides of the screen have been included as

* Fog bank of Mercury Boiler is considered equivalent of superheater on Steam Boiler.

(Correction to Table 1: In column 2 (Essex) superheater data, read 1,773,000 for 1,733,000 and 279 for 379. In column (Burlington) steam used, read 31,906 for 23,020.)

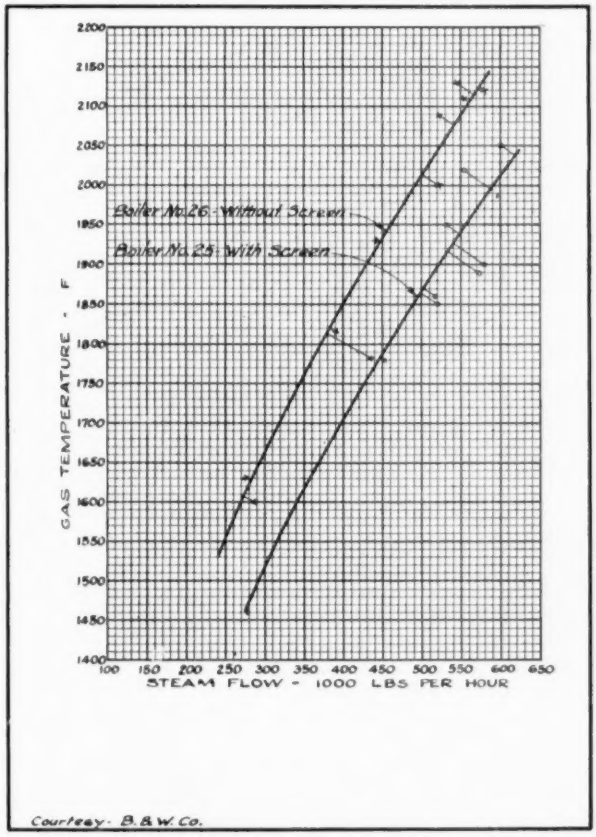

FIG. 9 AVERAGE GAS TEMPERATURE, SUPERHEATER INLET, WITH AND WITHOUT SLAG SCREEN BETWEEN PRIMARY AND SECONDARY FURNACES
(Boilers Nos. 25 and 26, Essex Station.)

heat absorbing surface. Whether the same result could be obtained with any arrangement of the additional surface placed in the hot portion of the furnace, or whether the arrangement which shades the secondary furnace from the primary is necessary to obtain the benefit, was not determined. It was found necessary to install the screen after the initial operating period as the superheater had been designed for a furnace which included the screen, and steam temperatures were too high without it.

DISTRIBUTION OF FURNACE GASES

Fig. 10 shows a typical gas-analysis traverse leaving one of the boilers of design 2. The tendency for high excess air on one side persists in spite of normal adjustments which can be made to the coal and air at the burners. The cause has not been determined, but is probably due to poor distribution of coal and air in the burners. This is an example of local conditions often found in the field which make snap comparisons inaccurate.

Fig. 11 indicates a temperature traverse entering the superheater of one of the boilers of design 2. Temperatures at this point vary from 1500 to 1990 F across the gas pass. The wide variation is typical and is another illustration of the problem involved in obtaining accurate comparative results.

Fig. 12 shows the flow paths of gases in the furnace of one of the units of design 3, and Fig. 13 shows isothermals in the same furnace. The wide variation in distribution of furnace gases illustrates the difficulty in determining furnace-performance factors. Any comparative tests which may be planned must take these variations into account.

FURNACE TUBE WASTAGE—BURNER PERFORMANCE

A peculiar type of corrosion which was unknown two or three years ago has been encountered on the gas side of the furnace tubes in connection with the later designs described. Although no tubes have been lost on this account, replacements have been necessary because of excessive corrosion in localized areas. In

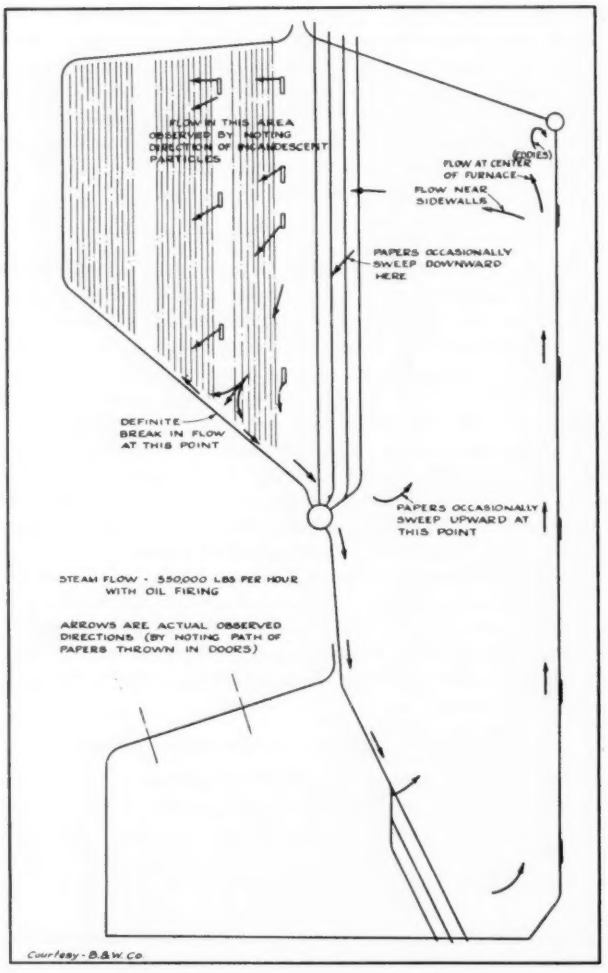

FIG. 12 GAS FLOW STUDIES, BOILER NO. 12, BURLINGTON STATION

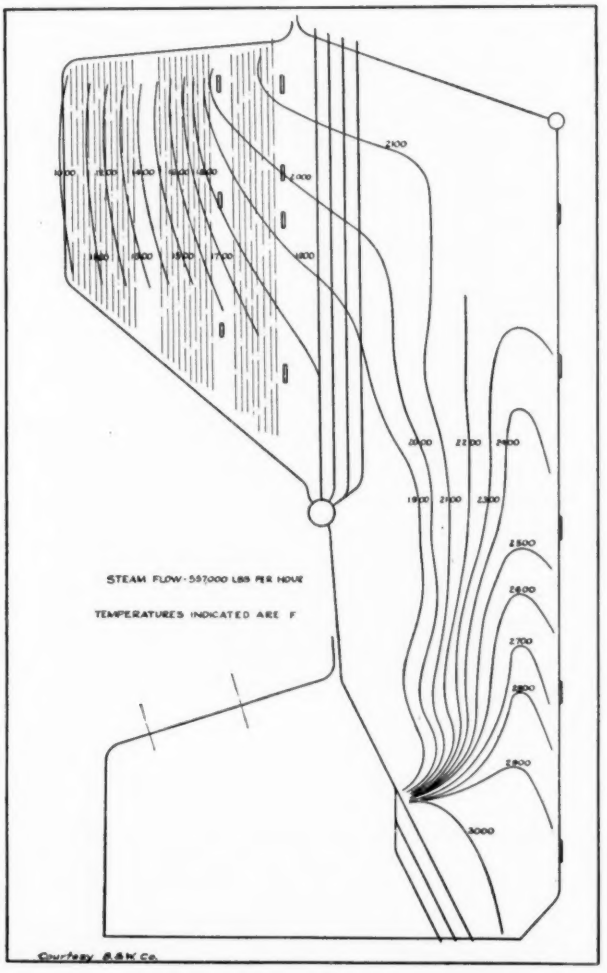

FIG. 13 ISOTHERM PLOT, BOILER NO. 12, BURLINGTON STATION

connection with design 2, replacements have been made on the side walls opposite the burners. In design 3, maximum corrosion occurs at the lower end of the side wall tubes for a distance approximately 18 in. up from the slag bottom. In the mercury boiler furnace, design 4, which has a dry bottom, wastage having an entirely different appearance occurs more uniformly over the entire lower portion of the furnace. In this case the tube wall temperature is approximately 1250 F compared to normal temperature in the order of 750 F on high-pressure steam boilers.

Corrosion seems to be connected with a deficiency of air for combustion and usually occurs where there is CO in the furnace gas even though this condition is intermittent and the amount of CO is small. The remedy appears to be better mixing of coal and air in the burners. Temporary relief can be obtained on the steam boilers if the action is not too severe by closely spaced horizontal fins welded to the tubes, with the spaces between fins packed with chrome ore. Tube wall temperatures are too high for this construction to be used on the mercury furnace. Nonmetallic coatings are being tried out in actual service. For the hot portions of the furnace there seems to be no satisfactory substitute for closely spaced tubes without extended surfaces. Extensions waste away no matter how they are installed. Thorough mixing of coal and air in the burner is essential and the furnace should not be depended on for completing the mixture.

Circular turbulent burners appear to give better results than any rectangular burner yet developed. A properly adjusted circular burner will have a shorter flame travel. The flame shape of the circular burner can be controlled, to a large extent, by manual adjustment while operating, which is advantageous for variable loads. Indications are that circular-burner-fired furnaces are less subject to fused slag accumulations on the waterwalls, and there are few cases of tube wastage in furnaces equipped with this type of burner.

SUMMARY AND CONCLUSIONS

The advent of pulverized coal resulted in a marked improvement in the performance of boiler furnaces, and there has been steady progress since that time. Design, however, is based on limited experience and is still an art rather than a science. The information presented herewith shows that a number of different arrangements may perform satisfactorily but their maximum capabilities have not been determined. Fundamental research on the factors involved is needed if we are to have more economical installations and take care of the higher pressures and higher temperatures of future power cycles. More specifically, information is needed on the following items of design: burners; arrangement of water-cooled furnace walls for maximum heat absorption; methods for predicting and controlling slag deposits on furnace walls; measures to eliminate destructive action of furnace atmosphere and slag on water-cooled metal wall surfaces; arrangement and spacing of tubes in convection bank for slag-free operation with various furnace-exit-gas conditions.

(1) Low Volatile - District No. 1 - Central Pennsylvania (From Station storage pile which was made up of coal from various mines).
(2) High Volatile - District No. 2 - Western Pennsylvania (From 2 separate mines).
District No. 3 - Northern West Virginia (From various mines).
Individual shipments were made up of coal from one mine or a mixture from 2 or more separate mines and from District No. 2, No. 3 or both.
Most High Volatile coal is from District No. 3.

MERCURY BOILER

KEARNY STATION

Appendix B

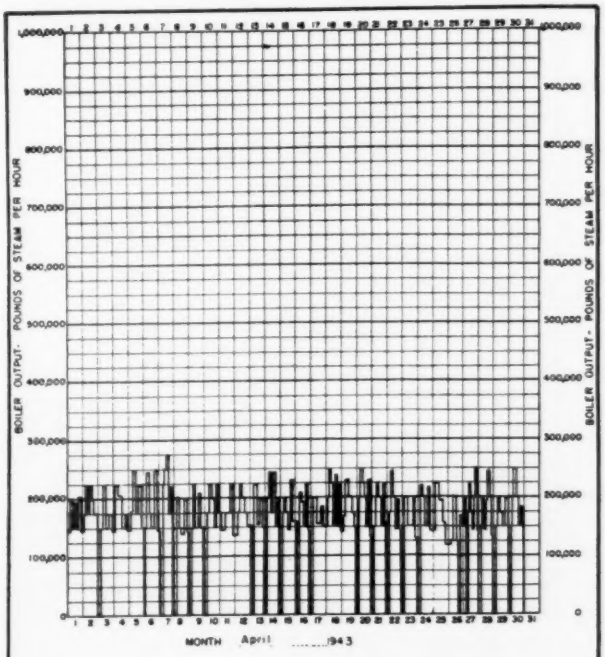
Description and Performance of Boilers 12 and 14, Trenton Channel Plant, and Boilers 9 and 10, Marysville Plant, The Detroit Edison Company

By R. J. BRANDON[1] and W. A. CARTER,[2] DETROIT, MICH.

SLAGGING IN BOILERS 12 AND 14 TRENTON CHANNEL PLANT

NO serious trouble has ever been encountered because of slagging on any of the tube surfaces of these boilers, when burning coals having ash-softening temperatures of 2500 F or higher.

Some plugging of the gas passages in the front convection banks has occurred, especially at the higher steaming rates, when burning coals having ash-softening temperatures of 2300 F or lower. These ash deposits are of the nodulized type and they are readily removed by steam-lancing once every eight hours.



At times, ash in the form of dust collects on the hearth-screen tubes, thereby reducing the heat absorption in these tubes and increasing the furnace temperature to such a point as to cause slag reaction with the air-cooled refractories in the furnace walls, especially on the side walls where the gases turn abruptly upward.

The pressure of the primary air entering with the coal must be maintained high enough to carry the flame down in the furnace until it almost sweeps the hearth-screen tubes. If this is not done, combustion occurs nearer the apex of the furnace with the result that the ash is still plastic when it enters the front convection banks and deposits as nodulized ash on the tubes at the entrances to these banks.

More slagging of the air-cooled refractory furnace walls has been experienced with these boilers than slag collecting on the convection-tube surfaces. Slagging of these walls usually occurs before any deposits start to collect on the tubes. When the walls begin to slag, corrective air adjustments can usually be made before any slag deposits on the tube surfaces.

SLAGGING IN BOILERS NO. 9 AND 10, MARYSVILLE PLANT

SLAGGING of the waterwall tube surfaces in these boilers has not been of a serious nature since, in general, the light or nodulized ash deposits can be removed readily with an air lance. Slag accumulates more quickly when the flame is sluggish and impinges on the waterwall tube surface, but this condition is improved to some extent if the secondary air is regulated to obtain optimum air velocity and distribution over the range of steaming rates. One setting of the secondary-air dampers will produce a good flame for boiler steaming rates of 300,000 lb per hr and higher, but it appears advantageous to alter the secondary-air-damper setting at lower steaming rates in order to obtain air velocities that will provide good mixing of coal and air, thereby avoiding a sluggish flame and ash impingement on the waterwall surfaces. A change in steaming rate causes some deslagging of these surfaces.

In order to indicate the distribution of slag on the waterwall tube surfaces, the furnace has been divided sectionally as shown in Fig. 1. Very little slag collects on the waterwalls in sections *A* and *C*, but the tubes in section *B* become heavily covered with nodulized deposits which are removed regularly for steam-temperature control. The entire area in section *B* becomes covered, and the deposited ash is removed by air lancing when approaching two inches in thickness. All four walls receive about the same amount of slag, with the heaviest deposits forming above and on one side of the burners, as shown in Fig. 2, and decreasing in amount higher up in the furnace. In No. 9 boiler, the slag in section *B* collects more quickly and extends to a greater height than in No. 10 boiler, which is a duplicate boiler. The height to which the slag extends in the furnace of each of these boilers is indicated in Fig. 1.

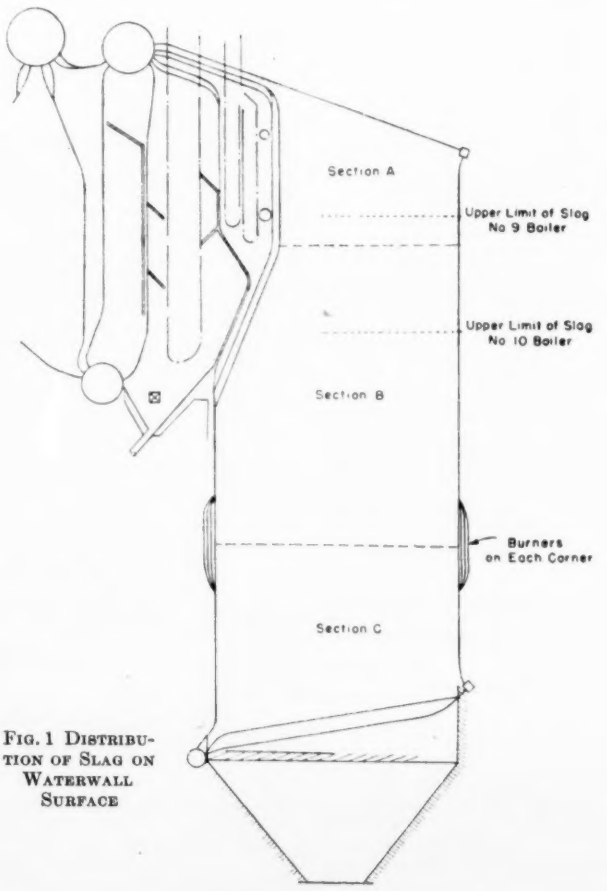

FIG. 1 DISTRIBUTION OF SLAG ON WATERWALL SURFACE

Nodulized ash deposits form on the tubes in the convection bank preceding the semiradiant superheater of No. 9 boiler and carry through to the superheater tubes in that section of the boiler where the direction of the gas flow from the firing circle is perpendicular to the superheater. This condition is illustrated in Fig. 2. Some decrease in the quantity of ash deposited has been effected by adjusting the distribution of secondary air at the burners, but as yet conditions are not as good as those obtained in No. 10 boiler. In the latter boiler, a light dust covers the fronts and backs of the tubes in the convection bank preceding the semiradiant superheater.

These boilers have been in service for only a few months, during which time the usual adjustments required on new boilers have been made. Continued operation and adjustments may result in some improvement in the slagging conditions encountered during this early service period.

Performance of Pulverized-Coal-Fired Boilers on Philadelphia Electric Company System

By JAMES H. HARLOW,[1] PHILADELPHIA, PA.

PARTICULARS in regard to three types of pulverized-coal-fired boilers in the Philadelphia Electric Company System are shown on the accompanying forms. All of these boilers are rated at 600,000 lb of steam per hr normal capacity. The Richmond Station boilers which were put into operation in 1935 operate at 425 psig with feedwater at 315 F and a steam temperature of 850 F. The Schuylkill Station boilers started operation in 1938. The steam conditions at this location are 1350 psig and 910 F with feedwater at 400 F. The Chester Station boilers, which went into service in 1941, produce steam at 1350 psig and 925 F with feedwater at 400 F. There are two boilers of each type at their respective locations.

Fuel

All of these boilers are pulverized-coal-fired. In general, slack coal from a number of operators in the central Pennsylvania fields is used. The coal is from a number of seams and varies somewhat in proximate analysis. Following are three typical analyses:

Seam	*B*	*D* + *E*	*E*
Fixed carbon, dry	67.8	70.9	75.3
Volatile, dry	23.2	22.0	17.3
Ash, dry	9.0	7.1	7.4
Sulphur, dry	2.4	1.7	1.7
Btu per lb, dry	14120	14400	14400
Moisture	2.4	2.5	3.8

The grindability of these coals is 115 to 125 on the Hardgrove index, and the fusion temperature of the ash ranges from 2450 to 2600 F.

Coal Preparation and Burning Equipment

At Richmond the coal for each boiler is pulverized by two type-B Babcock & Wilcox mills which have two rows of balls and which operate as part of a bin system. Each boiler is equipped with eight intertube, downfired burners which have individual feeder control at the bin. The burners are arranged on the roof of the furnace in two rows of four each. Each burner has four nozzles, each nozzle being directly over alternate tubes. The tubes are protected against erosion by semicircular guards. Secondary air is supplied around the burners through individual burner wind boxes.

At Schuylkill a unit system is installed which employs three Raymond bowl mills per boiler. Each mill supplies four burners, a total of twelve per boiler, one in each corner of the furnace, arranged for tangential firing. These burners fire horizontally; the coal stream is surrounded by the secondary air with additional provision for admitting secondary air through ports above and below the three burners in each corner.

At Chester a unit system is also installed. This installation comprises three type-E Babcock & Wilcox pulverizers per boiler. Each mill supplies coal to two intertube, downfired burners. The six burners are arranged in one row along the roof of the furnace. The burners are similar to the Richmond burners with the exception that each burner has sixteen smaller nozzles, four over each of four tubes, and that a steeple-type splitter is provided over the tubes instead of the semicircular tube guard.

The coal at all locations is pulverized so that from 75 to 80 per cent passes a 200-mesh sieve.

Slag and Ash Disposal

The three types of furnaces are arranged for slag tapping; the Richmond furnace is intermittently tapped and the others drain continuously. The Chester boilers are of the open-pass design which requires a second disposal hopper under the second open pass. The material which collects at this location is quite different from that at the furnace tap. The slag particles are much larger in size and include a considerable number of clinkers.

Fly-ash particles which do not settle out of the gases are collected by dust eliminators at each station and somewhat over one half of the total coal ash is collected in this manner.

The soot-blower and telescopic-lance arrangements and the operating cycle of these devices are shown on the attached drawings. The mechanical cleaning is supplemented by hand lancing.

Boiler Loading

Graphs showing a month of typical loading are attached for the boilers at each of these locations. In all cases, it will be noted that these boilers are required to carry a sustained load at or near their rated capacity for most of the time. This results from the fact that they supply the most efficient turbines on the system, and that the aggregate capacity of these turbines is low enough so that normal load variations can be carried on other less economical units without reducing load on these boilers, except during periods of high output on hydro. The months selected were months of comparatively low hydrogeneration. Full hydro output is normally expected for only 30 per cent of the year.

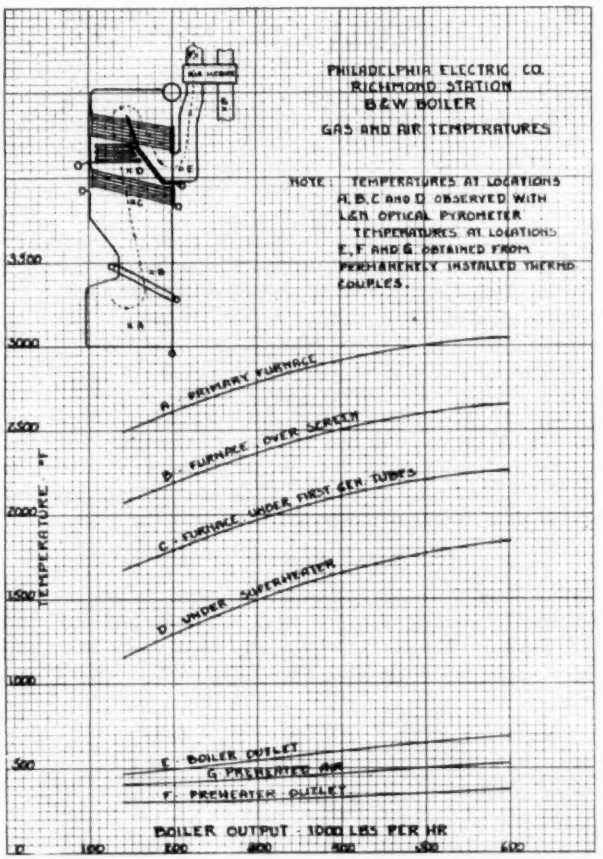
Some comment on each of the graphs is required. The Richmond graph shows a steady output of about 580,000 lb per hr. This is slightly low due to turbine limitations during the period covered by the graph. On the Schuylkill graph, it will be noted that there is a daily drop in output of short duration just after midnight. This drop is to about one third of boiler rating and lasts for about one-half hour. It has been found that following this procedure serves to crack the slag from the furnace walls thus reducing the amount of lancing required to keep the steam temperature within required limits. The output of the Chester boilers is reduced slightly on about a daily schedule to permit the operators to clean thoroughly slag from the upper third of the second open pass.

Slag Troubles

Richmond Station

The normal load at Richmond is such that practically no trouble has been encountered in tapping the furnace. With the

[1] Assistant Superintendent, Station Economy Section, Philadelphia Electric Company. Mem. A.S.M.E.

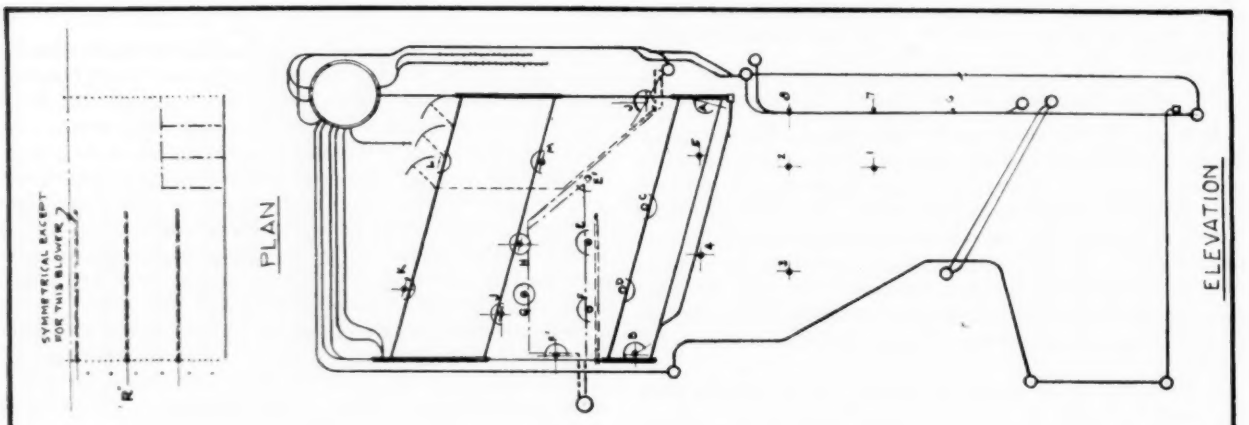


Contributed by Special Research Committee on Furnace Performance Factors with the co-operation of the Fuels, Power, and Heat Transfer Divisions and presented at the Annual Meeting, New York, N. Y., November 29–December 3, 1943, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

type of coal normally burned, satisfactory tapping can be obtained at about two thirds of rated capacity.

During the early period of operation of these boilers, considerable difficulty was experienced with heavy slag accumulations on the furnace screen and in the lower bank of generating tubes. A considerable amount of sintered ash also accumulated in the superheater. At this time the spaces between tubes in the furnace screen, which is made up of two rows of tubes, were closed over by a series of chrome cement baffles connecting tubes in the lower row with tubes in the upper row in such a manner as to form a sort of louver construction. This allowed passage for the gases but prevented the generating tubes from "seeing" the fire in the primary furnace directly. It also provided an excellent shelf for slag particles to land on once they had passed through the screen and started to fall back into the furnace or for drippings from the generating tubes to land on. Also at this time, no provision was made for mechanically cleaning in these furnace areas.



At the present time the chrome baffles are nonexistent, having had a relatively short life in the furnace and not being replaced. Retractable wall blowers using steam have been installed to remove the slag on the screen and telescopic lances using water have been installed in the lower bank of generating tubes. The regular operation of these mechanical cleaning devices, together with about 160 man-hours per week per boiler of hand lancing serves to keep these boilers in condition for almost steady operation.

Schuylkill Station

Slag tapping at Schuylkill has not been a problem with the coal normally used. The minimum satisfactory tapping load appears to be about two thirds of rated capacity.

Some trouble was experienced with slag attack on the floor tubes and on wall tubes in the section under the floor due to penetration of the furnace bottom by the molten slag. This was cor-

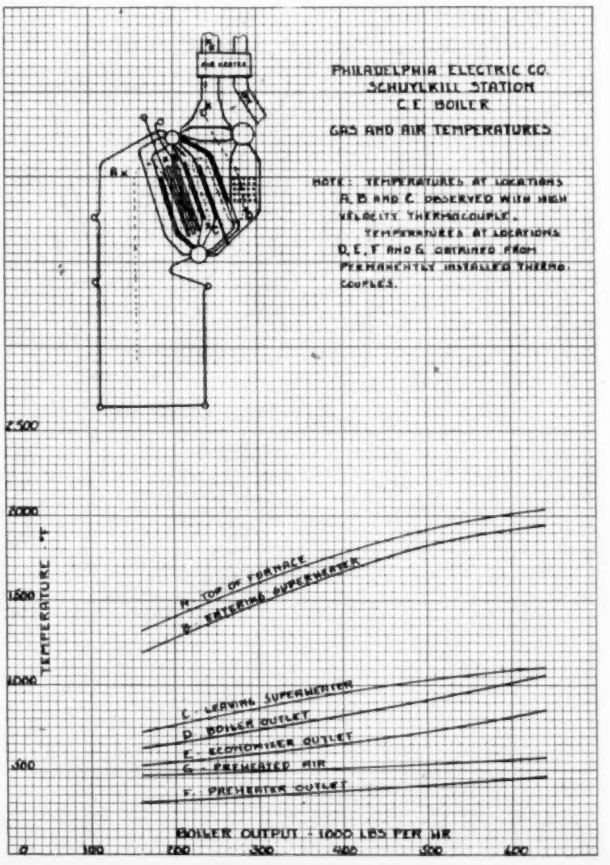
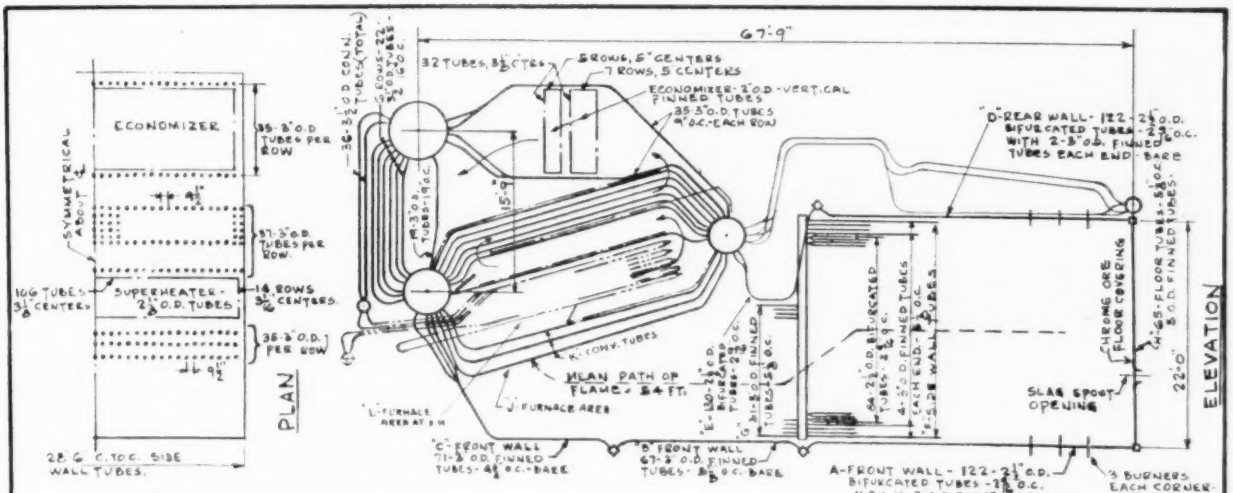
rected by using plastic chrome ore on the surface of the furnace floor instead of loose chrome ore.



It has been found necessary to keep the furnace walls of these boilers nearly slag-free because of a high superheat condition. Whether or not furnace-wall slag would otherwise accumulate in substantial amounts cannot be definitely stated. In addition to the daily drop in load, this slag is removed by hand lancing with air and water. About 20 man-hours per week per boiler are required.



A considerable amount of slag accumulates on the front bank of generating tubes and in the closely spaced superheater tubes of these boilers. This slag accumulation is in a zone not reached by the soot blowers and must be removed by hand lancing. About 60 man-hours per week per boiler are required. The normal base load for these boilers is about 90 per cent of rated capacity as can be noted from the load graph.

Chester Station

No troubles have been experienced in the removal of primary furnace slag on these boilers, with the exception that after a period of low-load operation, and therefore an increase in furnace-wall and first open-pass slag accumulation, a heavy rush of slag is experienced when the load is increased. This has not been a serious problem; the answer is found in paying somewhat more attention to slag removal on the part of the operators during such changes in load. The minimum load for satisfactory slag tapping appears to be about two thirds of rated capacity.

The problem of ash handling in the second open-pass hopper, however, has been quite difficult. Originally, this hopper was dry and slag dripping from above accumulated into large clinkers which were very difficult to remove. A hydraulic system for removal of this material is provided and the splash from the chunks of slag spalled the brick ash-hopper lining. The ash hopper was then filled with water. This served to reduce the size of the

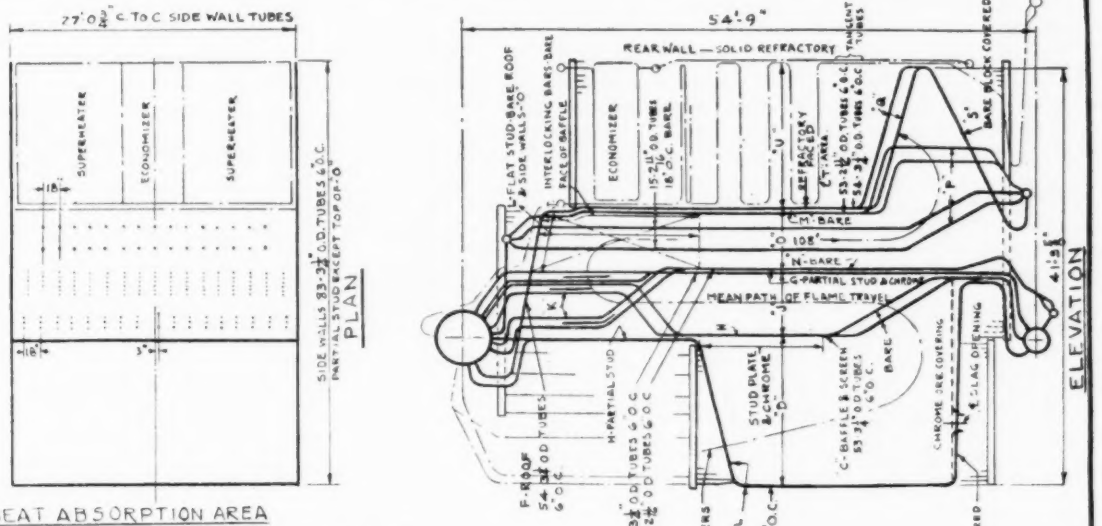
clinkers but the spalling of the brickwork continued. A steel lining for the hopper was tried and was destroyed by the acid water. At present, experiments are under way using a water-cooled cast-iron lining.



No trouble has been experienced with slag in the superheater and very little with slag on the generating tubes under the superheater. Some slag accumulates on the sloping floor under the superheater which must be removed by hand lance.

Most of the slag which must be removed accumulates on the upper third of the second open pass or in the nest of tubes at the top of the second baffle wall where the gases pass through from the first to the second open pass. At present slag accumulations in these areas are removed by hand lancing which requires about 55 man-hours per week per boiler. It is planned to install a retractable lance, using steam, in this zone in the near future, and it is hoped that most of the need for hand lancing will be eliminated thereby.

Furnace Wall Wastage

The problem of a very rapid loss of metal from furnace wall tubes was acute about two years ago. This condition was recognized first on the Philadelphia Electric Company System at Schuylkill Station. The furnace tubes of the boilers at this location were originally provided with fins, and in the course of the first two years of operation some flattening of the wall tube surface exposed to the fire and considerable loss of fin metal were noted. This was attributed, probably erroneously in view of later experience, to erosion from the coal stream and to the action of the water used in lancing the furnace walls for superheat control. It was therefore decided to change the arrangement of the furnace walls to provide tube-to-tube construction using bifurcated tubes. It was anticipated that such an arrangement would increase the furnace heat absorption and thus serve to bring the

steam temperature under better control, and so reduce the amount of lancing required. This end was accomplished in a measure but not to the extent hoped for.

Some time after the change to bifurcated tubes, the furnace was inspected and particular attention was given to discover any recurrence of the flattened-tube condition. None was noted. However, about four months later, it was necessary to take the boiler off the line on a forced outage resulting from a furnace tube leak. On inspection it was discovered that nearly all of the tubes in the lower furnace were badly wasted from the outside, and it was realized that an extensive retubing job was indicated for the immediate future. The wasted area varied from three to ten feet from the furnace floor. The tubes in the affected area were covered with a dark, hard, and firmly attached scale and an iridescent bluish material which were primarily iron-sulphite, or with a glossy yellowish green coating which was analyzed to be composed primarily of sodium and potassium sulphates and iron oxides. Several theories have been advanced as to the mechanism of the wastage and the matter remains the subject of investigation to the present time.

In order to find a practical solution to the problem exhaustive analyses of the furnace atmosphere at the wall surface were undertaken. These showed that where wastage occurred the furnace atmosphere was heavily reducing in nature as indicated by the presence of large percentages of carbon monoxide and little or no unconsumed oxygen. A means was then developed to supply air to the affected wall areas by passing the air through the space between the tubes. This had beneficial results but the air did not reach the whole affected area, and it was apparent that the real answer to the problem lay in rearranging the burners so that the atmosphere on the furnace walls would be kept on the oxidizing side. A program to accomplish this was instituted by the manufacturers of the boilers and it now appears that a much improved burner design has been obtained. The new burner has riffled edges for better coal-air mixing.

On investigation, it was found that a similar wastage condition, at a much slower rate, existed at Chester and in a limited area at the lower end of the furnace screen at Richmond. Part of the trouble at Chester and most of the trouble at Richmond appears to have resulted from infiltration at points after the furnace, which had the effect of reducing the excess air in the furnace. Experiments to the end of improving burner design and wind-box arrangement are now under way at Chester.

Gas and Air Temperatures

Curves showing gas temperatures within the furnace and at various locations throughout the boiler unit are attached for each type of boiler. A curve of preheated-air temperature is included. In all cases, combustion conditions are regulated to maintain about 15 per cent CO_2 at the boiler outlet. Each boiler is equipped with combustion control and with CO_2 recorders for this purpose.

Heat-Transfer to Water-Cooled Furnace Walls

By HENRY KREISINGER[1] and R. C. PATTERSON,[2] NEW YORK, N. Y.

THIS paper gives the results of measurements of the heat transfer to water-cooled furnace walls of two pulverized-coal-fired boiler furnaces. One of these was a slagging-bottom intermittent tap, and the other a dry-bottom furnace. Both furnaces were tangentially fired; the slagging-bottom furnace had two burners and the dry-bottom three burners in each corner of the furnace. The heat transfer was measured with small heat-absorbing units placed at different elevations in one of the walls of the furnace. Each of these units was supplied separately by water, and the quantity of heat absorbed was determined by weighing this water and measuring its temperature rise. On the tests of the dry-bottom furnace the water was supplied approximately at atmospheric pressure and 100 F, whereas on the tests of the slagging-bottom furnace the pressure was about 80 psi gage and the temperature about 70 F. The test units remained in the furnace over a period of several weeks so that the condition of their external surface was substantially the same as that of the rest of the walls.

The water-cooled walls of the slagging-bottom furnace consisted of 3-in. plain tubes spaced on $3^1/_2$-in. centers, backed up by $2^1/_2$ in. of refractory and 4 in. of insulating material. The furnace was 30 ft × 21 ft, 5 in. in cross section and averaged 49 ft, 4 in., in height between the bottom and the sloping roof. The total combustion space was 21,000 cu ft. The side walls were fully water-cooled only to the center line of the lower drum. Above this level the side walls were refractory-lined with riser tubes from the lower part of the wall placed over the refractory lining on 14-in. centers. The front wall was fully water-cooled, and the upper portion was bent over the furnace and formed the roof. The actual total frontal water-cooled surface of the walls was 4803 sq ft, of which 1411 sq ft were in the side walls, 1347 sq ft in the rear wall, and 2045 sq ft in the front wall and the roof. The actual frontal surface is the furnace half of the circumferential area of the tubes; in the fin-tube furnace it includes the front face of the fins. The total projected surface of the furnace, including the boiler, was 4470 sq ft. The projected boiler-tube surface facing the furnace was assumed to be the product of the length of the front row of tubes multiplied by the width of the furnace, which amounted to 795 sq ft. Normal rating of the steam-generating unit was 400,000 lb of steam per hour at 870 psi pressure and 825 F temperature from feedwater at 383 F.

The dry-bottom furnace water-cooled walls consisted of 3-in. finned tubes spaced on $5^1/_8$-in. centers and backed up by $2^1/_4$ in. of refractory and $3^3/_8$ in. of insulating material. The furnace was 21 ft, 10 in., × 20 ft, $1^1/_2$ in., in cross section and averaged 55 ft in height between the floor screen and the roof, and contained 19,300 cu ft of combustion space. All the walls were completely water-cooled. The actual total frontal water-cooled surface of the walls was 4613 sq ft, of which 2214 sq ft were in the side walls, 900 sq ft in the rear wall, and 1499 sq ft in the front wall and roof. The floor screen contained 740 sq ft of total surface of which one half faced the furnace and one half the ash hopper. The projected surface of the furnace including the boiler was 4460 sq ft. The projected surface of the boiler tubes facing the furnace was 645 sq ft obtained by multiplying the length of the front row of tubes by the width of the furnace. The normal capacity of the steam-generating unit was 365,000 lb of steam per hour at 860 psi, and 900 F from feedwater at 385 F.

Figs. 1 and 2 show the test units fitted into the walls of the two furnaces. Each unit consisted of extra-heavy $1^1/_4$-in. seamless pipe with $^1/_2$ × $^1/_4$-in. fins welded to its sides. The ends of the pipe were plugged and pieces of $^1/_2$-in. pipe were fitted into the back of the unit close to the plugged ends for water supply as shown in the figures. The units were 36 in. long and $2^{11}/_{16}$ in. wide, including the fins. The actual frontal surface was 121.5 sq in. or 0.844 sq ft. In addition to this frontal surface there was the surface of the plugged ends amounting to 4.33 sq in. and the $^1/_4$-in-wide band along the sides of the fins equal to 18.5 sq in. summing up to 22.8 sq in. However, this surface was much less effective in heat transfer than the frontal surface. The projected

Contributed by Special Research Committee on Furnace Performance Factors with the co-operation of the Fuels, Power, and Heat-Transfer Divisions and presented at the Annual Meeting, New York, N. Y., Nov. 29–Dec. 3, 1943, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

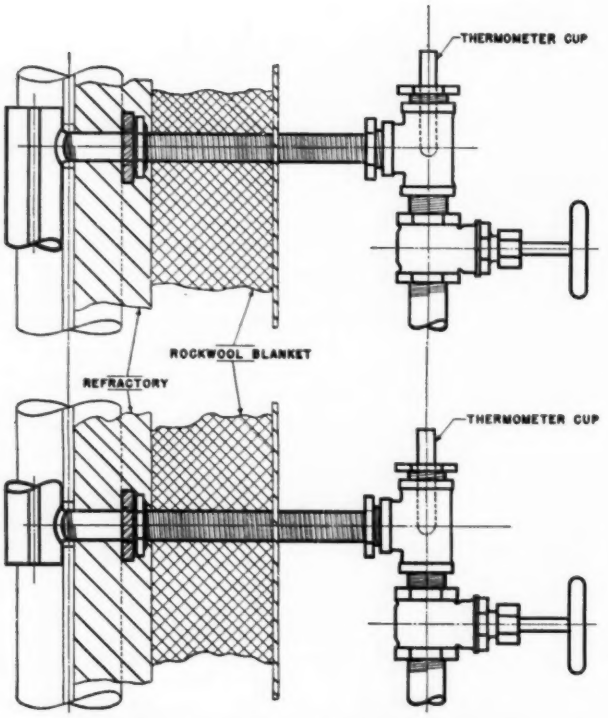

FIG. 3 TEST UNIT WITH WATER-SUPPLY LINES ASSEMBLED IN A FIN TUBE WALL FOR TEST

frontal area was 96.8 sq in. or 0.67 sq ft. The units were fitted into the walls between two adjacent tubes as shown in Figs. 1 and 2. Plastic refractory was packed into the space between the test units and the wall tubes to prevent the flow of hot gas behind the units, and to reduce the heat exchange between them and the adjacent wall tubes. Fig. 3 shows a test unit and water-supply connections with thermometer wells and control valves assembled in a fin-tube furnace wall for test.

The slagging-bottom furnace had three of these units located in the front wall at three elevations as shown in Fig. 4, designated as bottom *B*, middle *M*, and top *T*. The dry-bottom furnace had four units located in a side wall at four elevations as shown in Fig. 5 and the units were numbered from the bottom up. Pulverized coal was fired through burners located near the bottom of the furnace. The burning mixture flowed up through the furnace and imparted some of the heat generated by combustion to the furnace walls, mostly by radiation. In the slagging-bottom furnace the heat transfer was the highest near the bottom, whereas in the dry-bottom furnace it was highest just above the burner belt. The heat transfer varied with the temperature of the burning mixture and also with the cleanliness of the surface of the walls.

Readings on the test units were taken in succession, starting with the lowest and ending with the top unit. The flow of water through the test units was adjusted to a temperature rise of 40 to 70 F depending on the location of the unit. With such temperature rise, a flow of 100 lb of water in 6 to 7 min could be obtained, and a set of readings on four test units could be completed in about 30 min.

The water from the test units was piped to a common station where a weighing tank was located. While the flow of water was being adjusted to the desired temperature rise, water from all the units was discharged into a drain. When a test was started, the water from the unit on which the readings were to be taken was turned into the weighing tank. At the end of this test period the water was turned back to the drain. The period of time during which water was run into the weighing tank was measured with a stop watch. To facilitate the change of flow of water from drain to weighing tank and back again, the end of the water discharge pipe from each unit was provided with a piece of flexible hose so that the end could be quickly moved from one place to another, and thus make the time necessary for a complete set of readings as short as possible. Short periods were desirable to avoid appreciable changes in the furnace conditions between the first and last readings of each set.

With the constant rate of firing which was maintained during these tests, the principal change in the furnace conditions was the ash deposit on the walls. The effect of this ash deposit on the heat transfer depended on how soon after cleaning of the furnace walls the test readings were made. A layer of slag $^1/_{16}$ in. thick deposited on clean wall tubes had a quite marked effect on the heat transfer, whereas the same thickness of slag deposited on top of an inch layer has practically no effect.

The rate of accumulation of slag on the furnace wall varied with the height from the furnace floor. The highest rate was in the burner zone and the lowest at the top of the furnace. In the dry-bottom furnace the rate of accumulation of slag in the zone below the burners near the bottom of the furnace was also low.

To check the accuracy of the results a number of duplicate tests were made. The check tests were started immediately after the completion of the first test. Some of these check tests were on the entire set of test units and some on individual units. Usually a check test on the whole set of units showed a small decrease in the rate of heat transfer, whereas a check test on individual units showed no decrease in the heat transfer. The change in heat absorption due to slag accumulation in the dry-bottom furnace could be best observed over the period of a few hours after a thorough cleaning of the walls.

The ash deposit on the furnace walls was different in the two furnaces. In the slagging-bottom furnace the ash deposit was a thin sheet of slag extending from the bottom of the furnace to a height of 10 to 12 ft. The surface of this slag was in semiliquid condition and flowed slowly down the walls. Above this height the deposit gradually became thicker, changing from somewhat porous slag with rough surface to a spongy crusted ash near the top of the furnace. This porous slag and crusted ash was falling off in pieces so that at normal rating the deposit remained at nearly constant thickness. The furnace walls on this steam-generating unit were not cleaned during normal operation.

In the dry-bottom furnace the deposit on the furnace walls varied from a thick layer of porous slag in the burner belt through crusted ash at the elevation of the lower drum to a dusty film at the top of the furnace. Below the burner belt the deposit consisted mostly of crusted ash and dust. The walls in the burner belt and immediately above were lanced two or three times a day, depending somewhat on the kind of coal burned and the steam temperature, which in this plant was controlled almost entirely by the amount of deposit on the furnace walls. The nature of the deposits in the two furnaces is indicated by the belts *A*, *B*, *C*, and *D* in Figs. 4 and 5.

The bottom unit *B* was located in the belt where the deposit on the wall was a thin sheet of slag with the surface in semiliquid state flowing down the wall, so that the thickness of the layer remained nearly constant at any given rating. The middle unit *M* was located in a belt where the deposit on the wall was thick and sticky but did not flow; it was somewhat porous and dropped off in pieces. The top unit *T* was located in a belt where the deposit was of granulated and crusted ash which did not adhere tightly to waterwalls and small pieces were dropping off continually.

Test unit No. 2 in the dry-bottom furnace was in a belt similar

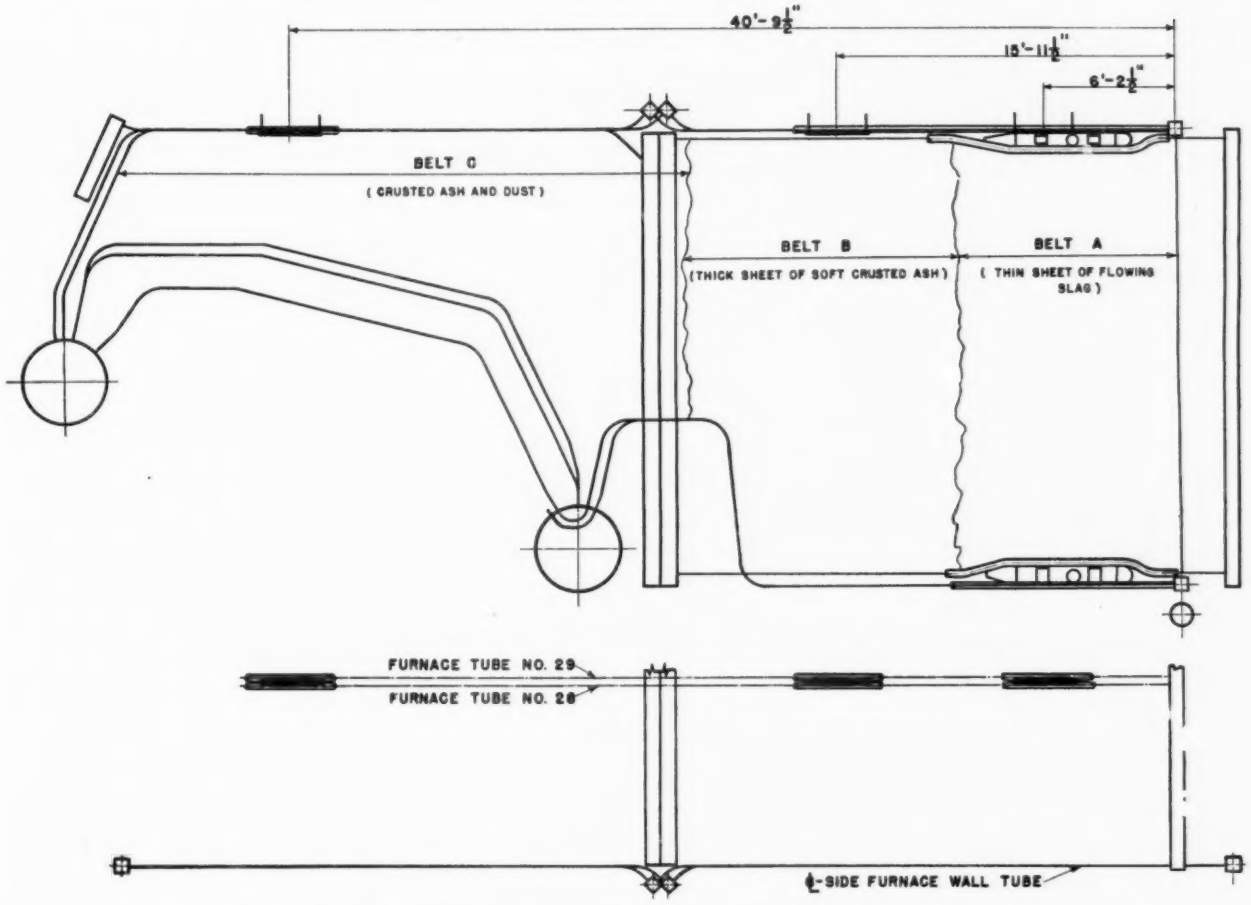

FIG. 4 LOCATION OF TEST UNITS IN THE FRONT WALL OF SLAGGING-BOTTOM FURNACE

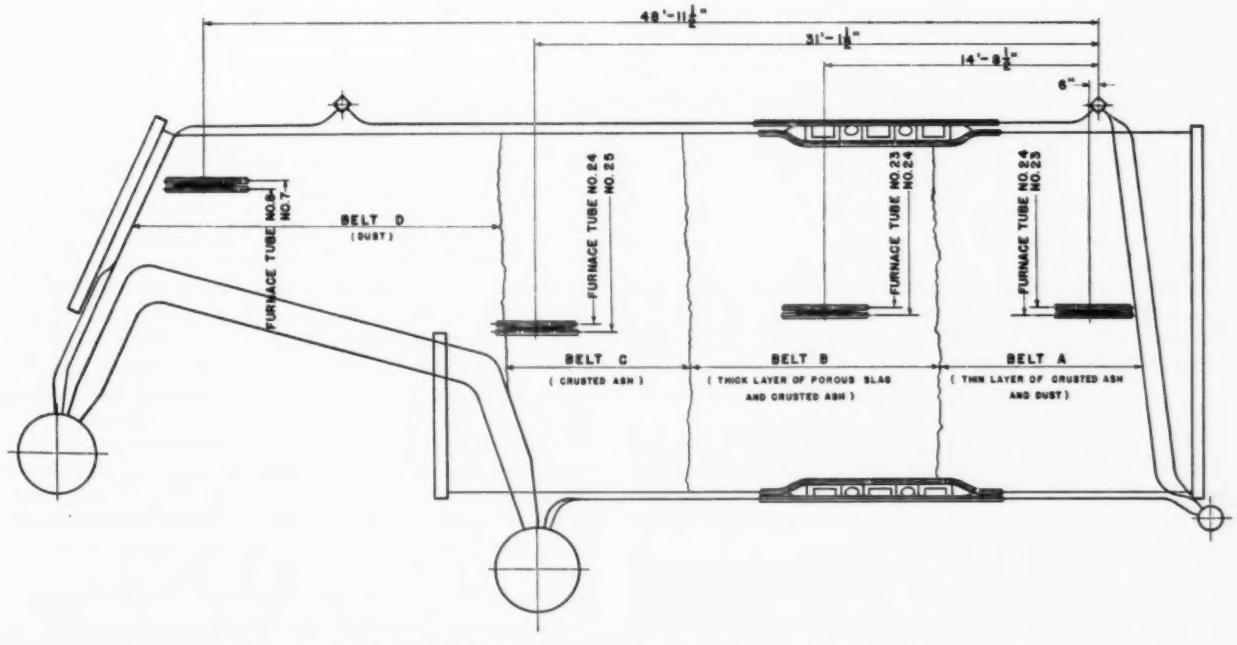

FIG 5 LOCATION OF TEST UNITS IN A SIDE WALL OF THE DRY-BOTTOM FURNACE
(Belts indicate the nature of ash deposits.)

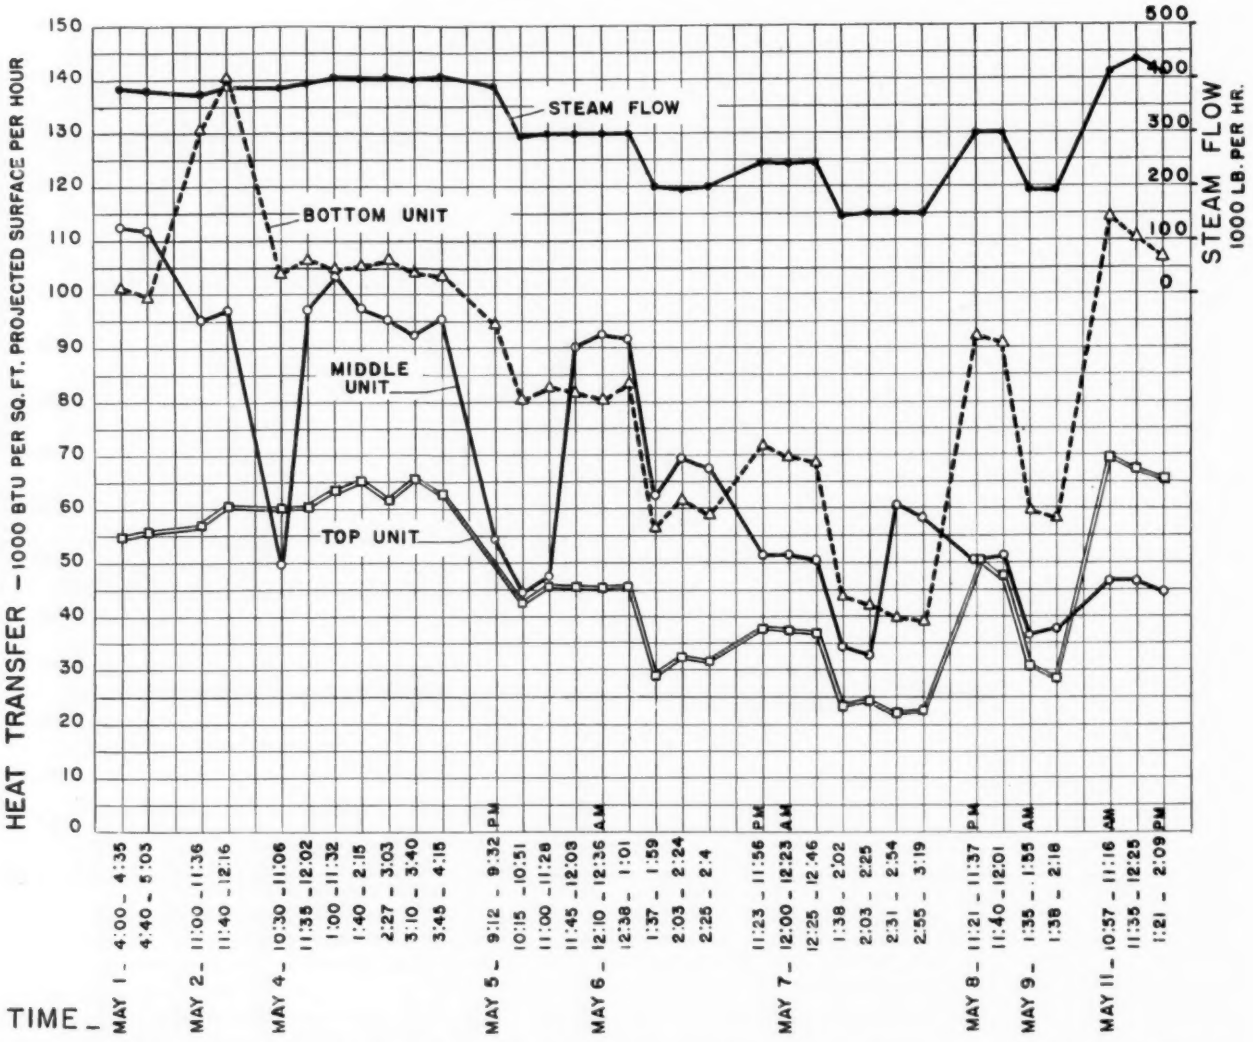

FIG. 6 HEAT TRANSFER BY THREE TEST UNITS *B*, *M*, AND *T* IN SLAGGING-BOTTOM FURNACE EXPRESSED IN 1000 BTU PER SQ FT OF PROJECTED SURFACE PER HR
(Top line is steam output in 1000 lb of steam per hour.)

to that in which unit *M* of the slagging-bottom furnace was located, and there was at times a heavy deposit on the unit. Test units Nos. 1 and 4 were in zones where the deposit was somewhat similar to that of belt *C* where unit *T* was located. The deposits were rather thin and varied only to a small extent.

On the slagging-bottom furnace a total of 37 tests were made, extending over a period of 11 days and covering steam output rates from 150,000 to 440,000 lb per hr. On the dry-bottom furnace 120 tests were made over an operating period of 56 days and covering ratings from 175,000 lb to 460,000 lb of steam per hour.

Table 1 is an illustration of the principal data collected, and the calculated results of four tests, two on the slagging-bottom furnace and two on the dry-bottom furnace. The particular four tests have been selected for illustration because they show the effect of ash deposit on the heat transfer.

When the deposit on the *M* unit was peeled off by a rod, the heat transfer was about doubled. Similarly, when No. 2 unit was cleaned with an air lance the heat transfer was increased about 50 per cent.

Fig. 6 gives the results of all the tests made on the slagging-bottom furnace, and Fig. 7 all the tests on dry-bottom furnace. The tests are plotted approximately on a time basis with gaps indicating periods when no tests were made. The ordinate is heat transfer to the test units and is expressed in 1000 Btu per sq ft of projected surface per hour. The points of the same unit of all the tests are connected by lines. The line at the top of the chart gives the steam output of the boiler in 1000 lb per hour at the time of the test. The charts give the essential results in compact form which shows at a glance some of the peculiarities.

The heat transfer varies directly with the steam output of the boiler, and inversely as the thickness of the ash deposit on the test units. The variation with the steam output would undoubtedly be definite and the results could be reproduced if the condition of the surface as to cleanliness could be kept constant. Such constant surface condition could be obtained with natural gas but is impossible with pulverized-coal firing, where the ash is continually deposited on the surfaces and runs down in some places and drops off intermittently in small pieces or in patches in other places. If a test is to be checked, the check test must be made immediately after the first test has been completed, before appreciable changes have taken place in the surface condition.

The heat transfer to the test units is somewhat higher than the

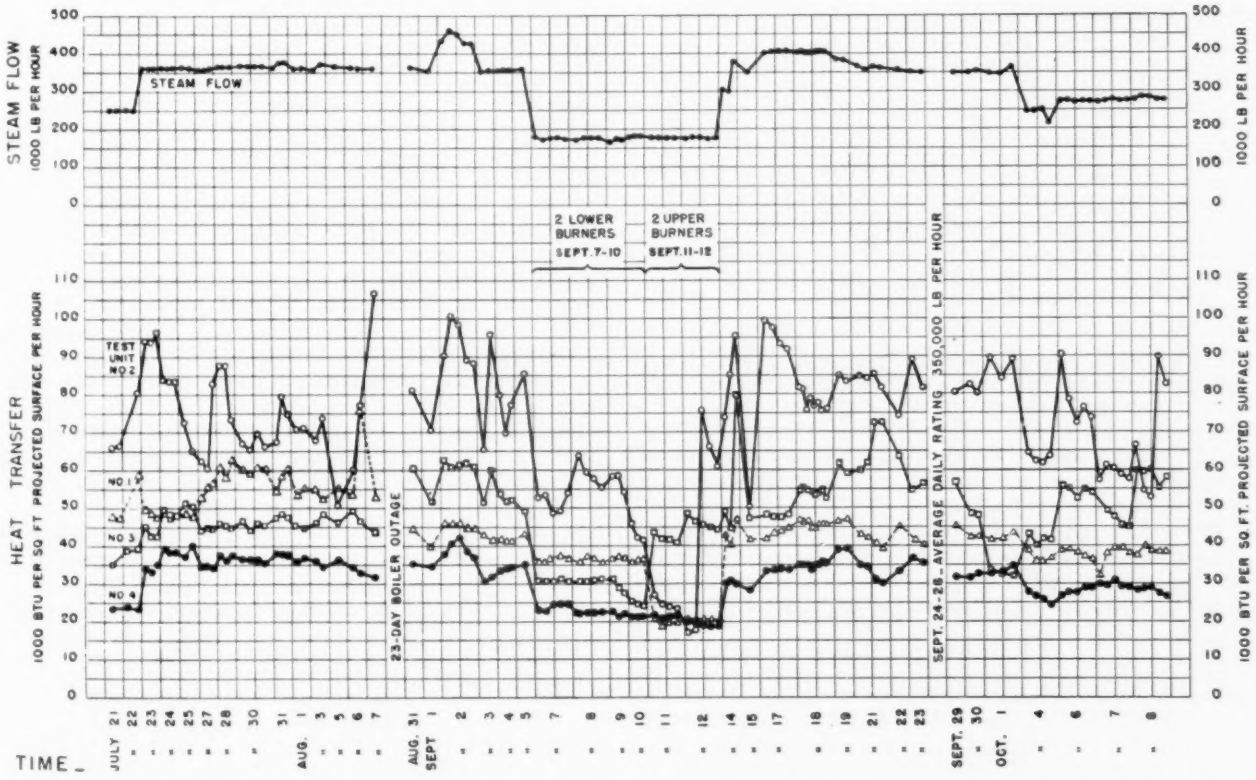

FIG. 7 HEAT TRANSFER BY FOUR TEST UNITS, NOS. 1, 2, 3, AND 4 IN THE DRY-BOTTOM FURNACE EXPRESSED IN 1000 BTU PER SQ FT OF PROJECTED SURFACE PER HR

(Top line is steam output in 1000 lb of steam per hour. September 5–10, the lower two of the three burners in each corner were in operation; September 10–12, the upper two burners were in operation.)

heat transfer to the waterwall, because the temperature of the test units is lower than the temperature of the furnace wall tubes. However, the difference is small, particularly in the hot part of the furnace. The average temperature of the metal surface of the test units was about 250 F and the average temperature of the furnace wall tubes was about 550 F. Heat is transmitted from the flame to the surface of the ash deposit on the tubes mostly by radiation, and through this ash deposit it is transmitted to the metal of the tube mostly by conduction. The heat transmitted by radiation is proportional to the difference between the fourth power of the absolute temperature of the flame and the fourth power of the absolute temperature of the surface of the ash deposit. The heat transmitted by conduction is proportional to the difference between the temperature of the surface of the ash deposit and the temperature of the tube metal, and inversely proportional to the thickness of the ash deposit.

Fig. 8 shows the path of the heat travel from the flame to the furnace-wall tube and also to the test unit. Although the temperature of the test unit is 300 deg lower than that of the wall tube, the thickness of the ash deposit on the test unit is almost enough thicker to offset the lower temperature. In the hot part of the furnace, particularly of the slagging-bottom furnace, the ash accumulates until the outer layer is far enough from the cooling effect of the tube so that it becomes molten and

flows down the wall. The greater cooling effect of the test unit requires a little thicker layer of ash to produce a flow of molten ash down the test unit. The amount of ash removed by this flow is equal to the amount deposited on the surface and, as a result, the thickness of the deposit remains constant. Similar equilibrium condition of the ash deposit is reached in other parts of the furnace where the ash drops from the wall in pieces. The

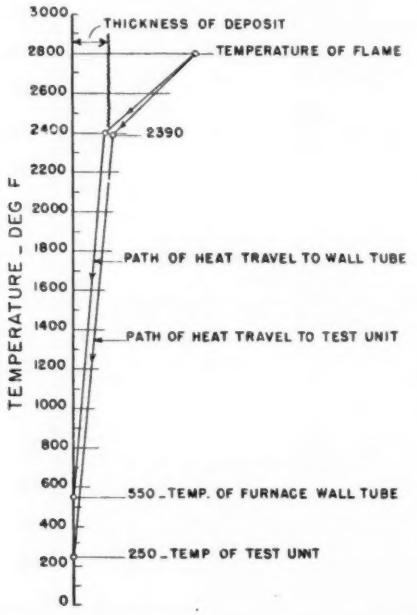

FIG. 8 PATH OF HEAT TRAVEL FROM FLAME TO SURFACE OF ASH DEPOSIT AND FROM THIS SURFACE TO THE METAL OF THE WALL TUBES AND TEST UNIT

surface of the deposit is rough and the dropping occurs from the protrusions where the ash is hotter and softer, and for that reason the pieces break off easily.

In Fig. 8 the ash deposit of the test unit is shown somewhat thicker than that of the wall tubes. The temperature of the surface of the ash deposit on the test unit is shown 10 deg lower to indicate the very small difference in heat transfer.

The ash deposit on the furnace walls is the greatest factor affecting the heat transfer from the flame to the furnace walls. The factor varies over a wide range and is difficult to ascertain for any given set of conditions. It varies with the composition and physical properties of the ash, the method of firing, the burner adjustment, excess of air, and fluctuation of load. All these factors affect the thickness and the conductivity of the ash deposit.

The uncertainty of the ash deposit factor makes calculation of the temperature of gases leaving the furnace and entering the superheater questionable. There are no reliable formulas or methods for such calculation. It is safer to base the design of a superheater on direct temperature measurements in a similar furnace burning similar fuel and operating under similar load conditions. Variation of load changes the ash deposit. Sudden reduction of load lowers the furnace temperature which usually causes the ash deposit to drop off in patches. To what extent the furnace walls can be stripped of the ash deposit depends largely on the length of time the furnace is operated at low rating. In some plants it is regular practice to reduce the load to one half or one third of the normal rating for one hour to remove a large part of the ash deposit.

The falling of the ash deposit in patches may cause local overheating. It has been shown that by peeling off the ash deposit on test unit *M*, Table 1, the heat transfer has been doubled. Another case of greatly increased heat transfer by the removal of the ash deposit is shown in Fig. 9. In this case the waterwalls consisted of small tubes 1.25 in. outside and 0.92 in. inside diameter spaced on 1.375-in. centers. Water entered the tubes at 1700 psi pressure and at saturation temperature with a velocity of $4^1/_2$ fps. Three groups of four thermocouples were attached to the surface of the tubes about $2^1/_2$ ft above the bottom of the furnace. The tubes normally had an ash deposit about $^3/_4$ of an inch thick with a surface in semiliquid condition, and the thermocouples indicated a temperature of 10 to 50 deg above saturation. As shown in Fig. 9, when the ash deposit was peeled off the tubes in the location of two of the three groups of thermocouples, the temperature indicated by these couples became 116 to 172 deg above saturation temperature. The uncovered tube surface received so much more heat from the flame that its temperature was raised over 100 deg F to transmit this large quantity of heat to the water inside of the tubes.

The high heat transfer obtained by uncovering furnace-wall

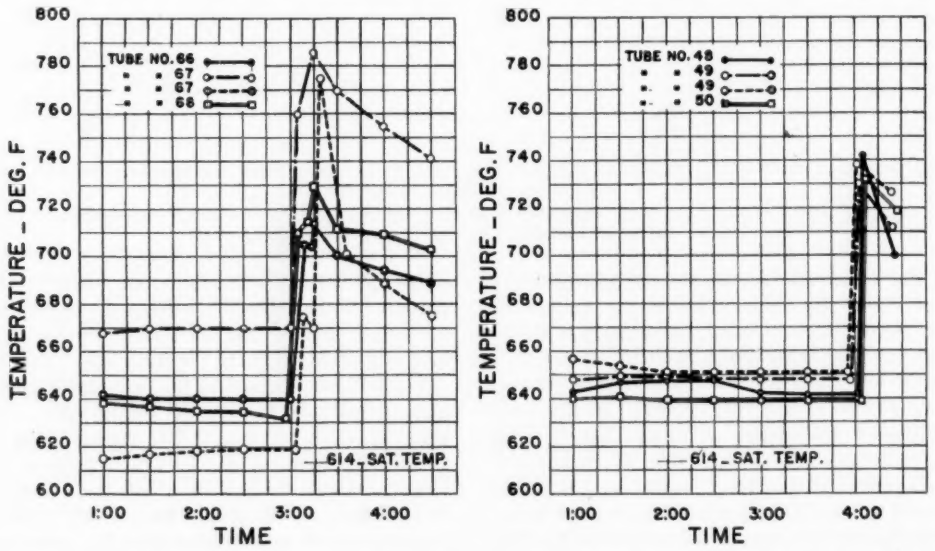

FIG. 9 RISE IN TEMPERATURE OF FURNACE WALL TUBES WHEN THE ASH DEPOSIT WAS PEELED OFF THE WALL

tubes may explain some of the failures from overheating and blistering of furnace tubes. Usually when the heat transfer is increased by higher rating on the boiler, the increase in the heat transfer is nearly uniform the full length of the tubes and there is an increase in the circulation which facilitates the transfer of heat from the metal of the tube to the water, and thereby makes overheating of the tube less probable. If the tube is covered with an ash deposit of nearly uniform thickness for its full length, and a patch of this deposit drops off, the heat transfer of the uncovered part is greatly increased. However, as the increase in the heat transfer is only over a small part of the tube it does not cause a corresponding increase in circulation, and the uncovered part of the tube may become overheated and blistered. The overheating and blistering is more likely to occur if the uncovered part of the tube is near the top end, because in such case the additional steam made by the uncovered part of the tube passes through only a short length of the tube with practically no effect on the circulation. If, however, the uncovered part is at the lower end of the furnace tube, the additional steam made by the increased heat transfer passes through nearly the full length of the tube and markedly increases the circulation, and thereby the heat transfer from the metal of the tube to the water, with less chance of the tube becoming overheated.

The average of the heat transfer to the test units of a number of tests made at the same rating on the boiler, is probably close to the average of the heat transfer to the belts of the furnace walls where the test units were located. This statement is truer of the dry-bottom furnace tests because the furnace walls were cleaned systematically.

The calculation of the average heat transfer for the entire furnace from the heat transfers of the test units would be difficult and the results of such calculations would be doubtful. The heat transfer to each test unit would have to be given the proper weight proportional to the area of the furnace walls which they represent and the determination of this weight factor would be largely a matter of opinion. It should be kept in mind that the area of the projected surface of the test units was a very small part of the total area of the furnace walls. Thus, the projected area of the four test units used in the dry-bottom furnace was 2.7 sq ft, whereas the projected surface of the furnace walls was 4460 sq ft. Each square foot of the test units represented 1650 sq ft of the furnace walls. The question is: How well did one square foot of the test units represent the 1650 sq ft of the furnace walls? Some of the surface in the furnace wall transmitted 100,000 Btu and some other surface only 30,000 Btu per sq ft per hr.

Measuring heat transfer to furnace walls by test units is like measuring temperature of a gas stream having a large cross section. For example, in a large boiler the gas stream leaving the furnace may be 300 sq ft in cross section. If the temperature of the gases is measured with a thermocouple the area of the part of the gas stream that surrounds the hot junction of the couple is about one square inch. If the temperature is measured at 36 points the area covered by the measurements is 36 sq in. or $^1/_4$ of a sq ft. This area is only $^1/_{1200}$ part of the area of the cross section of the gas stream. Usually the range of temperature variation across the gas stream is much smaller than the range of the heat transfer to the furnace walls so that the average of these measurements may be very close to the actual temperature of the gas stream.

In addition to the large variation of the heat transfer with the height in the furnace, there is a variation around the belt. With any method of firing there may be areas of the furnace walls which are swept by flame more than others and consequently have a higher heat transfer. Areas in the middle of the wall are more exposed to the flame than the areas in the corner of the furnace and therefore receive more heat.

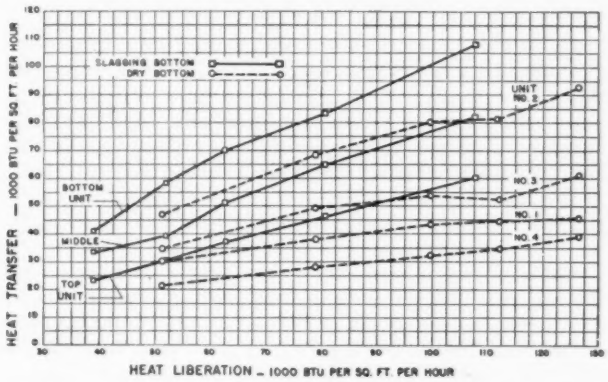

FIG. 10 HEAT TRANSFER OF TEST UNITS PLOTTED ON THE BASIS OF AVERAGE HEAT LIBERATION PER SQ FT OF PROJECTED SURFACE OF FURNACE WALLS

(The points are the averages of all tests made at the same heat liberation. Points of the same test units but of different heat liberation are connected by lines, a solid line being used for slagging-bottom furnace and broken line for dry-bottom furnace.)

Fig. 10 gives the heat transfer of the test units in the two furnaces plotted on the basis of the rate of heat liberation. The points in the chart are the average of all the tests made at the same rating. The points of different heat liberation of the same unit are connected by lines; a solid line is used to connect points of the slagging-bottom furnace, and a broken line the points of the dry-bottom furnace. The rate of heat liberation is the average per square foot of projected furnace walls per hour and was obtained by multiplying the steam flow by a factor. For the slagging-bottom furnace this factor was 0.272 and for the dry-bottom furnace 0.286. The rate of heat liberation was much higher near the bottom and lower at the top of the furnace. It will be noted that the bottom test unit in the slagging-bottom furnace shows heat transfer about equal to the average rate of heat liberation. It is probable that 95 per cent of the heat was liberated within the first 10-ft height of the furnace so that the actual rate of heat liberation of the belt of the bottom test unit might have been three times the average of the whole furnace.

The average heat transfer of the three test units in the slagging-bottom furnace is too high because the bottom unit, which has very high heat transfer, represents a very much smaller wall surface than the top unit which shows low heat transfer. The average heat transfer of the four units in the dry-bottom furnace is much closer to the average heat transfer of the furnace walls.

Discussion

W. E. CALDWELL.[3] A study of the heat absorbed by the test elements in the slagging furnace, as shown in Fig. 6 of the paper, affords useful information for evaluating furnace performance. The absorption curve for the upper test element follows quite closely the variations in boiler output, which would seem to indicate that it was relatively free from fouling. The absorption by the bottom element, however, appears to vary quite independently of the boiler output curve, indicating that it is probably more sensitive to variations in the slag coating than to variations in furnace heat input. The lower element, if clean, would probably receive 3 or 4 times as much heat as the upper element, due to the larger convection component and the greater heat concentration in the region of the burners. Obviously, the burner arrangement is a major influence in the heat distribution and absorption rate within the furnace and there is some room

[3] Mechanical Plant Engineer, Consolidated Edison Company of New York, Inc., New York, N. Y. Mem. A.S.M.E.

for improvement in this connection. Experience with tangentially fired furnaces indicates that better over-all results may be obtained by increasing the height of the burners and increasing the number of coal nozzles. With more conservative burner design, furnace conditions may be substantially improved by increasing the diameter of the firing circle, without impairing the high combustion efficiency which characterizes tangential firing. An upper limit of about 3000 lb of coal per nozzle per hr seems justified. For large direct-fired units this introduces complications since it necessitates subdividing coal and air streams between mills and burner. With appropriate arrangement the flame may be directed along the walls, thus increasing the convection component of heat absorption without causing tube wastage. The average rate of absorption by the furnace walls may be increased, while the extremes are reduced, which aids in maintaining cleaner walls and better over-all performance.

H. F. Mullikin.[4] The writer would like to concur in certain statements made by the authors. They state: "The uncertainty of the ash-deposit factor makes calculations of the temperature of gases leaving the furnace and entering the superheater questionable. . . . . It is safer to base the design of a superheater on direct temperature measurements in a similar furnace burning similar fuel and operating under similar load conditions. . . . . Usually the range of temperature variation across the gas stream is much smaller than the range of the heat transfer to the furnace walls. . . . ."

In a paper published 9 years ago[5] test data were given on ten boiler furnaces. Experiments were made using a number of test procedures including radiation calorimeters or "thermaprobes." The thermaprobe consisted of a flat-faced hollow steel block located in the furnace walls through which water was circulated to absorb the radiant heat. It was discarded as unsatisfactory for the following reasons: (1) Limitation as to number and location of openings which may be made in the furnace walls; (2) difficulty in controlling the water flow at a constant value; (3) difficulty of operating more than one thermaprobe at the same time; (4) lag in responsivity during time intervals in which furnace conditions change; (5) difficulty in obtaining the same amount of slag on the thermaprobe that existed on the furnace tubes, or of allowing for it by correction, and (6) possibility of considerable error due to peculiar local conditions.

Because of the foregoing objections thermaprobes were not used and the ten boiler-furnace units were tested by measuring furnace outlet temperatures by means of the high-velocity thermocouple.

Victor Paschkis.[6] In Fig. 10 of the paper, heat liberation is plotted as abscissas and heat transfer as ordinates both being expressed in 1000 Btu per sq ft per hr. Taking for example the heat transfer of 52,000 Btu, the heat liberation is shown to be 21,000 Btu. Evidently part of the liberated heat is lost. It will be helpful if the authors would state what happens to the lost energy.

Authors' Closure

Mr. Paschkis asks the question of what becomes of that part of the heat liberated in the furnace which is not absorbed by the furnace wall. On the average, about 50 per cent of the heat liberated in the furnace is absorbed by the water-cooled furnace walls. The remaining 50 per cent is held in the products of combustion mostly as sensible heat, when the products leave the furnace. As the products pass over the superheater, convection tubes of the boiler, economizer, and air heater, additional 35 to 40 per cent of the heat is absorbed, so that the total heat absorption is 85 to 90 per cent of the heat in the fuel fired.

It is essential that the products of combustion contain enough heat at sufficiently high temperature when they enter the superheater to give the desired superheat.

Absorption of Heat by Walls of a Furnace

By JOHN BLIZARD,[1] NEW YORK, N. Y.

This paper gives an account of the direct measurement of the rate of absorption of energy by the walls of a furnace, which were composed of brick, and of superheater tubes. It was also found possible to estimate the average temperature at which the gas left the furnace from the input energy to the furnace, the amount of energy absorbed by the superheater, and the composition of the flue gas and oil.

WHEN fuel burns in a furnace, heat is transferred from the products of combustion to the walls of the furnace, mainly by radiation. The rate at which it is being transferred may be determined by measuring the difference between the rate of flow of the energy of the fuel and air to the furnace, and the rate of flow of the energy of the products of combustion from the furnace. The determination of the rate at which energy is supplied to the furnace presents few difficulties; but the determination of the rate at which the energy leaves the furnace requires the measurement of the temperature and composition of the gas at many points over a large area. It happens occasionally that the rate of absorption of energy by the walls of the furnace may be measured directly, and this paper gives an account of such measurements made on a furnace, the walls of which were composed of brick, and of superheater tubes. It has been found possible also to estimate the average temperature at which the gas left the furnace from the input of energy to the furnace, the amount of energy absorbed by the superheater, and the composition of the flue gas and oil.

Boiler Used in Experiments, and Procedure

The boiler used for these experiments is shown in Fig. 1. It is fired by oil and has two furnaces. At the left is a furnace bounded on the sides by superheater tubes, and below the main bank of boiler tubes is another furnace. The products of combustion from the superheater furnace pass over two rows of superheater tubes and four rows of boiler tubes before entering the main furnace, whence they proceed through the main bank of boiler tubes to the economizer and uptake. The gases from the main furnace pass over the main bank of boiler tubes and economizer tubes before reaching the uptake. It is intended in this paper to consider only the relation between the rate of firing, the excess air, and the rate of heat absorption in the superheater furnace. Some particulars of the superheater furnace are given in Table 1.

TABLE 1 SUPERHEATER-FURNACE DATA

Volume of furnace, cu ft	358

Outside diameter of superheater tubes, in.	1.5
Number of tubes	108
Average pitch of tubes on outer wall, in.	1.6
Average pitch at outlet from furnace, in.	3.2
Number of passes for steam	4

During the tests, the total supply of oil and water to the boiler was weighed and the distribution of the oil between the two furnaces was estimated from the relative values of the pressure of the oil at the two sets of burners, and the number of burners in use in each furnace.

The enthalpy of the steam entering the superheater was measured by a throttling calorimeter, and its enthalpy leaving was determined by measuring its temperature and pressure. The composition of the gas leaving the economizer was measured at eight points, and was used, in conjunction with the weight and composition of the oil supplied to the furnaces, to calculate the total supply of air to both furnaces. Dampers had been provided to enable the pressure of the air before the registers of the burners of each furnace to be varied separately, and from the relative values of the number of burners used in each furnace and the drop of pressure of the air across each set of burners, it was possible to estimate the proportion of air going to each furnace. A few samples of the gas were taken on its path from the superheater furnace to the main furnace by means of a water-cooled sampler. However, it was felt that, in view of the somewhat wide variation in the composition of the gas at various points leaving the economizer, the composition of the gas determined at a single point between the two furnaces would be an unreliable measure of the mean composition of the gas leaving the superheater furnace. No combustible was detected in the gases leaving the economizer; but this does not assure us that combustible was not present in the gases leaving the superheater, although there is some reason to suppose that combustible was seldom present since none was detected in the few samples taken with the water-cooled sampler from the space between the two furnaces.

The boiler was required to deliver steam at 700 F and 575 psia when using the same-size sprayer plates on both sets of burners. During the first series of six tests, 84, 85, 86, 92, 94, and 100, the temperature of the steam on five runs varied between 697 F and 703 F, while on the sixth it reached 719 F. A second series of four tests, 101 to 104, inclusive, was made with the intention of delivering steam at 850 F. Actually, it varied from 834 to 866 F. The fuel oil used on the latter series of runs differed but slightly from that used on the first series, as shown in Table 2.

TABLE 2 PROPERTIES OF OIL FUEL

	Tests (six), Nos. 84–100 per cent	Tests (four), Nos. 101–104 per cent

Calorific value, net, Btu per lb	17770	17730
Minimum air/oil	13.8	13.9
Minimum air/10,000 net Btu in oil, lb	7.77	7.83

Results of Tests

Table 3 gives the principal results of the tests. The rates of firing and rates of heat absorption per square foot are given per square foot of projected area (168 sq ft).

The rate of heat absorption by convection (item 5) was estimated from the rate of flow of gases over the two rows of superheater tubes and from the temperature of the gas leaving the superheater. The average temperature of the gas leaving the superheater (item 15) was calculated by equating the enthalpy of the gas leaving the superheater to the difference between the

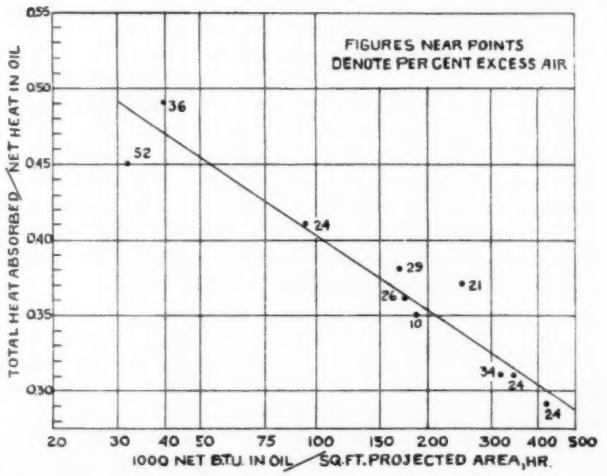

FIG. 2 RELATION BETWEEN FRACTION OF HEAT IN OIL WHICH WAS ABSORBED BY SUPERHEATER AND RATE OF HEAT LIBERATION IN SUPERHEATER FURNACE

energy entering with the fuel and the heat absorbed by the superheater per unit weight of gas.

The temperature, which the products would have reached with adiabatic combustion at atmospheric pressure (item 13), was calculated from the excess air (item 18), and the composition and heating value of the fuel. Allowance was made for the dissociation of the steam and carbon dioxide at this temperature. For convenience it will be called the "adiabatic" temperature.[2]

[2] The adiabatic temperature was used in the paper, "Heat Transmission in Steel-Reheating Furnaces," by J. E. Eberhardt and H. C. Hottel, Trans. A.S.M.E., vol. 58, 1936, pp. 185–193.

The mean temperature of the products of combustion after giving up heat by radiation, but not by convection, while crossing the two rows of superheater tubes (item 14), was calculated from the temperature of the gas leaving the superheater (item 15) and from the calculated absorption of heat by convection.

The radiation factor K is based on the equation

$$-\left(\frac{q}{T-T'}\right)\frac{dx}{ds} = K\,(x^4 - a^4) \qquad \ldots\ldots [1]$$

from which

$$K = \left(\frac{q}{T-T'}\right)\frac{1}{2a^3}\left[\frac{1}{2}\log_e\frac{x+a}{x-a} + \tan^{-1}\frac{x}{a}\right]_{x=T}^{x=T'} \qquad \ldots\ldots [2]$$

where

q is rate of heat absorption by radiation per unit projected area

s is ratio of time taken to reduce temperature of products of combustion from T to x, to time taken to reduce them from T to T'

T is adiabatic temperature of products of combustion, deg R

T' is temperature of products of combustion after radiating to superheater, deg R

x is temperature of products of combustion, deg R, which are assumed to begin to radiate when $x = T$, and to continue to radiate to the superheater until $x = T'$ when products leave furnace

a is average temperature, deg R, of the outside wall of tube receiving radiation. This temperature was calculated from rate of absorption of radiation, thermal conductivity and, dimensions of tube and from heat-transfer coefficient from inner wall of tube to steam.

Fig. 2 shows the relation between the proportion of the energy fired, which was absorbed by the superheater, by radiation and convection (item 7), and the logarithm of the rate of firing. The numerals near the points in the figure show the excess air present. Actually, it was found possible to increase the superheat by as much as 30 deg by reducing the supply of air to the superheater furnace, while still maintaining the same flow of steam through the superheater, and the same flow of oil to the burners. But Fig. 2 discloses no consistent relationship between the absorption and excess air for the same rate of firing for the different tests.

Fig. 3 shows the relation between the logarithm of the rate at which heat was absorbed by the superheater and the logarithm of the absolute temperature at which the gas left the superheater. It will be seen that, for the four runs at the highest rates of heat absorption, the rate of heat absorption was approximately proportional to the fourth power of the absolute temperature at which the gas left the superheater, and in fact it is approximately equal to the rate of radiation from a black body at the temperature at which the gas left the superheater. But at the two lowest

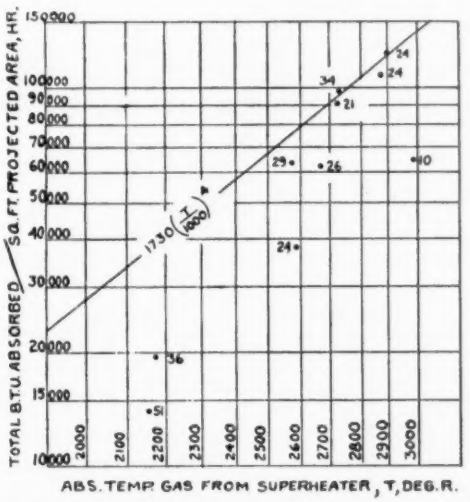

FIG. 3 RELATION BETWEEN INTENSITY OF ABSORPTION OF HEAT BY SUPERHEATER AND MEAN TEMPERATURE AT WHICH GASES LEFT SUPERHEATER

(Figures near points denote excess air.)

rates of firing, the absorption was only about one half that corresponding to full radiation at the temperature of the gas leaving the superheater.

It will be observed that for test 100, with only 10 per cent excess air, the calculated temperature of the gas leaving the superheater (2990 deg R) was very high for the observed rate of absorption (65,000), and it is probable that during this run combustible was present in the gas leaving the superheater, so that the temperature of the gas actually was less than that calculated on the assumption that no combustible was present.

Figs. 4 and 5 show the relation between the rate of absorption by radiation only (item 6), the rate of firing, adiabatic temperature, and the temperature reached by the gas after giving up heat by radiation only.

Fig. 4 shows that the radiation factor K increased with the rate of firing, and approximately

$$K\,10^9 = 0.54 \log (Q/17{,}000) \ldots [3]$$

where Q is the net Btu fired per square foot of projected area. Certainly this relation does not apply to rates of heat input below those used on the tests, since K would become equal to zero when Q had a finite value of 17,000, corresponding to a rate of firing of 175 lb per hr of oil. In fact, further difficulties in the use of this relation would arise, since it gives a minimum value for Q/K when Q is as high as 46,000 Btu per sq ft per hr. This would mean that, for a particular temperature of the tube and ratio of air to fuel, the minimum temperature of the gas, after radiating to the tube, would be reached when firing as much as 46,000 Btu per sq ft per hr, which is contrary to common experience.

In Fig. 5, the ratio of the rate of absorption of radiation to the fourth power of the absolute temperature at which the gas left the furnace is plotted on a

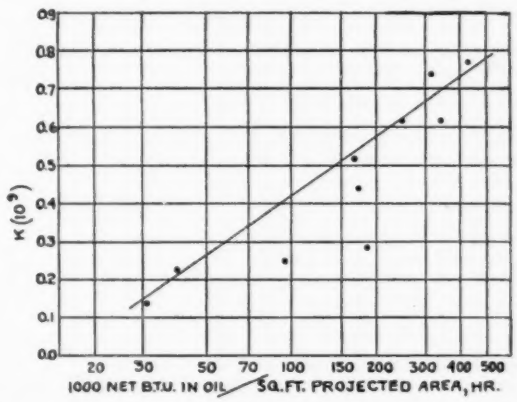

FIG. 4 RADIATION FACTOR K, AT VARIOUS RATES OF FIRING

base representing the rate of firing, and it will be observed that this ratio increased with the rate of firing.

It thus appears that if we assume the radiation to be proportional to the fourth power of the mean absolute temperature of the products of combustion, as defined by K and shown in Fig. 4, or to the fourth power of the absolute temperature, at which the gases left the furnace, as in Fig. 5, we must also assume that the radiation varies with the rate of firing. Actually, the radiation in a furnace is partly that due to chemiluminescence, which is approximately proportional to the amount of fuel burned, and mainly that due to thermal radiation.[3]

The amount of radiation from a molecule of carbon dioxide or steam from the time of its formation to the time when it leaves the furnace involves very many factors. These factors include its position in the furnace, when formed, and its subsequent path through the furnace, both of which will be affected by the turbulence in the furnace. At the lower rates of combustion it is probable that the gas did not sweep through the whole of the furnace as thoroughly as it did at high rates. This would mean

[3] "Radiation From Non-Luminous Flames," by H. C. Hottel and V. C. Smith, Trans. A.S.M.E., vol. 57, 1935, pp. 463–470.

that, at these lower rates of firing, some parts of the furnace contained stagnant gas, and that the active flame was smaller, both of which would reduce the total radiation from the flame to the superheater.

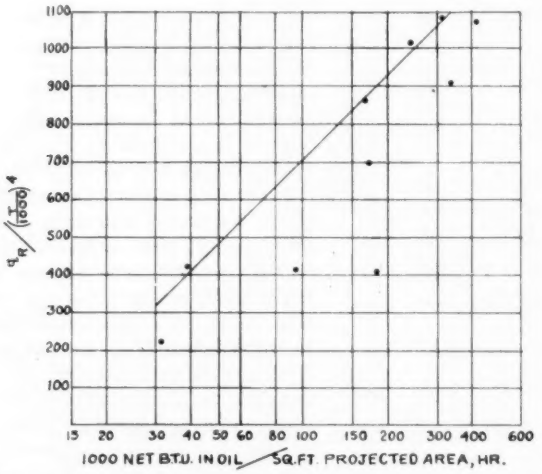

FIG. 5 RELATION BETWEEN RATIO OF HEAT ABSORPTION BY RADIATION PER SQUARE FOOT OF PROJECTED AREA (q_r), TO FOURTH POWER OF ABSOLUTE TEMPERATURE OF GAS LEAVING FURNACE AND RATE OF HEAT LIBERATION IN SUPERHEATER FURNACE

H. F. MULLIKIN.[4] There are comparatively few steam-boiler furnaces with the furnace circulation so arranged as to measure furnace radiant heat transfer directly. In the tests given in the present paper this was possible because the furnace under test consisted of a radiant superheater.

[4] Department of Mechanical Engineering, College of the City of New York, New York, N. Y. Mem. A.S.M.E.

In 1934 some data on six units similarly tested were reported.[5] These units consisted of boiler furnaces in which the furnace circulation was separate from the main boiler circulation.

Unfortunately this method of obtaining data can be used only in specific units and is not generally applicable to all furnace units.

A method of measuring furnace heat-transfer frequently used in investigating heat absorption in boiler units[6] and applicable to any unit consists of measuring furnace-outlet gas temperatures and calculating a furnace heat balance.

Mr. Blizard's Fig. 3, indicating nearly black-body furnace radiation at high loads, is in accord with findings of the writer.

AUTHOR'S CLOSURE

The inclusion in Dr. Mullikin's discussion of references to two valuable papers on absorption of radiation in furnaces and his reminder that he found nearly black-body furnace radiation at high loads enhances the value of the paper.

The suggestion that radiation to the walls of a furnace may be that of a black body at the temperature at which gas leaves a furnace occurs in Bureau of Mines Bulletin[7] 22, which was published in 1923.

But the present paper shows, as may be seen in Fig. 5, that the ratio of the rate of absorption of radiation to the fourth power of the absolute temperature at which gas left the superheater furnace was by no means constant but more than doubled when the rate of firing increased in the proportion of 400 to 40.

The Flow Characteristics of Coal-Ash Slags in the Solidification Range[1]

By W. T. REID[2] and P. COHEN,[3] PITTSBURGH, PA.

Data on the flow properties of coal-ash slags below the temperature where crystals separate from the melt on cooling have not been available previously. This paper, which is presented as a report for the Special Research Committee on Furnace Performance Factors, describes the behavior of slag under these conditions, and shows that coal-ash slags act in a similar manner to comparable systems at ordinary temperatures. The viscometer used in a previous study was modified to include a motor drive, and was of the conventional concentric-cylinder type; a reducing atmosphere was used to control the state of oxidation of the iron forms in the slag. The temperature where an abrupt increase in viscosity occurs as the result of slight cooling is called the "temperature of critical viscosity." It is shown to be caused by the presence of solids in the melt and is lower than the "liquidus" temperature. Its importance in fixing the flow characteristics of slags is given, as well as a figure relating the temperature of critical viscosity with composition and with the state of oxidation of the iron forms in the slag. Similar relationships are also given for the freezing temperature of coal-ash slags. Comparison of cone-fusion data of 35 slags with the equilibrium values of slag viscosity shows that the viscosity is not constant for any given state of deformation of cones, although a relationship between the cone fluid temperature and absolute viscosity is given which is useful as a rough guide in predicting the viscosity of slags from the cone-fusion data. Also, within wide limits, the cone-softening temperature is an approximate indication of the temperature of critical viscosity. A nomogram is given by which the viscosity of coal-ash slags can be predicted from the composition. A brief discussion of the factors affecting the equilibrium thickness of slag deposited on heat-receiving surfaces is given, together with data computed for typical cases, and it is shown that the liquid viscosity and the temperature of critical viscosity are both important in determining the thickness of slag on wall tubes in operating furnaces.

THE purpose of this paper is to describe recent developments in the study of the flow properties of coal-ash slags. It is one of a series reporting progress on an investigation of coal ash conducted by the Bureau of Mines over the past 15 years and may be considered as the first report on this subject to the A.S.M.E. Special Research Committee on Furnace Performance Factors. This committee, concerned with the collection and rationalization of data on the performance of commercially important furnaces as an aid to design and operation, considers the action of ash and slag deposits within such furnaces of great importance in controlling performance; the physical chemistry of ash and slag is one of the factors involved and has been the principal subject of the Bureau's study.

Because of the extreme complexity of the subject and the large number of variables to be considered, no early solution of all the difficulties faced by the designers or operators of coal-burning equipment can be offered, but by a study of the more important factors, enough information can be made available to permit more complete understanding of ash behavior in furnaces. It is with the thought that this study of the flow characteristics of slags in the solidification range may replace purely speculative notions, and that preliminary knowledge of such factors will assist in the final evaluation of the action of slag in furnaces, that this paper is sponsored by the committee.

Previous Work by the Bureau of Mines

The previous four reports to the Society on this investigation of the fundamentals affecting the flow characteristics of coal-ash slags were based on work performed in co-operation with the now disbanded A.S.M.E. Special Research Committee on Removal of Ash as Molten Slag from Powdered-Coal Furnaces. They included (1) a study[4] of the factors involved in the flow of slag from an early slag-tap furnace; (2) a laboratory study[5] of the use of fluxes to increase ease of tapping; (3) the relationship[6] between coal ash, slag, and fly ash in 18 operating slag-tap furnaces, and the effect of reducing atmospheres on some of the properties of the slag; and (4) the development of a viscometer[7] to measure the absolute viscosity of coal-ash slags at high temperatures, as well as to determine the effect of composition on the viscosity-temperature relationship above that temperature where gradual crystallization of the cooling slag radically affects its flow properties. These investigations culminated, therefore, in the construction of an instrument by means of which it is possible to measure the absolute flow characteristics of coal-ash slags, and which is capable of yielding data suitable for predicting the behavior of these slags under various conditions of composition, temperature, thermal history, and state of reduction.

The coal-ash-slag viscometer permits an exact and direct measurement of the flow properties of slags; it replaces empirical tests in that the data obtained are independent of the method of test and thus can be applied to any type of equipment. But because tests made in the viscometer are expensive from the standpoint of both equipment and time required, it is not to be expected that

it can be utilized as an instrument for control, much as the standard cone-fusion determination is now being used. Instead the viscometric data are being correlated with the composition of the slag, so that the flow properties of the slag can be predicted if its chemical analysis is known. As will be shown, under equilibrium conditions the source of the constituents making up a slag are unimportant so long as they result in a melt of the desired chemical composition.

Unfortunately, at present, no short-cut methods of chemical analysis are known which are suitable for this application. Present analytical methods are tedious and involved, and are based upon schemes devised for the exact analysis of rocks; they yield data of more than necessary precision. Less exact, more quickly performed methods are required. As the ability to predict the flow characteristics of coal-ash slags as a function of composition increases, it is expected that the methods of chemical analysis will be improved to supply satisfactorily precise data at a low cost and with a reasonable expenditure of time.

Test results reported in this paper have been obtained with slags preheated to the point where they were converted to a homogeneous liquid, thus no further reaction was occurring between constituents. The flow properties of the slag were determined subsequently by measurements made during the cooling of this melt.

Description of Apparatus

Furnace. The high-temperature furnace and the first viscometer have already been described.

Briefly, the furnace consists of a 2-in. × 3-in-diam silicon-carbide tube mounted vertically between water-cooled copper electrodes, thermally insulated with porous kaolin refractory and loose Sil-O-Cel, and enclosed in a gastight welded-steel shell 13 in. diam and 12 in high. Electrical energy is supplied by a transformer having a 440-v primary; the multitapped secondary is capable of furnishing 250 amperes at 20 v and is connected to the furnace through two radial switches. A variable autotransformer in the primary circuit permits essentially stepless control of power.

Temperature Measurement. Slag temperatures are measured by a platinum rhodium-platinum thermocouple embedded in the porcelain stool supporting the platinum crucible containing the slag. A determination of the temperature gradient in the melt and the deviation of the mean temperature of the melt from that indicated by this embedded thermocouple was made on a soda-lime glass which did not contaminate the probing thermocouple as would a coal-ash slag; the observed temperatures are thereby corrected to the mean slag temperature. The crucible is positioned in the furnace so that the temperature gradient through the melt is a minimum and does not exceed 10 F in a vertical direction. The embedded thermocouple is calibrated regularly against a secondary standard.

Temperature Controller. A thermocouple of low thermal capacity, exposed directly to radiation from the furnace wall, operates through a potentiometer connected to an electronic-contacting galvanometer[8] to control furnace temperatures. Such control is necessary because momentary excessive cooling at certain stages in the test may induce abrupt freezing of the melt. An additional synchronous-motor-driven potentiometer having a long helical slide wire is used to give the rates of cooling required for the maintenance of fixed conditions in the solidification tests. This instrument also energizes a motor connected to the variable autotransformer, adjusting the energy input to the furnace to the point where most satisfactory temperature control is possible.

Oscillating Viscometer. This instrument, used in the previous study of the viscosity of slags in the liquid state, has not been changed. Viscosity in the lower ranges is determined by measuring the logarithmic decrement of the torsional oscillation of a bob immersed in the slag and hanging from a calibrated suspension. At higher viscosities the same apparatus is used but the moment of inertia of the system is decreased and the time determined for the bob to rotate through a fixed angle while in aperiodic motion. For the measurement of the viscosity of Newtonian fluids, that is, true liquids, where the rate of shear is proportional to the applied stress, the instrument is completely satisfactory and is in continued use. However, during cooling, coal-ash slags at some temperature no longer behave as true liquids, and the oscillating viscometer becomes first erratic and then inoperable. Basically, failure of the instrument under these conditions results from the insufficient energy available in the oscillating system in harmonic motion of in the twisted suspension wire in aperiodic motion to continue to produce shear when solids are present in the slag. To furnish this energy it is necessary to supply an external source of power to the instrument, therefore the rotating-bob viscometer was designed and constructed.

Rotating Viscometer. The rotating viscometer operates on the principle first described by Margules in 1881;[9] he confined the liquid under test between two concentric cylinders, one of which was rotated at constant speed while the torque exerted upon the other was measured. This method is applicable to a wide range of viscosities and has been used successfully to study flow characteristics of many different materials. A modification was used by Feild[10] for determining the viscosity-temperature relationships of blast-furnace slags, while Herty[11] investigated other metallurgical slags, and Lillie[12] studied the viscosity of glass over a wide temperature range. Each of these investigators found it expedient to rotate the outer cylinder and to measure the torque exerted on the inner stationary cylinder. However, for coal-ash slags, the test atmosphere must be controllable so that the forms of iron in the melt can be maintained at a desired ratio; thus it was required that the bottom of the furnace be gastight to prevent the infiltration of air. Consequently, to make unnecessary the use of stuffing boxes or other seals around a bottom rotating shaft, it was decided to maintain the outer cylinder stationary and to drive the inner cylinder by way of a spindle extending through a small opening at the top of the furnace. This resulted in simplifying both furnace construction and crucible support, but introduced the problem of measurement of torque in the rotating driving system. Of the methods considered, those introducing measured amounts of energy, such as by slowly falling weights or by determining the wattage input to a driving motor, were discarded because of unavoidable and variable frictional losses. Therefore the inner cylinder was rotated by an external motor drive, and the torque was measured by the twist in a calibrated suspension wire serving as one member of the driving train.

The apparatus is shown in Fig. 1. A fractional-horsepower series-wound motor having its speed controlled by an adjustable centrifugal device, and with a built-in speed reducer, drives the

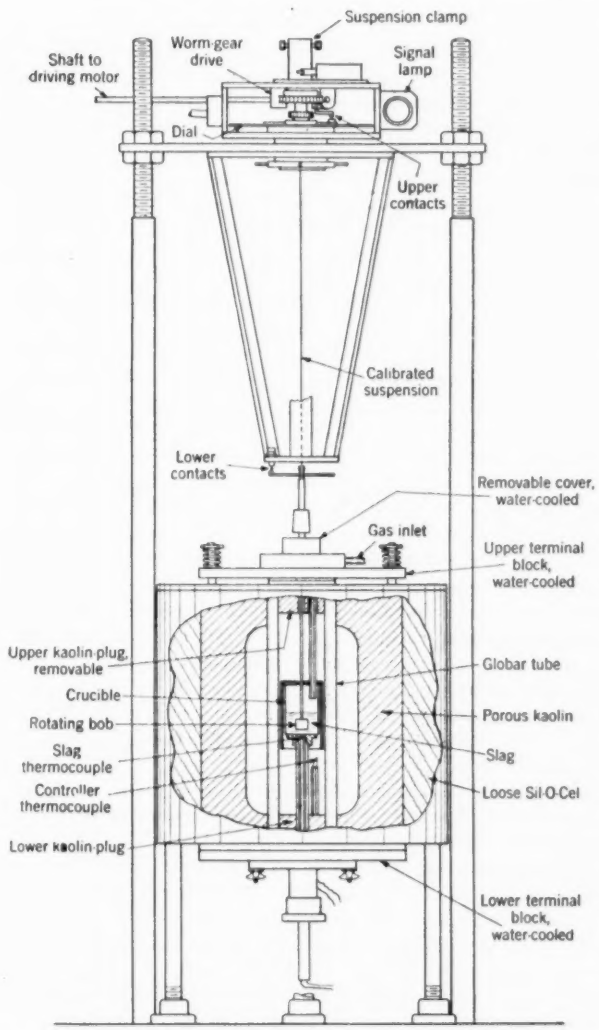

FIG. 1 FURNACE AND VISCOMETER FOR DETERMINATION OF VISCOSITY OF COAL-ASH SLAGS IN SOLIDIFICATION RANGE

viscometer through a worm-gear assembly mounted at the top of the instrument, the upper end of the suspension being clamped in the worm gear on its axis of rotation. The suspension wire, which is 15 in. long, is attached at its lower end to a member connected to the spindle attached to the bob. An inverted rigid tripod serves as a jig for insuring alignment and as a guide for the lower end of the suspension. Electrical contacts on the rotating members at each end of the suspension are used for measuring twist, the lower contact touching a fixed point on the tripod and the upper one contacting a point mounted on a dial which can be rotated manually; an electronic circuit through these contacts illuminates a signal lamp if both contacts are made simultaneously. Because the lower contact pressure must be extremely light to prevent disturbing the measurement of twist, moderate electrical resistance may occur, but the electronic circuit is capable of signaling through a circuit resistance as high as 500,000 ohms.

At the start of a test, when the slag is at a high temperature and, consequently, at its minimum viscosity (which has been previously determined with the oscillating viscometer), the motor is started and the upper adjustable contact rotated until the signal indicates that the electrical circuit through both sets of contacts is being made. A reading of the dial is then taken and the zero setting computed from the known speed of rotation of the bob, the constants for the suspension, and the viscosity of the melt. Later, as the viscosity increases with fall in temperature, the twist in the suspension increases so that the graduated dial must be rotated to keep the contacts in phase and maintain the signal; the angle, through which the dial and therefore the adjustable contact is rotated to maintain the signal, is identical with the additional twist in the suspension caused by the increase in viscosity. The dial is graduated in 200 divisions; a vernier permits measurement of twist within 0.1 division.

Two suspensions are in regular use, one having an upper limit of 10,000 poises, and the other, 100,000 poises. They are made of steel music wire, 0.018 in. and 0.034 in. diam, respectively, and are calibrated against liquids for which the viscosity has been determined by other methods. An alternate method of calibration was to load the suspensions radially and to measure the torsional deflection for various loadings.

The dimensions of the crucible and the bob, the two cylinders of the Margules viscometer, are the same as were described for the oscillating viscometer, the crucible being $1^1/_2$ in. ID and $2^1/_4$ in. deep; the bob is 0.500 in. diam and 0.500 in. long, but with an increased spindle diameter of 0.125 in. to withstand the greater torque of the driving system. Both units are of platinum alloy, the crucible containing 4 per cent rhodium and the bob and spindle 20 per cent rhodium. A careful check is made of the dimensions of the bob and it is returned to the manufacturer for reworking whenever the deviations from the desired size exceed 0.002 in. The crucibles are reshaped on a mandrel to the correct diameter following each test.

Control of Atmosphere. Because the state of oxidation of the iron in coal-ash slags is important in fixing certain of their flow properties, it is necessary to control the ratio of ferric to ferrous iron in the slag by controlling the atmosphere over the slag both during the original melting of the charge and during the test itself. Because of unavoidable diffusion of air into the furnace which would gradually oxidize the melt, some provision must be made other than flushing the apparatus continually with nitrogen to prevent the oxygen in this air from having access to the molten slag. In previous tests it was found that using a carbon tube for the nitrogen inlet was satisfactory; the tube projected into the crucible where, at furnace temperatures, it effectively converted any oxygen to carbon monoxide. However, because this tube required replacement at 1-hr intervals, it was not suitable for tests of long duration, therefore some other method of removing or compensating for the oxygen was required.

After a considerable number of tests, it was found that adding regulated amounts of hydrogen to the nitrogen permitted the use of a porcelain inlet tube and gave adequate control of the state of reduction of the slag. Present practice is to use 2 to 10 per cent hydrogen in the gas mixture during the premelt period when the slag has the greatest surface exposed and is most susceptible to oxidation, the exact amount being fixed by the required ratio of forms of iron and the composition of the charge. During the test itself, which may require 12 to 120 hr, the atmosphere is adjusted to 2 per cent hydrogen and 98 per cent nitrogen; the gas mixture is introduced at the rate of 1 cfh to the crucible through the porcelain tube and flows directly over the exposed surface of the slag. A platinum cover on the crucible with holes for the bob spindle and the porcelain tube assists in maintaining constant conditions. In all cases, the hydrogen is mixed with raw nitrogen from the cylinder and passed over copper gauze at 850 F to remove the small quantities of residual oxygen in the nitrogen, after which water is removed from the gases by passing them through calcium-chloride drying tubes. The amount of hydrogen used is corrected for that required to convert the residual oxygen in the nitrogen to water.

The effectiveness of the method in preventing oxidation of the slag in recent typical tests is shown in Table 1. None of the slags

TABLE 1 CHANGE IN STATE OF OXIDATION OF SLAGS DURING TEST IN AN ATMOSPHERE OF 2 PER CENT HYDROGEN AND 98 PER CENT NITROGEN

Test no.	Equivalent Fe_2O_3 in slag, per cent	Duration of test, hr	Ferric percentage[a] At beginning of test	At end of test	Change, per cent
243	14.5	29.5	16	14	−2
220	24.3	18	18	14	−4
240	29.8	43	19	22	+3
239	30.9	27	26	27	+1
236	40.5	24	21	23	+2
246	41.1	35.5	45	40	−5

[a] Ferric percentage is defined as the actual ferric iron in the slag expressed as per cent of the total iron calculated to Fe_2O_3. It is a measure of the state of oxidation of the slag.

show appreciable change in ferric percentage during the test, indicating the suitability of the method. Tests 239 and 240 and tests 236 and 246 show the ability to maintain the desired ferric percentage in slags of similar composition following variations in procedure during the premelting period to give different original states of oxidation. It should be emphasized that a 2 per cent hydrogen atmosphere is suitable only for the furnace and test conditions described. In other apparatus where the leakage of air may be different, other concentrations of hydrogen will be required.

Rheology of Coal-Ash Slags

The various constituents of coal ash, when heated to a high temperature, react to produce slag; if this temperature is sufficiently high and if enough time is allowed for all the possible chemical reactions to occur, the otherwise solid components of the ash substance will be converted to a homogeneous liquid. Rheology, the science treating of the deformation and flow of matter, shows that, for liquids, viscosity increases with decrease in temperature and that, under conditions of nonturbulent flow, the applied stress is proportional to the rate of shear, the ratio being the viscosity. For most liquid substances, this linear relationship does not hold over a wide temperature range, because, when they are cooled, a change of state occurs either gradually or abruptly which radically changes the flow properties of the material The same fundamental laws describing the behavior of other liquids also apply to coal-ash slags. Slags are not true liquids over the entire temperature range of interest to fuel engineers; the analysis of the flow properties of coal-ash slags at temperatures at which they are not completely liquid is of great practical importance and is one of the principal functions of this paper.

Development of Yield Stress. If a coal-ash slag originally at a temperature at which it is completely fused (that is, completely in the liquid state) is slowly cooled, the first change is an increase in viscosity according to a definite physical law, the details of which are given in a later part of this paper. At a certain definite temperature for each composition and ferric percentage, a process of crystallization begins and continues as the temperature is lowered; this temperature is called the "liquidus" temperature and is analogous to the liquidus temperature of other systems. These crystals, in general, do not have the same composition as the liquid slag from which they are separating; thus the composition of the remaining liquid changes as the crystals form, but the effect on viscosity of the change of composition of the liquid and the hydrodynamic effect of the small amount of crystals is far outweighed by the continuous increase of the viscosity of the liquid with decrease in temperature. Thus the presence of a small amount of minute crystals does not cause an abrupt change in the flow properties of a coal-ash slag, as had been formerly believed, and there is no break in the viscosity-temperature curve at the liquidus temperature of the slag.

Because this contradicts former statements referring to the liquidus temperature, this point was thoroughly studied for a synthetic slag having a silica: alumina ratio of 2.0, an equivalent Fe_2O_3 content of 30 per cent, and CaO 20 per cent. By quenching melts held in air at progressively lower temperature and examining the quenched charges under the microscope, the liquidus temperature was found to be 2515 F, whereas the break in the viscosity-temperature curve, in air, occurred at 2450 F. Bowen and Schairer[13] have discussed this subject at some length, though from a different viewpoint, and come to identical conclusions; namely, that there is no abrupt change in the rheological properties of a melt at the liquidus temperature, except in the special case of eutectic or compound compositions.

As cooling continues, more and more solid material separates from the melt, until, at a definite temperature (again depending upon composition and ferric percentage), an abrupt change in the flow properties of the coal-ash slag finally occurs. This change is evidenced by the fact that the applied stress is no longer directly proportional to the rate of shear but equals the viscosity times the rate of shear plus a constant force, and the slag is now said to be "plastic." This latter force, which impedes shear, is called the internal yield stress of the slag, and although it is not necessarily the yield value of the system it is generally understood in speaking of plastic flow that a definite shearing force must be applied before any deformation can occur. The internal yield stress is most conveniently measured and is in fact the only "yield" value not subject to ambiguity. Considerable controversy still exists over the behavior of "plastic" systems at low rates of shear, but for the purposes of this paper a simplified description is suitable.

This sudden development of internal yield stress occurs because the concentration of solids has reached such a value that the particles begin to interfere with each other in the flow process; a structure can be assumed to exist, made up of the suspended particles. To maintain flow, this structure must be continuously broken, and the internal yield stress is the force per unit area required to do so. The phenomenon of a critical volume concentration of solids for the development of internal yield stress is well known from studies of clay-water and pigment vehicle suspensions.[14]

Rheological behavior of this type was first systematically studied by Bingham,[15] and the equation that describes it bears his name

$$\sigma = \frac{F - f}{\eta}$$

where σ is the rate of shear, F the applied stress, f the internal yield stress and η the plastic viscosity. From a rheological point of view, internal yield stress can be considered as a measurable quantity indicative of the partial rigidity of a plastic substance. As a typical illustration, the behavior of a plastic material, in this case lithographic ink, is shown by a viscometric curve published by Green[16] and given in Fig. 2, where the torque on the suspension of the viscometer is plotted against the speed of rotation. It can be seen that the relationship is linear over a considerable range of rotational speeds greater than about 0.4 rps; the deviation from linearity at very low speeds has rheological significance but need not be considered here. The intercept at zero speed of

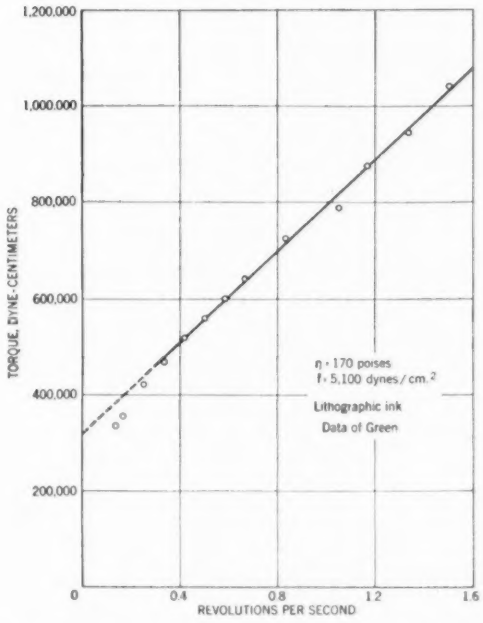

FIG. 2 TYPICAL CURVE FOR A THIXOTROPIC PLASTIC

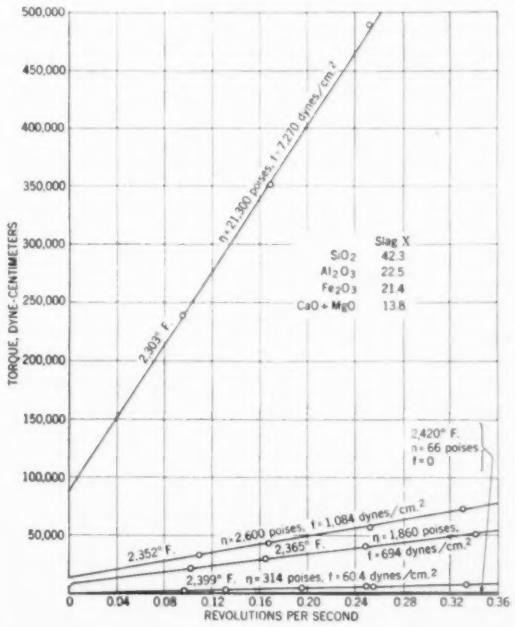

FIG. 3 DEVELOPMENT OF INTERNAL YIELD STRESS IN SLAG *X* ON COOLING IN AIR

320,000 dyne-cm of torque can be taken as a measure of the internal yield stress of the lithographic ink and indicates that this material has plastic properties, and that under lower stress, no shear would take place. The advantage of such flow properties for lithographic inks is obvious.

A similar effect is noted with coal-ash slags, where the internal yield stress, taken with the plastic viscosity, permits the description of the flow properties of a slag at temperatures below that at which crystals occur in sufficient quantity to cause deviation from the normal behavior for liquids. The actual determination of the internal yield stress and of the plastic viscosity for coal-ash slags is made by operating the viscometer at a constant speed until the torque on the suspension is constant. This equilibrium value is recorded, the speed changed, and the process repeated, the values of equilibrium torque being plotted against the corresponding speeds. A straight line is drawn through the points, the plastic viscosity being proportional to the slope, and the internal yield stress to the intercept at zero speed. This procedure is repeated at various lower temperatures, allowing crystallization to become complete at each temperature before readings are taken.

A typical set of Bingham curves for a coal-ash slag is shown in Fig. 3, where the effect of decreased temperature in increasing the plastic viscosity and the internal yield stress is clearly shown. The temperatures at which the accumulating crystals are effective in developing an internal-yield stress and plastic viscosity are below 2420 F; at that and higher temperatures no intercept is observed, the slag acting as a true liquid and having a linear relationship between stress and rate of shear. The conversion of the experimental values of torque intercept and slope to the rheological constants have been made by means of the Reiner[17] equation for the rotating viscometer with a Bingham (plastic) substance

$$T = \frac{8\pi^2 (l + h)\eta_0 S}{\left(\frac{1}{R_1^2} - \frac{1}{R_2^2}\right)} + \frac{9.212\pi (l + h)}{\left(\frac{1}{R_1^2} - \frac{1}{R_2^2}\right)} f \log \frac{R_2}{R_1}$$

where T is the torque in dyne-centimeters, η_0 the plastic viscosity in poises, S the speed of rotation in revolutions per second, R_1 and R_2 the radii of the bob and crucible, respectively, in centimeters, l the height of the bob in centimeters, h a correction to the bob height due to the effect of the ends, determined experimentally, in centimeters, and f is the internal yield stress expressed as dynes per square centimeter. These rheological constants are important because they are based upon absolute relationships and are thus independent of the apparatus in which the experimental work was performed. Therefore their use can be extended to practical applications with maximum effectiveness.

As noted previously, in determining the plastic viscosity and the internal yield stress of coal-ash slags, the viscometer is operated at a constant speed until the torque on the suspension becomes constant. This is necessary because coal-ash slags in the plastic range are thixotropic; that is, a definite time interval is required for equilibrium to be established between applied stress and rate of shear after the rate of shear has been changed. The Bingham law applies to the equilibrium values of stress and rate of shear; thus the values of plastic viscosity and internal yield stress must be obtained under equilibrium conditions. The non-equilibrium plastic viscosity and the internal yield stress of coal-ash slags are functions of the previous history of the slag, therefore they are of no use in this discussion. Further, for the long-time processes of slag flow, such as on wall tubes, it is the equilibrium values that apply.

The approach to equilibrium viscosity with time, following an abrupt change of temperature in the region of plastic viscosity, varies between different coal-ash slags as shown in Fig. 4. Curve *A* shows a peak value of viscosity with a subsequent reduction to the equilibrium value, and curves *B* and *C* show a simple exponential approach to equilibrium, differing only in rate. A reasonable explanation is based upon the formation of crystals in the liquid slag. When slags of type *A* are cooled, there is a rapid formation of a large number of minute crystals, causing an increase in viscosity. These small crystals, however, are unstable with respect to large crystals, the result being the formation of a smaller number of still larger crystals, with a con-

[17] "Theory of Plastic Flow in the Rotation Viscometer," by M. Reiner, *Journal of Rheology*, vol. 1, 1929, pp. 5–9.

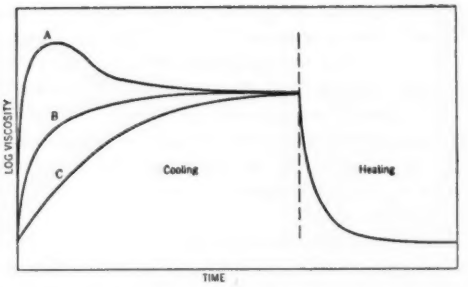

FIG. 4 APPROACH TO EQUILIBRIUM APPARENT VISCOSITY WITH TIME FOR DIFFERENT COAL-ASH SLAGS FOLLOWING AN ABRUPT CHANGE OF TEMPERATURE IN REGION OF PLASTIC VISCOSITY

sequent decrease in viscosity. In curve *B*, the rate of formation of crystals is moderate, and the growth in size parallels the formation of new crystals, giving no maximum. Curve *C* represents a case where the formation of new crystals is very slow and the increase in viscosity depends entirely upon this factor. The behavior on heating is identical for all three types, as is to be expected from the fact that at equilibrium the crystals are essentially the same size for the three types of slags.

Temperature of Critical Viscosity. The separation of crystals from a slag on cooling and the effect of these crystals on the rheological behavior of the slag have been shown to be of major importance. In Fig. 3, at viscosities of more than 66 poises the slag developed an internal yield stress because of the presence of crystals, but at lower viscosities it acted as a true liquid. This suggests that for this slag the viscosity of 66 poises represents a critical point in the cooling curve, and indeed it may be considered such. For this slag, we may consider the viscosity of 66 poises as being of special importance because it marks the division between fluid and plastic viscosities. This point will be called the "critical viscosity," which can be defined as that viscosity during the gradual cooling of a slag where there is a sudden transition from liquid to plastic flow, as evidenced by an abrupt increase in viscosity for a given small decrease in temperature or where internal yield stress is first developed in the slag.

Because, in general, the absolute viscosity, in poises, of a slag at the critical viscosity is of minor interest, whereas the temperature where it occurs is usually more important, this critical point will generally be considered in terms of temperature, hence the "temperature of critical viscosity," expressed as T_{cv}, will be used in much of the later discussion, as in Fig. 5, where curves are given for two typical coal-ash slags. Slag *X*, which is the same as in Fig. 3, can be cooled slowly from any high temperature where it exists as a liquid, there being a gradual increase in liquid viscosity until the critical viscosity of 66 poises is reached, when further cooling causes separation of crystals and there is a transition to plastic flow; this transition occurs at T_{cv}, which is 2420 F. Further cooling results in a rapid increase in plastic viscosity until at 2300 F, the slag suddenly freezes to an apparently solid mass and the bob can no longer be rotated. Slag *Y*, of different composition, behaves similarly, but its critical viscosity is 120 poises and T_{cv} is 2690 F; it freezes to a solid at 2390 F. It will be noted that the plastic-viscosity curves for these two slags are dissimilar in shape, a greater temperature effect occurring with slag *X* than with slag *Y*, so that slag *X* freezes 120 F below T_{cv}, whereas slag *Y* can be cooled 300 F below T_{cv} before freezing.

The development of internal yield stress as a function of the temperature below T_{cv} is shown in Fig. 6 for the same two slags; the rapid increase in internal yield stress of lag *X* as the result of cooling is in marked contrast to that of slag *Y*. The data of Figs. 5 and 6 permit the calculation of the flow properties of these two slags over the whole plastic range for any given conditions.

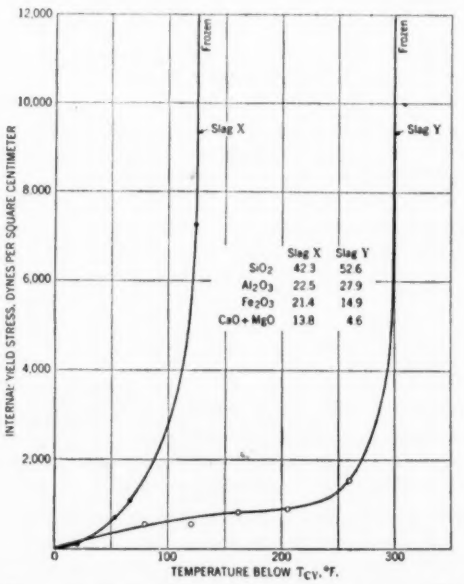

FIG. 6 DEVELOPMENT OF INTERNAL YIELD STRESS IN TWO COAL-ASH SLAGS OF FIG. 5, AS A FUNCTION OF THE DECREASE IN TEMPERATURE BELOW THAT OF THE CRITICAL VISCOSITY

Determining the rheological constants for coal-ash slags in the plastic range is a time-consuming process and may not always be possible. For some compositions, where the slag is quite fluid and there is a significant difference in density between the liquid and solid portions, stable suspensions of solid in liquid are not obtained, and measurements of the type previously described cannot be made. This fact in itself is worthy of note and is significant for slag-tap furnaces, especially of the intermittent-tapping

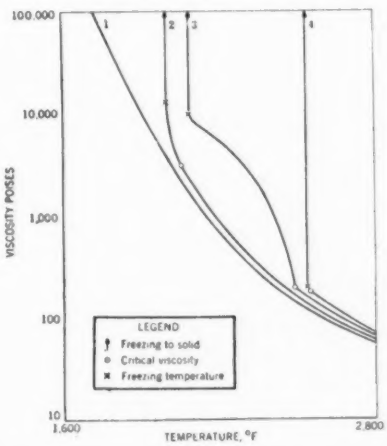

FIG. 7 TYPICAL VISCOSITY-TEMPERATURE RELATIONSHIPS OF COAL-ASH SLAGS IN SOLIDIFICATION RANGE

type. Because of these and other considerations, it was desirable to develop a method of routine laboratory test that would yield the maximum amount of useful information for the minimum expenditure of time and materials. The test procedure finally adopted was to cool the fluid slag at a constant rate of 1 deg F per min, found by experience to give almost identical results with the equilibrium tests in so far as the temperature of critical viscosity is concerned, and to operate the viscometer at a constant speed of 0.25 rps, which is both convenient and gives data of most usefulness. Torque observations are converted to apparent viscosities, that is, the viscosity of a true liquid that would give the same torque at the stirring speed used, and these data are plotted as a function of temperature; the temperature of critical viscosity is indicated by a sharp break in the apparent viscosity-temperature curve, similar to that shown for equilibrium conditions. The curves are followed to the limit of the apparatus, approximately 100,000 poises, or to the freezing temperature, whichever occurs first.

Typical cooling curves, representing the four distinct ways in which coal-ash slags act are shown in Fig. 7. Curve 1 is that for a true glass, cooling indefinitely without the development of internal yield stress; few slags are of this type. Curve 2 represents a slag approaching a glass in behavior, cooling to a low temperature before separation of solids causes the development of plastic viscosity and internal yield stress (T_{cv} is very low). Curve 3 represents a coal-ash slag which has a long cooling range but which begins to separate solids at a relatively high temperature at a low rate and freezes to a complete solid at a much lower temperature (T_{cv} usually high). Curve 4 represents a slag having a short freezing range, separation of solids being very rapid (T_{cv} may be high or low).

EFFECT OF COMPOSITION AND FERRIC PERCENTAGE ON TEMPERATURE OF CRITICAL VISCOSITY

As has been shown already, the temperature of critical viscosity T_{cv} is very important in describing the behavior of slag during cooling, because it designates that temperature at which a sudden change in rheological properties occurs. Later, the importance of T_{cv} in fixing the th ckness of slag on heat-absorbing surfaces, such as pulverized-coal furnace wall tubes, will be shown; meanwhile the variables affecting it will be evaluated, including change in composition and change in the state of oxidation of the iron in the slag.

Because coal ash is a complex substance, consisting primarily of silica, alumina, iron oxide, and lime, it is extremely difficult to present the effect of change in any one variable on the properties of a slag, variation in any one constituent causing a change in the effectiveness of every other constituent. Thus in studying systems of such complexity, it has become routine to fix certain variables which are either of little effect in themselves or are known to occur normally within relatively narrow limits. With such variables fixed, it is possible to study the system in a routine manner and with more thoroughness, although occasional compositions are encountered far outside the field being studied. In such special cases, these compositions must be considered individually although the principal fields may be a good guide as to expected characteristics.

In the study of the effect of composition, the components, as mentioned, alone have been considered, the relatively small amounts of magnesia, alkalies, titanium, and phosphorus being neglected until the future, when the studies of the principal constituents will have been completed. For this reason, many of the slags studied have been "synthetic;" that is, they have been formulated in the laboratory from chemically pure kaolin, quartz, ferric oxide, and calcium carbonate. For use in these tests, weighed quantities of these constituents are intimately mixed in a ball mill, compressed into small pellets in a tableting press, and added individually by an automatic feeding device to the platinum crucible in place in the furnace at 2700–2800 F; completion of the slagging reactions is indicated by cessation of gassing and by constant viscosity of the liquid over a 1-hr interval. An advantage of the synthetic slags is that definite compositions can be prepared for specific tests, whereas it is difficult to obtain coal-ash slags of particular compositions unless resort is made to fluxing.

Studies of synthetic and normal coal-ash slags of the same four-component composition, that is, identical except for the minor constituents, show that this simplified method is satisfactory for most purposes. Table 2 gives a comparison of the flow properties of three coal-ash slags from slag-tap furnaces and those of synthetic slags having the same four-component composition; the iron forms in the normal slags have been computed to equivalent Fe_2O_3 and the MgO has been included with CaO as a single component. The table indicates that small differences in composition may have a moderately great effect on the freezing temperature but that the liquid viscosity and the temperature of critical viscosity are but little affected. Consequently, for these last two flow properties, the data for synthetic four-component slags reported in this paper can be used for normal coal-ash slags without applying any corrections. For slags containing more than 3 per cent MgO and less than 5 per cent CaO, or where the alkalies exceed 2.5 per cent, these data should be applied with reservations until the effect of these constituent can be studied.

The relationship of the temperature of critical viscosity to composition is complex in that each of the four components making up the slag, as well as the state of oxidation of the iron in the slag, affects the critical viscosity and should be considered separately. Because the effect of change in five variables cannot be shown simultaneously by graphical means, the method of expressing the data must be simplified. The simplifications used in this case consist of combining the silica and alumina into a single variable by maintaining them at a fixed ratio of 2, which is most nearly representative of the average coal-ash slag. By making a series of plots at different CaO contents, another variable can be fixed, leaving only the equivalent Fe_2O_3 content, the state of oxidation of the iron in the slag, and the temperature of critical viscosity to be considered. By using the two compositional variables as co-ordinates and plotting the temperature of critical viscosity as isotherms, a useful family of curves results, as shown in Fig. 8, where the ordinate is the equivalent Fe_2O_3 content of the slag on the four-component basis and the abscissa is the ferric percentage.

The equivalent Fe_2O_3 content is computed from the forms of iron in the slag as follows:

$$\text{Equivalent } Fe_2O_3 = Fe_2O_3 + 1.11\ FeO + 1.43\ Fe$$

Generally, the metallic iron will not exceed 0.3 per cent and so has little significance. The equivalent Fe_2O_3 is computed to the four-component basis by recalculating the analysis of the slag so that

$$SiO_2 + Al_2O_3 + \text{Equiv. } Fe_2O_3 + (CaO + MgO) = 100$$

The ferric percentage is computed as

$$\text{Ferric percentage} = \frac{Fe_2O_3}{Fe_2O_3 + 1.11\ FeO + 1.43\ Fe} \times 100$$

and is defined as the actual ferric iron in the slag, expressed as percentage of the total iron calculated as ferric iron; it is a direct expression of the state of oxidation of slag, being 100 when the slag is completely oxidized and zero when the slag is completely reduced. Bailey and Ely[18] prefer to base a similar calculation on elemental iron, that is, as Fe, but the iron oxides have been continued as a base in these studies because they agree most closely with the actual forms of iron occurring in the slag.

The plots in Fig. 8 are given for definite CaO contents. In general, below the 10 per cent CaO level it will be better not to average the values from the figure for slags having intermediate percentages of CaO; sufficiently accurate results can generally be obtained by choosing the plot nearest in composition to the slag being studied. As just noted, MgO up to 3 per cent can be included as equivalent to CaO without introducing serious errors.

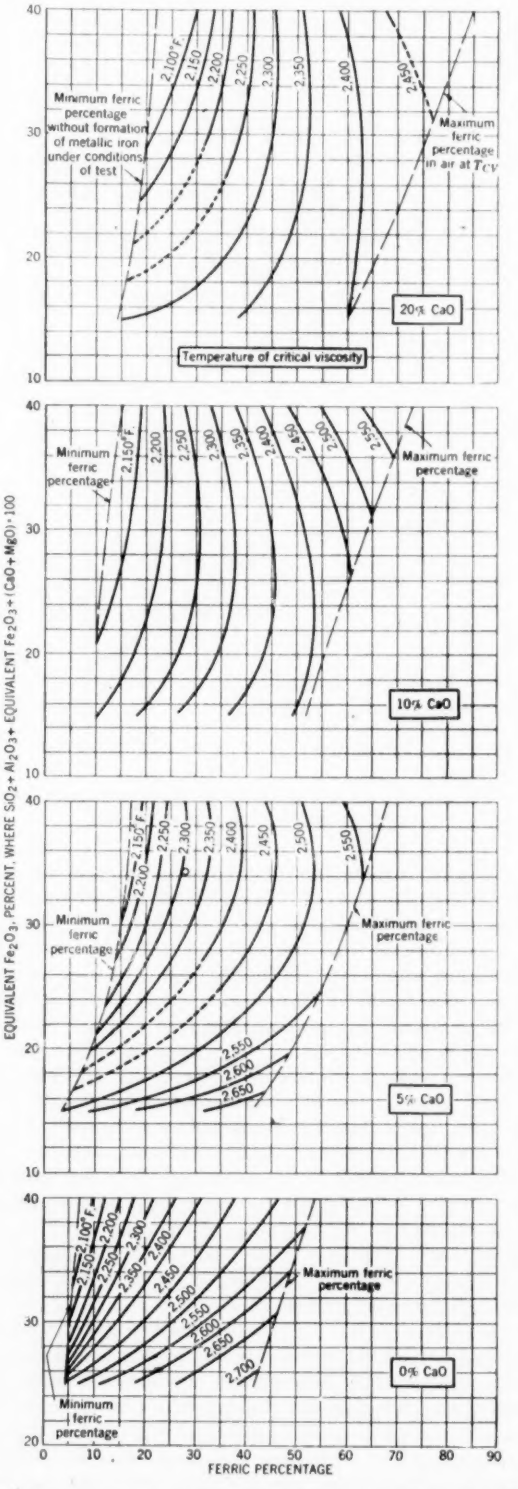

FIG. 8 TEMPERATURE OF CRITICAL VISCOSITY OF COAL-ASH SLAGS AS A FUNCTION OF COMPOSITION AND FERRIC PERCENTAGE, FOR A SILICA:ALUMINA RATIO OF 2

[18] "Significance of Coal-Ash Fusing Temperature in the Light of Recent Furnace Studies," by E. G. Bailey and F. G. Ely, Trans. A.S.M.E. vol. 63, 1941, pp. 465–471.

The effect of a given change in composition on the temperature of critical viscosity is readily obtained from Fig. 8. For instance, increasing the equivalent Fe_2O_3 content of a slag at a given ferric percentage results in decreasing T_{cv} with low values of CaO but has little effect when the CaO is 10 per cent; at 20 per cent CaO the effect is noticeable only for low ferric percentages. Decreasing the ferric percentage of the slag causes a lowering in T_{cv}, the effect of a given change in ferric percentage decreasing as the CaO content increases. For slags of a given equivalent Fe_2O_3 content, increase in CaO causes a decrease in T_{cv}, the decrease in general being largest for slags of moderate equivalent Fe_2O_3 content at the higher ferric percentages. For high-iron slags under highly reduced conditions, increase in CaO content lowers T_{cv} only slightly.

Because of the complexity of these relationships, it is suggested that each slag be considered individually. By locating it on the appropriate plot, the effect of change in furnace conditions, as regards oxidation or reduction of the slag, or change in composition whether by fluxing, blending with another coal, or change in the coal itself, can be readily determined. Calculations for a typical hypothetical slag would be made as follows:

SAMPLE CALCULATION OF A HYPOTHETICAL SLAG

	SiO_2	Al_2O_3	Fe_2O_3	FeO	Fe	CaO	MgO	SO_3 and alkalies	Total
As received, per cent.....	40.3	20.7	9.8	22.0	0.2	3.8	1.2	2.0	100.0
Iron forms recalculated to equivalent Fe_2O_3[a].....	40.3	20.7	34.5	..	...	3.8	1.2	2.0	102.5
Recalculated to four-component basis.....	40.1	20.6	34.3	..	...	5.0		...	100.0

$$\text{Ferric percentage} = \frac{9.8}{(9.8) + (1.11)(22.0) + (1.43)(0.2)} \times 100 = 28$$

$$\frac{SiO_2}{Al_2O_3} = \frac{40.1}{20.6} = 1.95$$

[a] Equivalent $Fe_2O_3 = 9.8 + (1.11)(22.0) + (1.43)(0.2) = 34.5$ per cent.

The slag has a silica:alumina ratio of 1.95, the MgO content is less than 3 per cent, and the alkalies less than 2.5 per cent; therefore the temperature of critical viscosity can be predicted from Fig. 8. The composition is plotted as a point on the 5 per cent CaO level, and T_{cv} is shown to be 2305 F. Under more oxidizing conditions in the furnace, T_{cv} could have increased to 2550 F as a maximum or could have decreased to about 2100 F if the atmosphere had been made more reducing. Changing the composition by blending with a coal having identical ash except for a greater Fe_2O_3 content would not affect T_{cv} appreciably, but lowering the equivalent Fe_2O_3 content would cause T_{cv} to increase. Similarly, increasing the CaO content while maintaining the other constituents constant would decrease T_{cv} to 2240 F at 10 per cent and to 2120 F at 20 per cent CaO. It is obvious that varying the state of oxidation of the iron forms in slag is one of the most effective means of controlling the temperature of critical viscosity.

The boundary indicated for maximum ferric percentages is a fundamental property of the slags. Higher states of oxidation than given by the boundary at the right are not possible in air because at these high temperatures there is equilibrium between the thermal dissociation of Fe_2O_3 to form lower oxides and their oxidation to form Fe_2O_3. At the left boundary, under the conditions of test, more highly reducing conditions will tend to form metallic iron, which results in a change in slag composition and consequently of slag properties. Under some conditions which could not be duplicated in platinum crucibles, it is possible to approach ferric percentages of zero without excessive reduction of FeO to Fe, but the need for such data at present is not great enough to warrant developing special test methods. It should be noted that the range of ferric percentage between oxidizing and reducing conditions increases as the total equivalent Fe_2O_3 and the CaO content increases.

A silica:alumina ratio of 2 was used for Fig. 8, because many slags are of this composition. It is believed that these data can be used successfully for slags having silica:alumina ratios ranging from 1.75 to 2.25 without introducing serious error. Work is being continued on this phase of the investigation to extend such plots to include ratios of 1.5 and 3 which should reliably cover the entire field of composition of coal ashes.

Relationship of Composition to Freezing Temperature

Although the temperature of critical viscosity is of great importance in evaluating the flow characteristics of coal-ash slags, the freezing temperature is also of considerable moment because it is the temperature at which the slag is essentially solid and cannot be deformed by any reasonable application of stress. The freezing of slag adjacent to the tap hole of intermittent-tapping furnaces, difficulty in maintaining flow, and the quantity of solid slag on the hearth are all problems associated with the operation of slag-tap pulverized-coal furnaces in which the freezing temperature of the slag is of importance. Its greatest significance, however, is in the formation and behavior of clinkers in fuel beds. So-called "tough" clinkers which are extremely difficult to handle in the furnace are sensibly plastic, that is, they have a high internal yield value while their liquid phase is highly viscous; they are intermediate in temperature between the temperature of critical viscosity and the freezing temperature. Because such clinkers are generally objectionable, it is of interest to know to what temperature they must be cooled to be reliably solid. Although comparisons of these data with actual clinkers have not been made as yet, based upon the behavior of slags in the laboratory it is suggested that clinkers below the freezing temperature will not exhibit any plasticity and therefore should no longer be tough. Because the rate at which slags or clinkers are cooled will affect the freezing temperature, care should be used in applying these data to limit them to materials that have not been rapidly chilled; the cooling rate used in the laboratory determinations has been 1 deg F per min, found to be in good agreement with equilibrium values, but cooling rates more rapid than this are usually found in practice.

The ability of slags to remain in the liquid state while being slowly cooled, that is, to behave as a glass, is not as great as was formerly believed. Under slow cooling conditions, most coal-ash slags do not gradually increase in viscosity indefinitely to give a supercooled liquid at room temperature, as has already been illustrated by the presence of a critical viscosity. Of 40 slags examined in the laboratory in 170 viscometer tests, only 1 slag behaved as a glass over the entire temperature range studied. With some few others, the freezing point had not been reached when the slag had attained an apparent viscosity of 100,000 poises, the limit of the viscometer, but in each instance the rate of increase of viscosity with temperature was so high that it was apparent that the slag was about to freeze. Also, because the slags contained a moderately large quantity of solids, their behavior should not be similar to glasses and they should have a definite freezing point. For slags that had a critical viscosity but where complete freezing to a solid did not occur, the freezing point was taken as the temperature where the viscosity had increased to 100,000 poises.

The data for the freezing temperature of typical coal-ash slags are given in Fig. 9, in which the co-ordinates are the same as for the previous figure on the temperature of critical viscosity. The relationship of composition to freezing temperature is as complex

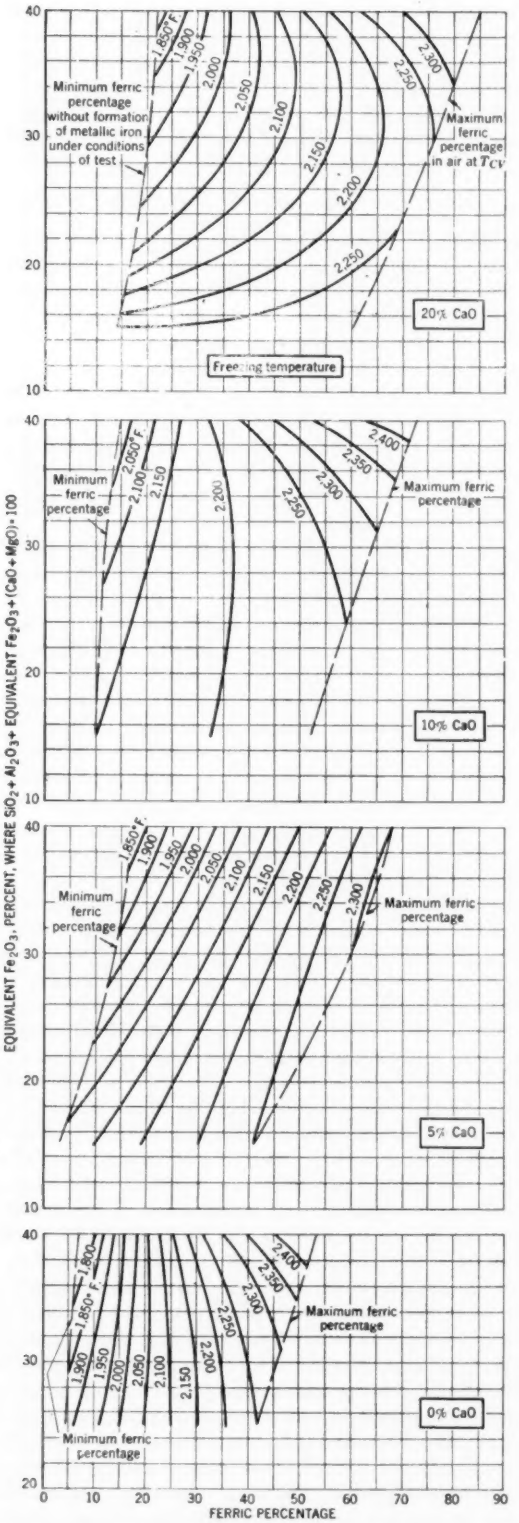

FIG. 9 FREEZING TEMPERATURE OF COAL-ASH SLAGS AS A FUNCTION OF COMPOSITION AND FERRIC PERCENTAGE, FOR A SILICA: ALUMINA RATIO OF 2

as for T_{cv}, but examination of the figure points out certain facts. Decreasing the ferric percentage of a given slag results in decrease in the freezing temperature; thus the well-known ability of slags to remain at least semifluid at lower temperatures when reduced than when oxidized is explained; a given decrease in ferric percentage is more effective in lowering the freezing point as the CaO content of the slag is less. Also, the freezing point for a given equivalent Fe_2O_3 content and a fixed ferric percentage is less at 5 per cent than at 10 per cent CaO. This agrees with the observation in a previous report[5] that the penetration temperature was lowered more by the first small additions of CaO as flux than by later additions when the CaO content of the slag was greater. It appears that for slags containing 25 per cent or less CaO, the minimum freezing temperature will occur at about 8 per cent CaO; this statement probably will not apply to slags having a silica : alumina ratio other than 2. Change in the equivalent Fe_2O_3 content of the slag has little effect on the freezing temperature, although its effect is variable with change in CaO.

As previously noted, the freezing temperature will be affected by change in the conditions of test, such as in the rapidity with which the slag is cooled. Small changes in composition may also cause large differences, such as were shown in Table 2, where the observed and predicted freezing temperatures for Windsor and for Springdale slag differed by 200 F. Thus the predicted freezing temperatures as given in Fig. 9 should be used only as a guide for actual operating practice.

SIGNIFICANCE OF CONE-FUSION DATA

Originally devised as a practical method of determining the fusibility of coal ash as a criterion of the tendency of the ash to form excessive clinker, the standardized cone-fusion determination has been accepted as a measure of the flow properties of ash at high temperatures. Easily and quickly determined with a fair degree of reproducibility, the cone-fusibility test has become firmly established and is now included in most specifications for coal. Because it is an empirical test, it cannot be directly related to fundamental properties; it expresses only the behavior of coal-ash cones under fixed conditions of preparation, dimension, and rate of heating. Despite these limitations, the method has been applied to evaluating the behavior of ash under widely varying conditions. As a result, the data are not always properly applied.

Consideration of the softening interval and the fluid interval as determined by the cone-fusibility determination has been mentioned[19] as helpful because it was obvious that reporting the softening temperature alone was not giving adequate information on the melting characteristics of the ash. Based upon furnace studies, Bailey[20] also indicated the desirability of using all three values in considering the action of ash in furnaces fired with pulverized coal. The importance of the initial deformation temperature was stressed by Gould and Brunjes,[21] who used it as a measure of the beginning of clinker formation. Recently, Bailey and Ely[18] have shown the significance of cone-fusion tests made under oxidizing as well as reducing conditions to interpret the actions of ash in different parts of furnaces.

It is apparent that the cone-fusion determination is useful in predicting ash behavior, and that fair results usually can be obtained in translating the data of this empirical test to operating conditions, but exact knowledge of the conditions responsible for any such results has been lacking. It has been one of the objectives of this investigation to determine the relationship between cone fusibility and the fundamental actions controlling the

[19] "Status of Knowledge on Properties of Coal Ash," by P. Nicholls and W. T. Reid, Proceedings 26th Fuel Engineering Conference, Appalachian Coals, Inc., Washington, D. C., June 21, 1940, pp. 77–95.

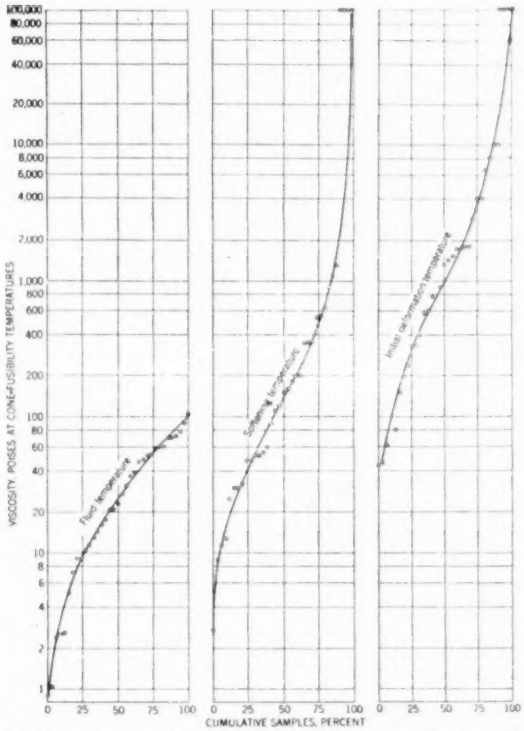

FIG. 10 VISCOSITY OF COAL-ASH CONES AT OBSERVED CONE-FUSION TEMPERATURES

flow of slag in an attempt to increase the usefulness of the cone method. For example, it would be helpful if the cone-fusion determinations could be used to indicate the viscosity-temperature relationship or the temperature of critical viscosity of coal-ash slags. Previous work on the subject in this laboratory was inconclusive; it was shown[19] that slags having similar softening temperatures could have radically different viscosities, and it was deduced that the viscosity curve could not be predicted from the cone-softening temperature alone. Since that time, many additional slags have been tested and information has been obtained on their behavior in the solidification range. As a result, further attempts have been made to correlate these different methods of measuring the flow characteristics of coal-ash slags.

The relationships to be described were obtained from a study of 35 coal-ash slags. Each slag was first melted in the viscometer and its flow properties determined, a portion of the melt being removed from the crucible at the end of the test by a platinum rod and quickly chilled to prevent oxidation. If the melts were in the liquid state before this sampling, chilling also prevented the formation of crystals, but no attempt was made to sample all the slags above their temperature of critical viscosity. The cone fusibilities were determined after the slag was ground to pass a 200-mesh screen; a gas-fired furnace was used for the reducing atmosphere, strictly following the A.S.T.M. specifications, while the determinations in air were made in an electrically heated furnace which is an exact counterpart of that used for the viscometer tests, except that it is mounted horizontally.

Because, in general, cone-fusion temperatures are lower for slags than for coal ashes of the same chemical composition, this fact should be noted in applying these data.

Viscosity at Cone-Fusion Temperatures. Inasmuch as viscosity obviously must be important in fixing the shape of a cone during heating, it has often been assumed that the viscosity is identical for every slag at a given state of deformation. In other words, it has been believed that all slags will have the same viscosity at the softening temperature, and therefore that the cone-fusion determination is a measure of viscosity. For instance, in a study of erosion caused by slag, Fehling[22] assumed a viscosity of 1000 poises as representative of the softening temperature. As mentioned previously, tests on a few slags in this laboratory indicated considerable deviation from this assumption; therefore it has been checked more carefully with these recent data. The results are shown graphically in Fig. 10, where the viscosity in poises for each of the 35 slags at the three fusion temperatures has been arranged in order of increasing viscosity. In cases where the cone temperatures are higher than T_{cv}, the viscosity is that of the liquid slag; when lower, the apparent viscosity is given.

It is obvious that there is no relation between viscosity and the observed cone-fusion temperatures; for each condition the viscosity varies over a ratio of more than 100:1.

Initial Deformation Temperature. Although many attempts were made to correlate the initial deformation temperature with the viscometric data, no relationships could be found. For instance, plotting the initial deformation temperature against the freezing temperature showed only an insignificant tendency for the two to increase together. Similarly, comparison of the softening with the freezing interval, that is, the difference between the temperature of critical viscosity and the freezing temperature, indicated no definite relationship. Although the initial deformation temperature probably has a definite significance, it is not related to viscosity alone nor to the tendency of slag to freeze while being cooled; the data of Fig. 10 indicate that the viscosity of slag at the temperature of initial deformation can range between 44 and +100,000 poises, while 50 per cent of the slags tested had a viscosity of less than 1000 poises.

Softening Temperature. The viscosity of slags at the softening temperature is also extremely variable, ranging from 2.7 poises to +100,000 poises. For the slags studied, 83 per cent had a viscosity of less than 1000 poises at the softening temperature. Because some coal-ash slags at temperatures near that of the critical viscosity are sensitive to the rate and direction of temperature change, the higher indicated viscosities at the softening temperature may not be important.

It has seemed reasonable to expect that the temperature of critical viscosity would be related to the cone-softening temperature, because with many slags the change in flow characteristics at

[22] "Erosion of Refractories by Coal Slag," by H. R. Fehling, *Journal, of the Institute of Fuel*, vol. 11, 1938, pp. 451–458.

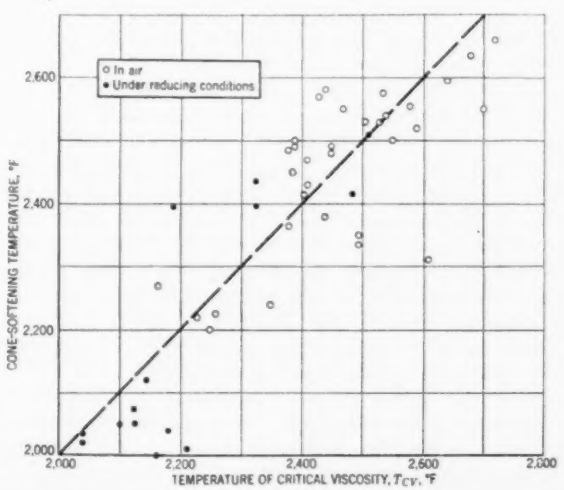

FIG. 11 COMPARISON OF CONE-SOFTENING TEMPERATURE WITH TEMPERATURE OF CRITICAL VISCOSITY

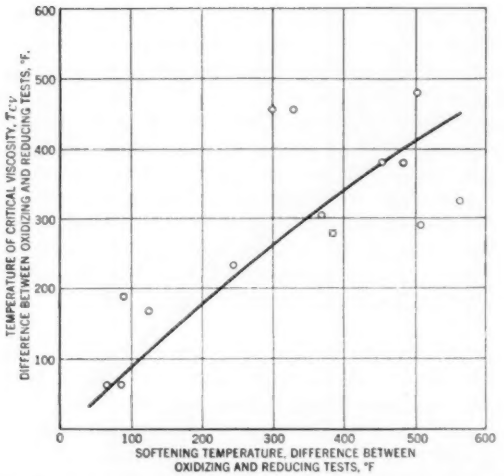

FIG. 12 EFFECT OF CHANGE IN STATE OF OXIDATION ON RELATIONSHIP BETWEEN CONE-SOFTENING TEMPERATURE AND TEMPERATURE OF CRITICAL VISCOSITY

T_{cv} should produce a radical change in the rate of deformation of the cone. Fig. 11 shows a comparison of the temperature of critical viscosity with the cone-softening temperature; the broken line as drawn would indicate a linear relationship between the two temperatures. It is apparent that this line is a fair representation of the data, although some points deviate considerably. Actually, for the 35 slags tested in air, the temperature of critical viscosity was higher than the cone-softening temperature for 18 slags, was lower for 16 slags, and was identical for one slag. The maximum difference was 300 F, whereas the mean difference was only 5.5 F.

For the slags under reducing conditions, the temperature of critical viscosity was predominantly higher than the cone-softening temperature in the lower range, but no definite relationship depending upon state of oxidation was apparent. In Fig. 12, the effect of changing the state of oxidation of a slag on its temperature of critical viscosity and on its cone-softening temperature is shown to be similar, the softening temperature being slightly more affected by reducing atmospheres than is the temperature of critical viscosity. Again, the individual points deviate considerably from the average, but the trend is definite.

Fluid Temperature. Fig. 10 shows that for these tests the viscosity of slags at the cone-fluid temperature ranged between 0.9 poise and 105 poises, although the fluid temperature occurred at less than 100 poises for 99 per cent of the slags tested and at less than 25 poises for 50 per cent of the slags. Thus the fluid temperature occurs at low viscosities but not at any definite viscosity. However, if the fluid temperature is compared with viscosity at a fixed temperature, a fair relationship is found, as shown in Fig. 13, where increase in the fluid temperature is accompanied by increased viscosity of the slag at 2600 F. Although some of the data again are in poor agreement, it is possible to use the fluid temperature as a guide to the viscosity of the slag at 2600 F, from which the viscosity at the observed fluid temperature or any other temperature above T_{cv} can be calculated as described later. It is interesting to note that the British Standards Institution method for the cone-fusion temperature of coal ash does not include observation of the fluid temperature.

A note of caution should be expressed regarding the determination of the fluid temperature, as it was observed during these tests that the fluid temperature in air was affected noticeably by change in composition of the refractory pat upon which the cones were mounted. The A.S.T.M. method specifies equal parts of kaolin and calcined alumina for the refractory pat, but it has been the habit in some laboratories to add a greater amount of kaolin to increase the plasticity of the wet mass for easier working. Studies were therefore made on pats prepared according to the specifications and those containing 2 parts of kaolin to 1 part of calcined alumina. The 2:1 pats fired to produce a denser body, therefore the slag was absorbed less readily and the cone-fluid temperature was increased; typical examples are given in Table 3. No corresponding change in the initial deformation or the softening temperature was noted. Because the data of this investigation were obtained with pats made according to the A.S.T.M. specifications, cone-fluid temperatures observed with cone supports having a different porosity should not be used for estimating slag viscosity according to Fig. 13.

TABLE 3 EFFECT OF COMPOSITION OF REFRACTORY PAT ON CONE-FLUID TEMPERATURE

Slag from viscometer test No.	Fluid temperature, deg F	
	1 kaolin: 1 alumina pat	2 kaolin: 1 alumina pat
188	2626	2736
189	2611	2713
204	2698	+2900
223	2697	+2900
227	2718	2870
228	2826	+2900

A brief summary of the comparison between viscosity and the cone-fusion determination indicates the following:

1 Viscosity is not a constant for any particular stage of cone deformation.

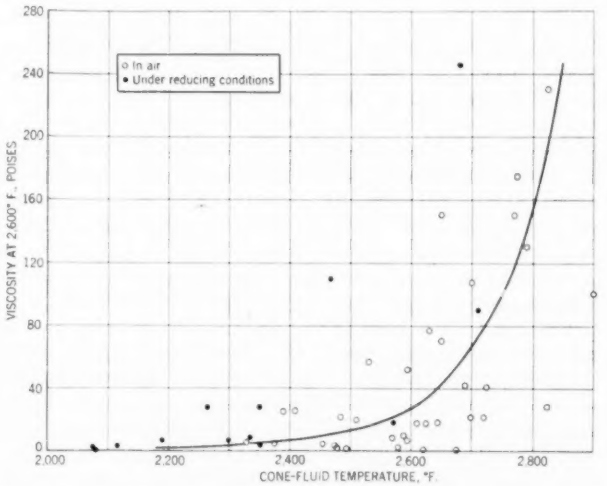

FIG. 13 VISCOSITY OF COAL-ASH SLAGS AT 2600 F AS RELATED TO THE CONE-FLUID TEMPERATURE

2 No correlation has been found between the initial deformation temperature and the flow properties of slag.

3 The softening temperature is a fair measure of the temperature of critical viscosity, although large unexplained differences can occur.

4 The viscosity of a slag at 2600 F can be predicted approximately from the cone-fluid temperature.

5 The "softening" and the "fluid" intervals probably are less significant than the values of the observed points, no relationship being found between these intervals and the viscometric data.

6 The cone-fusibility determination can be used as a rough measure of viscosity and, because of the simplicity of the test, is the most rapid method of evaluating the flow characteristics of coal-ash slags.

VISCOSITY OF LIQUID SLAGS

The absolute viscosity of slags in the liquid state, that is, at higher temperatures than T_{cv}, is equally as important as the

other flow characteristics. The equilibrium thickness of slag on wall tubes is partly determined by the viscosity of the liquid portion of the deposited slag, while the rate of flow of slag from pulverized-coal furnaces during tapping is related to this property, as is the tendency to form "sheet" clinker in stoker-fired furnaces. Knowledge of the viscosity of slag in the liquid state is essential and must be available for complete understanding of the action of coal ash at high temperatures. A previous report[7] was concerned primarily with the viscosity of coal-ash slags in the liquid state. Because additional data are now available, that information has been expanded and is being given in a slightly different form. It was shown in Fig. 9 of that report that (1) the rate of change of viscosity with temperature of any liquid coal-ash slag depends only upon the viscosity of the slag and not upon temperature, and (2) the rate of change of viscosity with temperature increases with increase in viscosity. The relationship was expressed as follows:

Viscosity, η, poises	$\frac{d\eta}{dt}$, poises per deg F
1	— 0.0028
10	— 0.04
100	— 0.58
1000	— 8.50

Plotting $\left|\frac{d\eta}{dt}\right|$ against η on logarithmic paper gives a straight-line relationship indicating that

$$\log \left|\frac{d\eta}{dt}\right| = a + x \log \eta$$

and

$$\left|\frac{d\eta}{dt}\right| = a\eta^x$$

or

$$\frac{d\eta}{dt} = -a\eta^x$$

This is the general differential equation for change in viscosity with temperature for the field of compositions of coal-ash slags studied, a and x being constants for the entire field. In the integrated form

$$\eta^{-z} = At - B$$

where z and A are related to x and a and are also constants for the entire field. Their values are 0.1614 for z, and 0.0004519 for A; the constant B is fixed for each particular slag.

The additional data have further substantiated the relationship between the SiO_2 content and the viscosity at 2600 F of coal-ash slags, as shown in Fig. 7 of the previous report.[7] It has been found desirable to continue the same basis of expressing composition, that is, to eliminate Al_2O_3 and recalculate so that SiO_2 + equivalent Fe_2O_3 + (CaO + MgO) = 100. Plotting the SiO_2 content on this basis against viscosity results in better agreement than when Al_2O_3 is included. It should be noted that this method of plotting gives the same results as plotting the sum of equivalent Fe_2O_3 and (CaO + MgO) on the same basis, except that the abscissa would be scaled in the opposite direction.

To simplify the use of these relationships between temperature, viscosity, and composition, a nomogram has been constructed. It is shown in Fig. 14 and permits prediction of the liquid viscosity at any temperature for any coal-ash slag whose composition is known. Scale C gives directly the relationship between the SiO_2 content of the slag and its viscosity at 2600 F, and can be used alone to determine the liquid viscosity at this fixed temperature.

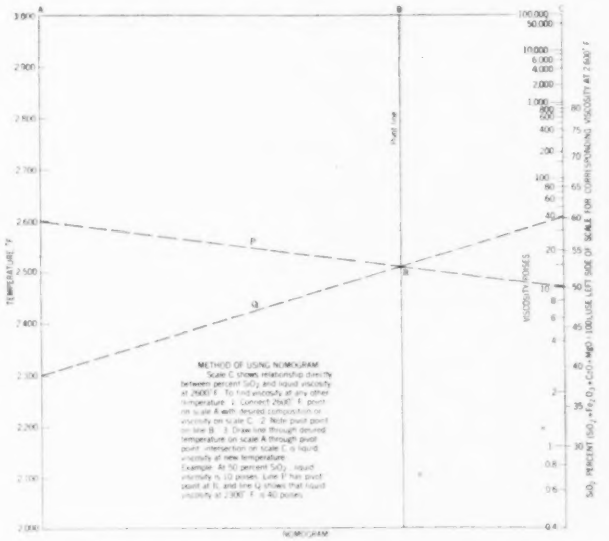

FIG. 14 VISCOSITY OF COAL-ASH SLAGS IN LIQUID STATE AS A FUNCTION OF COMPOSITION AND TEMPERATURE

To convert to other temperatures shown on scale A, pivot line B must be used as illustrated on the nomogram. This nomogram was used for predicting the viscosity at 2700 F of the three slags of Table 2. Because the effect of reducing or oxidizing conditions on the viscosity of slag in the liquid state is negligible, these data can be applied to either reduced or oxidized slags.

Extreme care should be taken in using the nomogram not to apply it to temperatures lower than the temperature of critical viscosity for the slag being considered, Fig. 14 being suitable only for slags completely in the liquid state. Before the nomogram is used, the temperature of critical viscosity of the slag should be determined from Fig. 8, and this temperature should be used as the lower limit in predicting liquid viscosity.

EFFECT OF RHEOLOGICAL PROPERTIES ON THE THICKNESS OF SLAG ON HEAT-ABSORBING SURFACES

A significant variable in the operation of slag-tap furnaces is the thickness of the slag deposits on the heat-absorbing surfaces. Although it is obvious that the more refractory coal ashes, or slags, will result in thicker deposits and consequently lower the rate of heat transfer from the furnace, it has been hitherto impossible to arrive at more definite conclusions. It is the object of this section of the paper to present a brief analysis of the flow of slag on furnace walls, with some quantitative results of the effect of the rheological properties of the slag on the relative thickness of deposits on heat-absorbing surfaces.

In any mathematical analysis of a complicated physical process, it is necessary to make simplifying assumptions and to limit the analysis to a small number of variables. The major premise in this case is that the flow of slag at temperatures below that of the critical viscosity can be neglected. This will generally be true and is absolutely essential to the setting up of a workable hypothesis. Further, it is assumed that the thermal gradient through the slag is constant. This assumption is more questionable, but in the absence of even average values for the thermal conductivity of coal-ash slag no better postulate can be supplied. An approximate allowance can be made for the porous nature of the slag in the vicinity of the metal or of relatively poor contact between slag and tube surface, by assuming the cold side of the slag deposit to be at a higher temperature than the metal. Because the thickness of this part of the slag deposit is usually quite small, the computed relative thicknesses are not greatly affected.

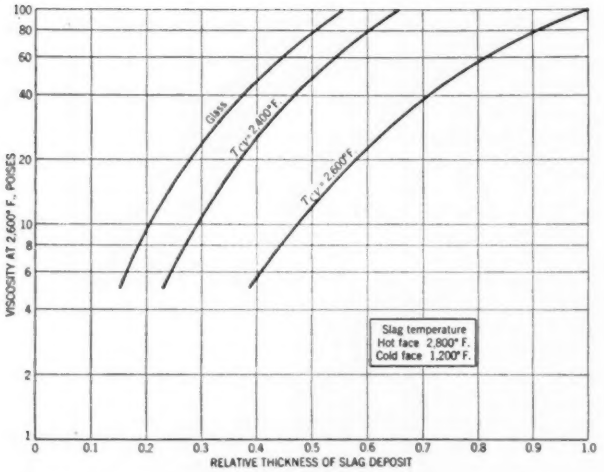

FIG. 15 COMPUTED EFFECT OF LIQUID VISCOSITY AND TEMPERATURE OF CRITICAL VISCOSITY, T_{cv}, ON THICKNESS OF SLAG LAYER ON HEAT-ABSORBING SURFACES

(Based on a thickness of 1 for a slag having T_{cv} = 2600 F, and a viscosity of 100 poises at 2600 F.)

Assumption of a constant slag density, independent of composition and temperature, can cause only minor errors. Finally, the variation of viscosity with temperature for coal-ash slags is taken into account by means of a formula given in a previous section of this paper.

Based on these factors, an equation has been derived relating the thickness of slag deposits to the temperature of critical viscosity, the viscosity as a function of temperature, the density, the rate of slag supply to the wall, and the temperatures of the hot and cold faces of the slag deposit. The development of this equation is too involved to be presented at this time, and only the results obtained by its use will be considered. The equation is given in functional form as follows:

$$V = \frac{\rho\, d^3 \sin \alpha}{A^2\, \bar{\Delta} t^2}\, f(A, B, z, t_w, \Delta t, T_{cv})$$

where

V = volume of slag flow
ρ = density of slag (assumed constant)
d = thickness of slag deposit
A, B, and z = parameters in equation relating viscosity to temperature, $\eta^{-z} = At - B$
α = angle of inclination of wall to horizontal
t_w = temperature at cold side of slag deposit
Δt = temperature drop across slag deposit
T_{cv} = temperature of critical viscosity

By use of the equation, the relative thicknesses of slag deposits have been computed as a function of the viscosity of the slag at 2600 F, and of the temperature of critical viscosity. Fig. 15 shows these thicknesses relative to that of a slag having a viscosity of 100 poises at 2600 F, and with T_{cv} also 2600 F, the computations being based upon a temperature for the hot face and for the cold face of the slag deposit of 2800 F and of 1200 F, respectively. Curves are shown for the effect of change in viscosity on the relative thickness of deposit for slags having a temperature of critical viscosity of 2600 F and of 2400 F, and for a slag that remains a glass when cooled slowly.

The plot shows that substituting a slag having a viscosity of 5 poises at 2600 F for one of 100 poises at that same temperature results in a decrease in the equilibrium thickness of the deposited slag to 38 per cent of its previous value, if both slags have a temperature of critical viscosity of 2600 F. Reducing T_{cv} of the new slag to 2400 F would result in a slag thickness only 23 per cent as great as formerly, whereas if the slag were a glass the deposit would be only 15 per cent as thick as the original deposit.

If, due to changes in operating conditions, the only change in the furnace is a decrease in the ferric percentage of the slag, with a resultant decrease in T_{cv} from 2600 F to 2400 F, the thickness of the deposit of a slag having a viscosity of 100 poises at 2600 F would be reduced to 65 per cent of its former value, and if T_{cv} were so low that the slag acts as a glass, to 56 per cent of its original value; the behavior at other viscosities can be estimated from the figure.

The more viscous slags, containing little flux, will not be changed appreciably in thickness by change in state of oxidation, because, for such slags, the change in the temperature of critical viscosity resulting from change in the ferric percentage is not great. For high-flux slags, those having a high equivalent Fe_2O_3 content will be more subject to variation in thickness than if the CaO is high, because the temperature of critical viscosity is more affected by change in ferric percentage for slags high in equivalent Fe_2O_3.

The foregoing results are not exact, in that operating changes that will usually occur simultaneously when the rheological properties of the slag are changed have not been considered. Such factors would include change in the temperatures of the hot and the cold faces of the slag deposit, variations in the quantity of ash impinging on the given surface, effect of change of rating of the furnace or of the heating value of the coal, and many others. This development is presented as a first approximation to an important factor governing furnace performance; it will undoubtedly be subjected to modification and extension as knowledge of the processes involved increases.

SUMMARY

An instrument is described for measuring the flow properties of coal-ash slags below the temperature at which solid material separates from the slag on cooling. These solids cause an abrupt change from liquid to plastic flow, the transition point being termed the temperature of critical viscosity. Plastic viscosity is demonstrated by the development of an internal structure in the slag, which requires the application of a finite stress to produce initial deformation. This internal yield stress is shown to be similar to that developed in other plastic materials; it offers an explanation for the variable behavior of slags while freezing.

The temperature of critical viscosity T_{cv} is affected in a complex manner by change in the composition and in the ferric percentage of a slag. No simple relationships exist, but charts are presented showing the results of laboratory determinations over a range of compositions representative of many slags. It is shown that, for a given state of oxidation, T_{cv} decreases as the equivalent Fe_2O_3 content of the slag increases, the effect being most noticeable for small quantities of CaO. Also, for a fixed equivalent Fe_2O_3 content, increasing CaO decreases T_{cv}. The largest change occurs with change in the state of oxidation of the slag, decreasing the ferric percentage being most effective in lowering T_{cv} as the equivalent Fe_2O_3 content of the slag increases.

Similar relationships are also given showing that decreasing the ferric percentage decreases the freezing temperature of coal-ash slags but that variations in equivalent Fe_2O_3 or in CaO contents have no regular effects.

Comparison of cone-fusion data with equilibrium values of slag viscosity show that viscosity is not a constant for any given state of deformation of cones; a relationship between cone-fluid temperature and absolute viscosity is given which may be useful in roughly predicting the viscosity of slags from cone-fusion data.

The cone-softening temperature is an approximate indication of the temperature of critical viscosity, but large unexplained differences can occur. No relation could be detected between the cone initial-deformation temperature and the flow characteristics of the slag.

Methods of expressing the liquid viscosity of slags as a function of composition and temperature have been simplified. A nomogram is given by which the viscosity of a slag can be predicted at any temperature above that of the critical viscosity.

These data have been applied to a theoretical study of the effect of change in rheological properties on the equilibrium thickness of a slag deposited on the heat-absorbing surfaces of boiler furnaces. A mathematical relationship has been derived from which the relative thickness of slag deposits has been computed as a function of the viscosity of the slag and the temperature of critical viscosity. It is shown that a decrease in viscosity from 100 to 5 poises at 2600 F reduces the thickness of slag to less than it would have been had T_{cv} for the more viscous slag been decreased from 2600 F to the point where the slag behaved as a glass. Although certain factors fixed by operating conditions are not considered, and the method will undoubtedly be modified later, it does permit consideration of the more important factors of slag properties in governing furnace performance, and thus should be of assistance in any study of the action of slag in furnaces.

Acknowledgments

This investigation has been performed under the authorization and encouragement of A. C. Fieldner, Chief, Fuels and Explosives Service, Bureau of Mines. The late P. Nicholls of this Bureau was largely responsible for the earlier developments in the study; his careful analyses of the various factors and his critical supervision of the methods and the apparatus employed added much to the value of the investigation. J. W. Myers and J. J. Pfeiffer assisted in the conduct of the viscometer tests.

The many chemical analyses for forms of iron were made in the Miscellaneous Analyses Section of the Bureau of Mines at Pittsburgh, under the direction of W. A. Selvig, and the cone-fusion determinations in the Coal Analysis Laboratory under the direction of H. M. Cooper.

Statistical Information on Large Pulverized-Coal Units on the Consolidated Edison System

By W. E. CALDWELL,[1] NEW YORK, N. Y.

STATISTICAL data on several pulverized-fuel-boiler installations of the Consolidated Edison Company of New York, Inc., are presented in accordance with the outline prepared by the Special Research Committee on Furnace Performance Factors. Each unit was installed to meet conditions expected at the time to prevail during the life of the apparatus. Since specific requirements differed for the individual units, they may not be directly compared, although useful trend information may be obtained from a study of the influence of design on the various factors. Economy considerations dictate sustained high-capacity operation for the high-pressure units, consequently their design provides more liberal proportions than in the case of the older low-pressure units. Later installations also reflect recent developments or advances in the art. Practically all of the units here presented were designed for installation in an existing building or to meet space restrictions imposed by city-site limitations. This condition, combined with the economic urge of producing the maximum capacity in the space available, accounts for certain features of design.

Since the survey was undertaken to determine the influence of the various relations on furnace performance and related conditions, a few general observations on the characteristics of these units may be in order, with emphasis on cleaning problems and maintenance of capacity.

In the older plants, with moderate superheat, furnace cleaning is necessary to keep the passes open to maintain capacity. In more recent high-temperature units cleaning is necessary, as in the case of the older boilers, but with an added limitation imposed by higher steam temperature. To assure full steam temperature at partial load and to permit limiting temperature at full load, gas-controllable by-passing of the superheater is resorted to. Since the gas by-pass affords a comparatively small range of steam-temperature control, fouling of furnace heating surface often increases the gas temperature and superheat beyond a safe limit, necessitating furnace cleaning or capacity reduction. There are several methods in use for cleaning boilers and furnaces, such as soot blowers, hand-lancing with air, steam, water, various combinations of the three, and by thermal shock induced by periodic load reduction. The latter method has proved attractive on more recent installations, since it requires a minimum of labor.

Deslagging Boilers

With high furnace temperature and a reducing atmosphere, a number of coals produce adherent slags which resist removal by soot blowers and lancing. These slags shed from the walls and boiler tubes freely when the load is reduced or the fire is extinguished. Where two boilers are installed per topping unit the customary method of deslagging is to shut down one boiler during the midnight watch for sufficient time to permit shedding of the slag. The bulk of this material usually falls during the first 15 min after extinguishing the fire. Where a single boiler is installed, complete shutdown is impractical, and approximately equal results are accomplished by reducing the load from full load to about half load for a period of 2 hr or more. Most of this slag appears to shed during the second hour. Where the superheater is suitably proportioned, cleaning once in 24 hr by this method gives satisfactory results. With certain coals this method must be supplemented by soot-blowing or lancing in order to remain within range of temperature control.

In cases where excessive superheater surface aggravates the cleaning problem, changes are being made to establish temperature control within a more suitable range. This is accomplished by baffle changes or by adding boiler surface ahead of the superheater. When these changes have been completed, cleaning requirements will be dictated by the grade of fuel, load demand, and combustion conditions.

Improper distribution of fuel and air supply aggravates cleaning requirements and, as circumstances permit, modifications are being made to improve furnace conditions. The burner arrangement has a pronounced effect on the heat distribution within the furnace, as well as on the fusion of the ash and cleaning problem throughout the unit. The larger the unit the more difficult this problem becomes, since a larger quantity of coal and primary air is delivered from each mill connection to the burner. Ideally, the coal and primary air should be delivered in an infinite number of small streams so that each ignited particle may be scoured by the turbulent secondary air with an oxidizing atmosphere in the furnace. This results in a uniform high heat absorption by the furnace walls without extreme concentrations in local areas. There should be no CO present in the furnace, since a reducing atmosphere results in a substantially lower ash-fusing temperature and more adherent slag. With an oxidizing atmosphere in the region of the high-temperature zones, slag troubles diminish and wall cleanliness may be more readily maintained. Practical considerations necessitate compromises and instead of a few pounds of coal injected per nozzle per hour, some burners deliver 3 tons or more per nozzle per hour. Even under these conditions, combustion is complete when the gas enters the convection bank and combustion is practically perfect. The furnace, however, suffers from the impingement of these large streams of burning coal against the opposite wall, which causes highly localized hot zones and tenacious slag coatings.

Types of Burners

Figs. 1 and 2 show an earlier type of tangential burner adjusted for a small firing circle. Accumulated experience seems to indicate that, from a furnace standpoint, better results would be obtained if the burners were taller in height and with a greater number of coal nozzles. With such an arrangement, the firing circle may be enlarged in order to increase the convection component and absorb more heat in the furnace. This reduces

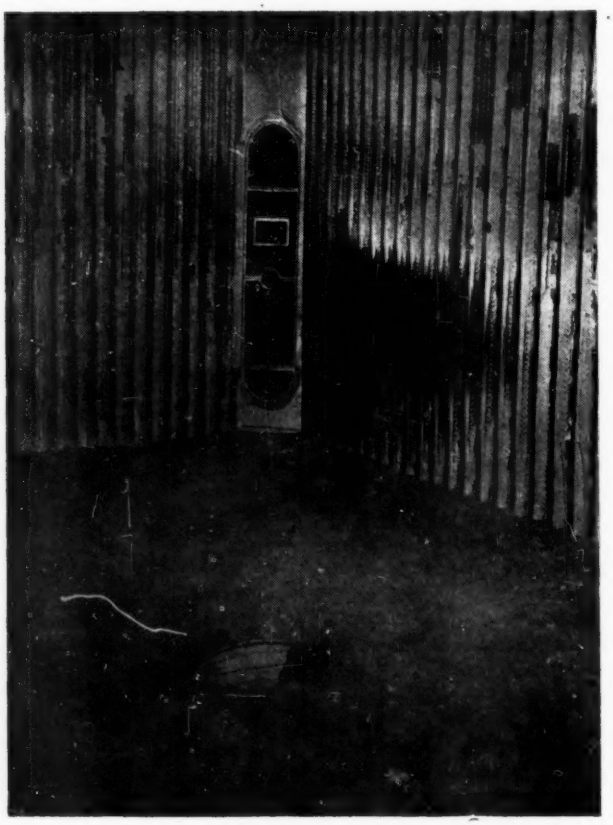

FIG. 1

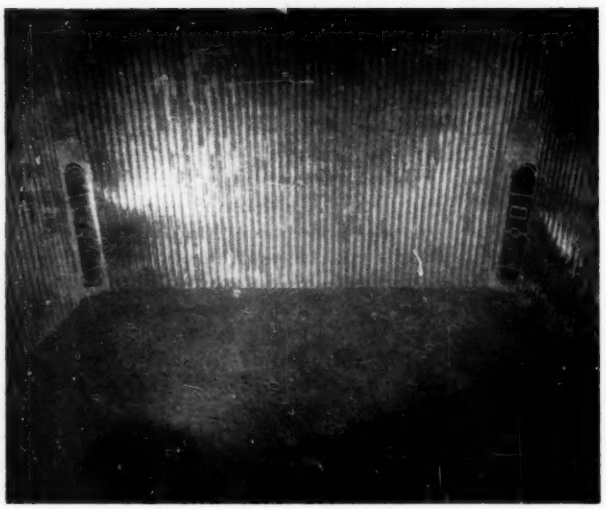

FIG. 2

temperature and fouling conditions within the convection bank.

Fig. 3 indicates relative proportions of two types of pulverized-coal burners on recent units covered in the tabulation. These burners are an improvement over earlier practice but some trouble is experienced with the production of CO in the region of the burner.

As boiler unit sizes and capacities increase the problem of burner disposition and furnace heat absorption becomes more difficult, since the ratio of wall surface to furnace volume diminishes as size increases. As the furnace walls account for a large portion of the total heat absorption, this size-factor relation is an important consideration. In the No. 90 unit, the Btu per cubic foot per hour is 20,000, while the heat release per square foot of furnace wall is 90,500 Btu. In the No. 72 unit, the furnace surface and convection surface are combined in the open-pass design to give the effect of a long narrow furnace. In this unit the Btu per cubic foot per hour is 30,000, while the Btu per square foot of surface is 54,700. Both units deliver high sustained capacity with excellent reliability and efficiency. Unit No. 9 is an earlier type with heat release of 27,000 Btu per cu ft and an absorption rate of 130,000 Btu per sq ft of furnace surface. Complete test data were previously presented on this unit.[2]

Tube spacing in the boiler banks of more recent units is adequate to eliminate the type of plugging experienced with earlier units, but operating vigilance is still required to avoid trouble. Wall cleaning is at present practiced as a capacity measure dictated by superheat limitations, while economizer cleaning may be justified by economy considerations. Boiler passes are usually blown once or more a watch, as dictated by grade of fuel and load conditions.

The cleaning schedule is established by experience and is organized to meet a wide range of fuel and load conditions, in which cleaning costs and results must be kept in balance. Corrective measures made to reduce superheat on one recent unit indicate a substantial reduction in cleaning requirements, but a longer period of operation will be required to establish the relation between the design factors and the cleaning schedule.

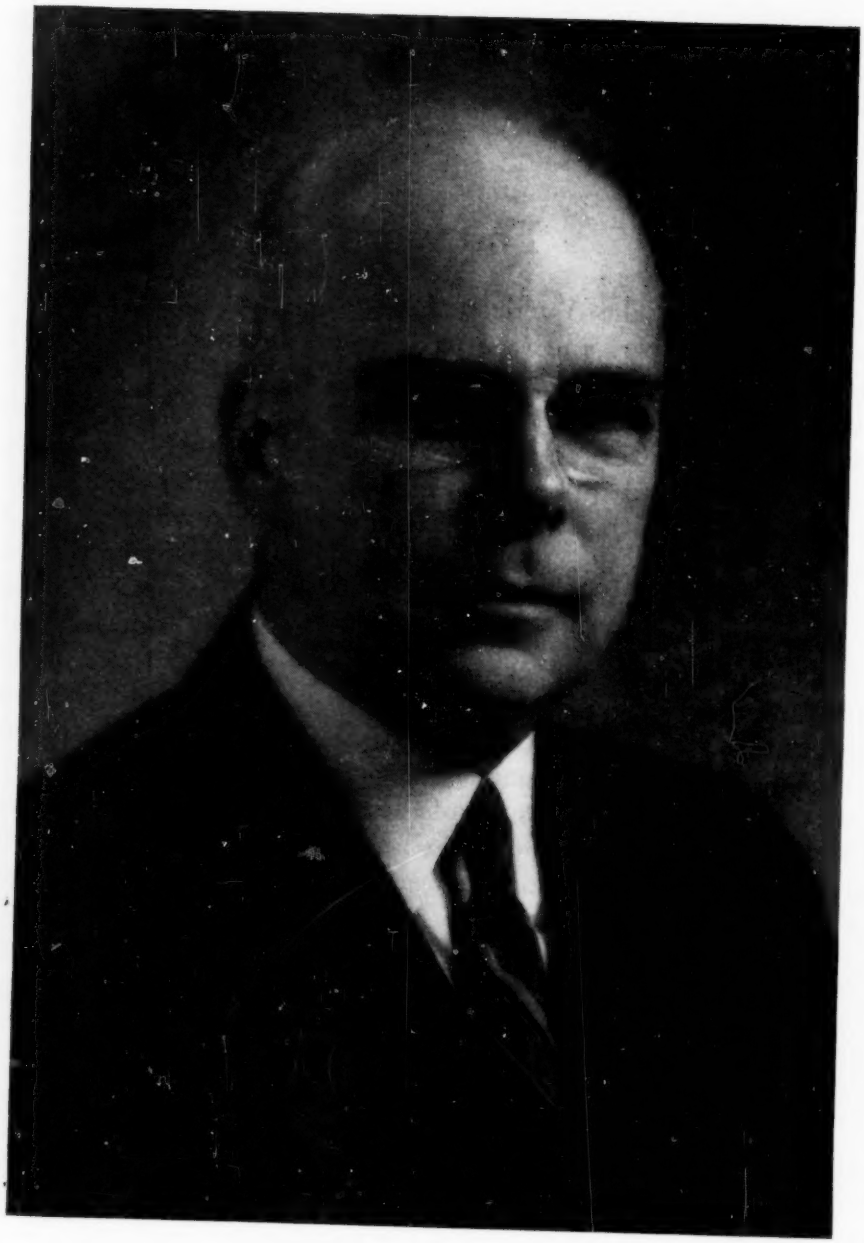
Published monthly by The American Society of Mechanical Engineers. Publication office at 20th and Northampton Streets, Easton, Pa. The editorial department is located at the headquarters of the Society, 29 West Thirty-Ninth Street, New York 18, N. Y. Cable address, "Dynamic," New York. Price $1.50 a copy, $12.00 a year; to members and affiliates, $1.00 a copy, $7.50 a year. Changes of address must be received at Society headquarters two weeks before they are to be effective on the mailing list. Please send old as well as new address. . . . By-Law: The Society shall not be responsible for statements or opinions advanced in papers or . . . printed in its publications (B13, Par. 4). . . . Entered as second-class matter March 2, 1928, at the Post Office at Easton, Pa., under the act of August 24, 1912. . . .

Copyrighted, 1944, by The American Society of Mechanical Engineers. Reprints from this publication may be made on condition that full credit be given the Transactions of the A.S.M.E. and the author, and that date of publication be stated.



Foreword

THE Transactions of The American Society of Mechanical Engineers include selected technical papers and reports delivered at meetings of the Society, its Professional Divisions, and its Local Sections, the *Journal of Applied Mechanics* (contributions of the Applied Mechanics Division), certain records of the Society of permanent value, and indexes to its publications.

In order to secure the advantages of timeliness and greater usefulness in issuing these Society Records, the material comprising them is divided into a number of parts, each one of which is mailed as a supplement to one of the regular monthly issues of the Transactions. For 1944, the first of these, the present issue, contains the personnel of the Council and committees for the year. Another, to be issued sometime later in the year, will contain memorial notices of deceased members. The indexes to miscellaneous publications, *Mechanical Engineering*, and to the Transactions themselves, must, necessarily, be issued in 1945, and will probably be mailed as a supplement to the January issue of that year.

In binding the 1944 Transactions, all of these parts of the Society Records will be assembled at the back of the volume as has been customary for several years. To aid in locating references in the bound volumes, the page numbers of the sections containing the *Journal of Applied Mechanics* and the Society Records are preceded by the letters A and RI, respectively.

THE COMMITTEE ON PUBLICATIONS

ROBERT M. GATES

PRESIDENT OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS
1943-1944

Robert M. Gates

Robert M. Gates, President of The American Society of Mechanical Engineers for the year 1943-1944, is a Fellow of the Society, president and director of the Air Preheater Corporation, formerly vice-president of The Superheater Company and its affiliate, Combustion Engineering Company, Inc., all of New York, N.Y. He was born in O'Brien County, Iowa, Sept. 7, 1883, and studied at the Manual Training High School, Indianapolis, Ind., and at Purdue University, where he received the degree of bachelor of science in mechanical engineering in 1907.

From 1907 to 1909 Mr. Gates was associated with the Browning Company of Cleveland, Ohio, after which he practiced as consulting engineer until 1912 when he became associated with the Thew Shovel Company of Lorain, Ohio. In 1918 he became Eastern manager for the Lakewood Engineering Company of Cleveland, Ohio, and located in Philadelphia, Pa. In 1922 he became associated with The Superheater Company.

Mr. Gates has participated in the design and construction connected with the builders of fuel-burning and steam-generating equipment, including all types of boilers, stokers, pulverized-coal equipment, economizers, air preheaters, and superheaters for stationary, railway, and marine service, as well as a wide variety of heavy equipment for the process industries. Outstanding among their installations are the world's largest high-pressure boilers, each producing over a million pounds of steam per hour.

Mr. Gates is a registered professional engineer in New York State and has long been active in the affairs of The American Society of Mechanical Engineers since becoming a member in 1918. He served as manager, 1928-1931, and as vice-president, 1931-1933, and he has been a member of various standing committees, including those on Meetings and Program and Professional Divisions. At the time of the World Power Conference in 1936 he was chairman of the Reception Committee. He has been serving as a member of the War Production Committee of the Society since 1942.

For the 1941 Annual Meeting of the Society Mr. Gates, as chairman of the Committee on Conservation and Reclamation of Materials in Industry, organized a "panel of experts" to conduct a session on conservation and reclamation. He served also as chairman of the first and many subsequent War Production Clinics which the A.S.M.E., at the request and with the assistance of the War Production Board, has been conducting for more than a year in industrial centers throughout the nation.

Mr. Gates has made numerous addresses before various engineering groups and given much time to counseling junior and student members of the Society. His keen interest in the problems of young engineers and engineering students is probably traceable to the fact that he supported himself during his entire education, including the high-school period, when he sold tickets in the Indianapolis Union Station.

Mr. Gates has written many articles and given a number of talks on handling of materials, power generation, personnel direction, and management. Aside from his engineering activities he finds time to take considerable interest in civic and economic

affairs of Scarsdale, N.Y., of which he is a resident. He is on the Board of Arbitration of the American Arbitration Association.

He is also a member of the following organizations: Institution of Mechanical Engineers, Newcomen Society of England, American Institute of Electrical Engineers, National Association of Manufacturers, National Association of Professional Engineers, American Management Association, American Iron and Steel Institute, The Engineers Club of New York, the Union League Club of New York, the Downtown Athletic Club of New York, the Manursing Island Club of Rye, N.Y., and the Scarsdale Golf Club, Scarsdale, N.Y.

The American Society of Mechanical Engineers

HEADQUARTERS: 29 West 39th St., New York 18, N.Y.
MID-WEST OFFICE: Room 1617, 205 West Wacker Drive, Chicago 6, Ill.

The members of the Council and of its standing and special committees given on the following pages are those in office on January 1, 1944, serving for the official year 1943-1944. The terms of office of members of other committees are not fixed by the official calendar.

UTAH
WESTERN WASHINGTON

GROUP VIII

COLORADO
KANSAS CITY
MID-CONTINENT
NEW ORLEANS
NORTH TEXAS
SOUTH TEXAS

SPECIAL COUNCIL COMMITTEES

(Dates in parentheses denote expiration of terms)

ADVISORY COMMITTEE TO COMMITTEE ON ADMISSIONS (FELLOW GRADE)

H. A. Lardner, *Chairman*
R. E. Flanders
E. C. Hutchinson
Alfred Iddles
J. H. Lawrence
Roy V. Wright

BOARD OF REVIEW

S. D. Sprong, *Chairman* (1944)
F. M. Gibson (1945)
John Haydock (1946)

BOARD ON TECHNOLOGY

R. F. Gagg, *Chairman*
C. B. Peck, *Vice-Chairman*
T. E. Purcell
S. R. Beitler (Local Sections)
L. K. Sillcox (Meetings and Program)
W. M. Sheehan (Professional Divisions)
F. L. Bradley (Publications)
Herman Weisberg (Research)

ENGINEERING OPPORTUNITIES

E. G. Bailey, *Chairman*
W. L. Batt, *Vice-Chairman*
R. E. Doherty
R. E. Flanders
D. C. Prince

ENGINEERS' CIVIC RESPONSIBILITIES

Roy V. Wright, *Chairman*
Gano Dunn
M. H. Fies
Lillian M. Gilbreth
H. B. Oatley
J. W. Roe
H. H. Snelling
D. Robert Yarnall

Junior Representative

W. Whitanen

Chairmen of Committees on Local Sections and Relations With Colleges, *Ex-Officio*

FREEMAN FUND

Clarke Freeman, *Chairman*
E. C. Hutchinson
Geo. A. Orrok

INDUSTRIAL CONSERVATION

A. M. Perrin, *Chairman*
R. D. Bullard
Graham Granger
R. A. Wheeler

LECTURESHIPS

C. B. Peck, *Chairman*
A. G. Christie
H. N. Davis
W. F. Durand
F. L. Wilkinson, Jr.

MANUFACTURING ENGINEERING COMMITTEE

L. C. Morrow, *Chairman*
Erik Oberg, *Vice-Chairman*
H. V. Coes
F. H. Colvin
J. L. Walsh

REGISTRATION

V. M. Palmer, *Chairman*
S. H. Graf
J. A. McPherson
F. H. Prouty
W. K. Simpson
H. H. Snelling

Junior Representatives

P. B. Petty W. Whitanen

SOCIETY OFFICE OPERATION

Alfred Iddles, *Chairman*
Wallace Clark
E. H. Schell

SOCIETY ORGANIZATION STRUCTURE

G. L. Knight, *Chairman*
Clarke Freeman
G. E. Hulse
K. M. Irwin
H. R. Westcott
D. Robert Yarnall

WAR PRODUCTION

James L. Walsh, *Chairman*
Major Gen. G. M. Barnes (Army Representative)
Rear-Admiral J. A. Furer (Navy Representative)

A.S.M.E. Divisions Representatives

K. H. Condit (Management)
C. F. Dietz (Materials Handling)
Sol Einstein (Production Engineering)
D. S. Ellis, W. M. Sheehan } (Railroad)
A. R. Stevenson, Jr. (Aviation)
T. H. Wickenden (Metals Engineering)

N. S. SNYDER
J. L. YATES

CENTRAL ILLINOIS

Organized: 1937
Territory: All the territory in Central Illinois between the following counties on the northern boundary: Bureau, LaSalle, Knox, Stark, Putnam, Marshall, Livingston, Peoria; counties on the southern boundary: Pike, Scott, Morgan, Sangamon, Macon, Piatt, Douglas, and Edgar
Place of Meeting: Hotel Pere Marquette or Caterpillar Show Room
Number of Members: 116

EXECUTIVE COMMITTEE

W. W. BABCOCK, *Chairman*
W. N. ESPY, L. P. WEINER } *Vice-Chairmen*
R. E. MCCLAIN, *Secretary-Treasurer*
U. L. DEFFENBAUGH, *Assistant Secretary-Treasurer*
B. L. BAILIE

CENTRAL INDIANA

Organized: 1916
Territory: Radius of eighty miles from Indianapolis, within Indiana
Place of Meeting: Indianapolis Athletic Club
Local Organization: Indiana Engineering Society
Number of Members: 169

EXECUTIVE COMMITTEE

R. B. BASS, *Chairman*
M. E. BECHTOLD, *Vice-Chairman*
D. P. MORSE, *Secretary-Treasurer*
H. A. BOLZ
G. A. HAWKINS
R. B. HOLMES
FERDINAND JEHLE
W. C. WISCHMEYER

CENTRAL PENNSYLVANIA

Organized: 1921
Territory: Radius of approximately sixty miles from State College, Pa.
Place of Meeting: State College and Altoona, Pa.
Number of Members: 74

EXECUTIVE COMMITTEE

R. Y. SIGWORTH, *Chairman*
H. A. SORENSEN, *Secretary-Treasurer*
J. S. DOOLITTLE
R. L. HULSIZER
F. T. MAVIS
F. C. STEWART
H. C. THUERK

CHICAGO

Organized: 1913
Territory: Radius of fifty miles from Chicago, Ill.
Headquarters: Mid-West A.S.M.E. Office, Room 1617, 205 West Wacker Drive, Chicago, Ill.
Place of Meeting: Civic Opera Bldg., 20 N. Wacker Dr.
Meetings: Tuesday, 7:30 p.m.
Local Organization: Western Society of Engineers
Number of Members: 918

EXECUTIVE COMMITTEE

J. P. MAGOS, *Chairman*

EAST TENNESSEE

Organized: 1922
Territory: All counties in Tennessee east of the west boundary of Scott, Morgan, Cumberland, White, Warren, Coffee, Moore, Franklin; Belle County in Kentucky; and Rossville, Dade, Walker, Cattasa, Whitfield, Murray, Gordon, Chattooga in Georgia
Place of Meeting: Places varies
Local Organization: Chattanooga Engineers Club and Knoxville Technical Club
Luncheon Meeting every Monday noon at Chattanooga Engineers Club
Number of Members: 119

EXECUTIVE COMMITTEE

L. A. SHIPMAN, *Chairman*
G. E. CAMPBELL, W. C. ELLIS, F. H. THOMAS } *Vice-Chairmen*
J. MACK TUCKER, *Secretary-Treasurer*
F. F. DEAN
VINCENT MATTHEWS
G. E. MORGAN
G. L. MORRIS

ERIE

Organized: 1917
Territory: Radius of thirty miles from Erie, Pa.
Place of Meeting: Erie County Court House
Number of Members: 99

EXECUTIVE COMMITTEE

E. C. IMS, *Chairman*
G. H. KAEMMERLING, *Vice-Chairman*
F. B. SCHNEIDER, *Secretary-Treasurer*
G. H. BACH
F. G. BRINIG
H. E. GOETZ
C. I. RAINESALO
MCDONALD S. REED
H. B. JOYCE, *Ex-Officio*

FLORIDA

Organized: 1925
Territory: State of Florida
Place of Meeting: Various cities in state
Local Organization: Florida Engineering Society, Gainesville, Fla.
Number of Members: 97

EXECUTIVE COMMITTEE

T. H. GARDNER, *Chairman*
JOHN HUNTER, *1st Vice-Chairman*
CHARLES BEENSEN, *2nd Vice-Chairman*
R. A. THOMPSON, *Secretary-Treasurer*
R. Y. POOL
S. L. STEWART
F. W. FINEREN, *Student-Chairman*

FORT WAYNE

Organized: 1939
Territory: Counties of LaGrange, Steuben, Noble, DeKalb, Whitley, Allen, Wabash, Huntington, Wells, Adams, Miami, Blackford and Jay in Indiana; Counties of Williams, Defiance, Paulding, Van Wert and Mercer in Ohio
Local Organization: Fort Wayne Engineers' Society
Number of Members: 46

EXECUTIVE COMMITTEE

K. K. COOPER, *Chairman*
EVERETT S. BUCK, *Vice-Chairman*
I. A. PLANCK, *Secretary*
F. C. MASON, *Treasurer*
W. H. CONNOR
F. L. RUOFF

GREEN MOUNTAIN

Organized: 1923
Territory: Entire State of Vermont and neighboring and closely related communities of Claremont and Hanover, N.H.
Place of Meeting: Springfield, Windsor, Vt., and Claremont, N.H.
Local Organization: Vermont Engineering Society
Number of Members: 51

EXECUTIVE COMMITTEE

C. H. ADAMS, *Chairman*
F. T. GEAR, *Vice-Chairman*
F. A. JOHNSON, *Secretary-Treasurer*
E. D. CLARK
H. L. DAASCH
D. T. HAMILTON
J. B. JOHNSON

GREENVILLE

Organized: As a Branch, 1923; as a Section, 1927
Territory: Radius of sixty miles from Greenville, S.C.
Place of Meeting: Meetings held at Greenville, Clemson College, S.C., Canton, Asheville, and Enka, N.C.
Number of Members: 45

EXECUTIVE COMMITTEE

W. PAUL TINDALL, *Chairman*
B. E. FERNOW, *Vice-Chairman*
J. W. VAUGHAN, JR., *Secretary-Treasurer*
R. B. FULLER
J. R. GILL
W. E. MCDOWELL
A. KEITH POOSER
E. M. WILLIAMS

HARTFORD

Organized: 1917, as Branch of Conn. Section; reorganized, 1923; New Britain Section merged with Hartford Section, July 1, 1940
Territory: Hartford County except that portion served by New Britain Section
Place of Meeting: Hartford Electric Light Company
Number of Members: 200

EXECUTIVE COMMITTEE

L. C. SMITH, *Chairman*
E. R. LEWIS, JR., HENRY MICHELSEN } *Vice-Chairmen*
R. D. KELLER, *Secretary-Treasurer*
J. S. APPLEYARD
HERBERT BURDICK
H. F. CASSIDY
F. O. HOAGLAND

H. F. RAMM
H. P. SMITH
G. E. STANWAY
C. C. STEVENS
S. J. TELLER
J. C. WALTERS
R. L. WEIL

INLAND EMPIRE

Organized: 1921
Territory: East of Columbia River in State of Washington, and Counties of Okanogan and Benton, and part of Northern Idaho
Place of Meeting: Davenport Hotel, Spokane
Luncheons: Wednesdays at 12:00 noon, Davenport Hotel, Spokane
Local Organization: Associated Engineers of Spokane
Number of Members: 22

EXECUTIVE COMMITTEE

F. W. CANDEE, *Chairman*
J. G. MCGIVERN, *Vice-Chairman*
N. W. HUMPHREY, *Secretary-Treasurer*
ALEXANDER LINDSAY
E. B. PARKER
L. J. POSPISIL

ITHACA

Organized: 1936
Territory: Radius of thirty miles from Ithaca plus following cities: Binghamton, Corning, Endicott, Geneva, Painted Post
Place of Meeting: Alternately in different cities of Section territory, as announced
Number of Members: 83

Executive Committee

C. Lyman Wilder, *Chairman*
S. S. Garrett, *Vice-Chairman*
F. S. Erdman, *Secretary-Treasurer*
D. S. Kimball
W. M. Sawdon
M. P. Whitney
N. R. Wickersham

KANSAS CITY

Organized: 1921
Territory: Radius of sixty miles from Kansas City, Mo.
Place of Meeting: University Club
Local Organization: Engineers' Club of Kansas City
Number of Members: 159

Executive Committee

F. R. Applegate, *Chairman*
L. T. Mart, *Vice-Chairman*
H. E. Manuel, *Secretary*
R. P. Hahn, *Treasurer*
E. E. Ambrosius
G. C. Boyer
C. B. Briggs, Jr.
Chester Cotter
C. C. Holt
M. A. Durland, *Ex-Officio*

LOUISVILLE

Organized: 1922
Territory: Radius of thirty miles from Louisville, Ky. (includes Lexington, Ky.)
Place of Meeting: University of Louisville, Louisville, Ky.
Local Organization: Engineers and Architects Club
Number of Members: 68

Executive Committee

H. V. Heuser, *Chairman*
J. K. Meyer, *Vice-Chairman*
F. P. Shannon, *Secretary*
O. C. Krause, Jr., *Treasurer*
C. D. Eldridge
W. F. Lucas
H. C. Murphy
F. L. Wilkinson, Jr.

MEMPHIS

Organized: 1923
Territory: Radius of sixty miles from Memphis, Tenn., and eastern half of Arkansas including all the territory east of a line drawn north and south through the western boundary of the city of Little Rock
Number of Members: 25

Executive Committee

W. H. Roberts, *Acting Chairman*
H. S. Livingston, *Secretary-Treasurer*
W. S. Carell
R. M. King
D. S. Pattershall

METROPOLITAN

Organized: 1910
Territory: Metropolitan District, New York and New Jersey
Place of Meeting: Engineering Societies Building, 29 West 39th Street, New York, N.Y.
Number of Members: 3,446

Executive Committee

H. C. R. Carlson, *Chairman*
A. Ehbrecht, *Secretary*
E. V. David, *Treasurer*
W. L. Betts
R. W. Flynn
G. E. Hagemann
H. E. Martin
G. J. Nicastro
P. T. Onderdonk
J. H. Sengstaken

Junior Group

P. B. Petty, *Chairman*
W. Wiitanen, *Vice-Chairman*
J. J. Jacobs, *Secretary*
Franklin H. Fowler, Jr.
F. M. Gibson, Jr.
John Pollak
Irving P. West

MID-CONTINENT

Organized: 1919
Territory: Entire State of Oklahoma; territory in Arkansas not included in Memphis Section; part of Louisiana; and territory in Texas north of the southern boundaries of the counties of Gaines, Dawson, Bordon, Scurry, Fisher, Jones, and Shackelford
Place of Meeting: Usually Mayo Hotel, Tulsa, Okla.
Luncheon Meetings with Engineers Club of Tulsa, Mondays at 12:00 noon
Local Organization: Engineers Club of Tulsa
Number of Members: 153

Executive Committee

D. A. Cant, *Chairman*
R. A. Colgin, C. H. Stevens } *Vice-Chairmen*
J. H. Keyes, *Secretary*
Nathan Janco, *Treasurer*
R. G. Ayers
D. O. Barrett
W. L. Ducker, Jr.
C. O. Glasgow
R. F. Hurt
D. K. Hutchcraft
A. J. Kerr
H. T. Sears
W. S. Sherman

MILWAUKEE

Organized: 1904
Territory: Radius of fifty miles from Milwaukee, Wis.
Place of Meeting: Wisconsin Club
Local Organization: Engineers' Society of Milwaukee
Luncheon Meetings once each month, 3rd Wednesday at Wisconsin Club
Number of Members: 287

Executive Committee

J. E. Schoen, *Chairman*
T. A. Wetzel, *Secretary-Treasurer*
R. J. Cramer
P. J. Imse
Edward Jacobi
C. S. Lincoln
W. C. Lindemann
Max E. Ruess
Russell J. Smith
W. J. Thuerman
E. J. Wellauer

Junior Group

Max E. Ruess, *Chairman*
Sebastian Judd, *Secretary*
Joseph J. Drinka
Arnold Ehlinger
Harry Gute

MINNESOTA

Organized: Minneapolis, 1913; St. Paul, 1913; the two Sections merged, 1934
Territory: Entire State of Minnesota
Place of Meeting: Minnesota Union, Univ. of Minnesota
Local Organization: Minneapolis Engineers' Club, Minnesota Federation of Architectural and Engineering Societies
Number of Members: 112

Executive Committee

W. H. Erskine, *Chairman*
R. W. Jones, Jr., *Vice-Chairman*
L. S. Whitson, *Secretary-Treasurer*
Charles Foster
F. L. Smith
L. C. Sprague
M. S. Wunderlich

NEBRASKA

Organized: 1922
Territory: State of Nebraska, and Council Bluffs, Iowa
Place of Meeting: Lincoln and Omaha
Local Organization: Engineers' Clubs of Lincoln and Omaha
Luncheon Meeting every Wednesday noon at the Omaha Engineers' Club—4th Monday Evening at Lincoln
Number of Members: 39

Executive Committee

C. F. Moulton, *Chairman*
W. L. DeBaufre, *Vice-Chairman*
A. A. Luebs, *Secretary-Treasurer*
J. W. Kurtz
G. A. Rogers
W. F. Weiland

NEW HAVEN

Organized: 1912, reorganized, 1923
Territory: Portions of New Haven and Middlesex Counties, Conn.
Place of Meeting: Mason Laboratory, Yale University
Number of Member: 99

Executive Committee

C. W. Phelps, *Chairman*
G. H. Eaton, *Vice-Chairman*
F. W. Preston, *Secretary-Treasurer*
A. F. Breitenstein
E. E. Caspell
A. S. Redway
A. D. Wilcox

NEW LONDON

Organized: 1930, as the Norwich Section; name changed, 1943
Territory: Counties of Tolland, Windham, and New London in Connecticut, and Westerly District in Rhode Island
Place of Meeting: New London Junior College, Pequot Ave., New London, Conn.
Number of Members: 54

Executive Committee

J. S. Leonard, *Chairman*
W. A. Hardy, *Secretary-Treasurer*
F. S. English
C. A. Gongwer
K. P. Hanson
W. H. Himes
Robert Wosak

NEW ORLEANS

Organized: 1916
Territory: All of Louisiana except the northern part allotted to Mid-Continent Section
Place of Meeting: Room 422, St. Charles Hotel
Local Organization: Louisiana Engineering Society
Number of Members: 135

Executive Committee

L. J. Cucullu, *Chairman*
A. M. Hill, *Vice-Chairman*
E. A. McLellan, *Secretary-Treasurer*
M. C. Abrahm
E. L. Cowan
D. H. McCuaig
R. F. Mendow
William Whipple

NORTH TEXAS

Organized: 1922
Territory: All of Texas north of an approximately straight line through Del Rio, Fredericksburg, Georgetown, Cameron, Nacogdoches, and center, including the cities mentioned, and south of north boundaries of the counties of Parmer, Castro, Swisher, Briscoe, Hall, and Childress. Also the City of Texarkana, Ark.
Place of Meeting: Dallas Power & Light Co. Bldg. Auditorium
Local Organization: Technical Club of Dallas
Number of Members: 121

Executive Committee

J. A. Noyes, *Chairman*
P. M. Cordell, H. F. Godeke } *Vice-Chairmen*
J. A. Lee, *Secretary-Treasurer*
Stanley Patterson
H. M. Robinson
H. W. Trump
E. J. Wacker

ONTARIO

Organized: 1917
Territory: Province of Ontario, Canada
Place of Meeting: Hart House, University of Toronto
Number of Members: 171

Executive Committee

H. G. Hill, *Chairman*
W. H. Hewitt, *Secretary-Treasurer*
E. A. Allcut
H. H. Angus
S. G. Clarke
J. G. Hall
Ernest Jones
K. D. Leitch
A. A. Moline
A. L. Scott
W. D. Sheldon, Jr.
A. D. Smith
Fred'k Truman
R. C. Wiren

OREGON

Organized: 1919
Territory: State of Oregon and that territory in Washington within a radius of thirty miles from Portland, Ore.
Place of Meeting: Usually Public Service Bldg., Portland, Ore.
Local Organization: Oregon Society of Engineers
Number of Members: 59

Executive Committee

E. P. Weiser, *Chairman*
M. M. Clayton, *Vice-Chairman*
A. J. Chaput, *Secretary*
E. D. Rowan, *Treasurer*
L. T. Hays
A. D. Hughes
J. C. Othus
Ivan Saunders

PENINSULA

Organized: 1923
Territory: West of the east boundaries of the following counties: Emmet, Charlevoix, Antrim, Kalkaska, Missaukee, Clare, Isabell, Gratiot, Clinton, Eaton, Calhoun, and Branch, Mich.
Place of Meeting: Grand Rapids, Mich.
Luncheon Meeting last Thursday noon each month
Local Organization: Engineers' Club of Grand Rapids
Number of Members: 60

Executive Committee

J. M. Gorrie, *Chairman*
Donald McSorley, *1st Vice-Chairman*
Kenneth E. Crowser, *2nd Vice-Chairman*
C. J. Kuenzel, *Secretary-Treasurer*
C. P. Buck
J. R. de Hamer
G. E. Gebben
C. G. Lohmann
C. A. Hamilton, *Ex-Officio*

PHILADELPHIA

Organized: 1912
Territory: Counties of Bucks, Montgomery, Chester, Philadelphia, Delaware, Pa., and the State of Delaware
Place of Meeting: Philadelphia Engineers' Club, 1317 Spruce Street, Philadelphia, Pa.
Local Organization: Philadelphia Engineers' Club
Luncheon Meeting every Thursday noon at 12:30 p.m. at Philadelphia Engineers' Club
Number of Members: 1,069

Executive Committee

L. N. Gulick, *Chairman*
F. W. Miller, *Vice-Chairman*
J. J. McCarthy, *Secretary-Treasurer*
C. S. Gotwals
A. G. Kisner
S. T. Mackenzie

Junior Group

F. P. Gooch, *Chairman*
Frank Ptacek, *Vice-Chairman*
H. J. Clyman, *Secretary*
T. J. Putz, *Treasurer*
M. E. Harvey
Harvey Schock, Jr.
Walter Sinton
R. W. Worley

PIEDMONT—NORTH CAROLINA

Organized: As a Branch, 1923; as a Section 1927; name changed from Charlotte Section to Piedmont—North Carolina, July 1, 1940
Territory: Radius of seventy-five miles from Charlotte, N.C.
Luncheon Meeting every other Monday at 1:00 p.m. at Efirds Department Store Dining Room
Local Organization: Charlotte Engineers Club
Number of Members: 47

Executive Committee

David Nabow, *Chairman*
B. L. Cotten, *Acting Vice-Chairman*
N. H. Brown, *Secretary-Treasurer*
E. L. Davis
Richard Ferguson
T. C. Heyward
I. W. Leggett
A. B. LeClerc, *Ex-Officio*

PITTSBURGH

Organized: 1920
Territory: Counties bounded by and including Beaver, Butler, Venango, Forest, Jefferson, Indiana, Somerset, Fayette, Greene, and Washington, Pa.
Place of Meeting: Engineers' Society of Western Pennsylvania, William Penn Hotel
Local Organization: Engineers' Society of Western Pennsylvania
Number of Members: 510

Executive Committee

L. E. F. Wahrenburg, *Chairman*
L. E. Hankinson, *Vice-Chairman*
E. W. Jacobson, *Secretary*
K. F. Treschow, *Treasurer*
R. B. Ambrose
R. L. Ehmann
T. G. Estep
J. C. Hoar
G. Sinding-Larsen

PLAINFIELD

Organized: 1921
Territory: Plainfield and territory included between Elizabeth, Bound Brook, Metuchen, and Watchung, N.J.
Place of Meeting: Elizabeth Carteret Hotel, Elizabeth, and Plainfield Masonic Temple, Plainfield
Local Organization: Plainfield Engineers Club, Singer Engineering Society
Number of Members: 199

PLAINFIELD
(Continued)

EXECUTIVE COMMITTEE

W. H. CHAFFEE, *Chairman*
E. T. BALL, *Vice-Chairman*
R. H. CHANKALIAN, *Secretary*
J. D. POTTER, *Treasurer*
G. E. LEAVITT, JR., *Past-Chairman*

PROVIDENCE

Organized: 1920
Territory: Radius of thirty miles from Providence, R.I.
Place of Meeting: Providence Engineering Society Building, 195 Angell St., Providence, R.I.
Local Organization: Providence Engineering Society
Number of Members: 168

EXECUTIVE COMMITTEE

R. M. SCOTT, *Chairman*
G. W. KELSEY, *Vice-Chairman*
E. W. HARRINGTON, *Secretary-Treasurer*
J. B. COLEMAN
W. M. DAVIES
HASBROUCK HAYNES
P. J. HOLTON
ALFRED H. MACGILLIVRAY
A. W. MEYER
P. V. MILLER
J. D. ROBERTSON, *Ex-Officio*

RALEIGH

Organized: As a Branch, 1923; as a Section, 1927
Territory: Radius of sixty miles from Raleigh, N.C.
Places of Meeting: North Carolina State College, Raleigh, N.C.; Duke University, Durham, N.C.
Local Organizations: North Carolina Society of Engineers, Raleigh Engineers Club
Number of Members: 37

EXECUTIVE COMMITTEE

F. J. REED, *Chairman*
G. W. BAITY, *Vice-Chairman*
F. C. BRAGG, *Secretary-Treasurer*
C. E. KERCHNER
R. B. RICE
F. B. TURNER
R. S. WILBUR

ROCHESTER

Organized: 1919
Territory: Radius of thirty miles from Rochester, N.Y.
Place of Meeting: Rochester Engineering Society Rooms, Sagamore Hotel
Local Organization: Rochester Engineering Society, Sagamore Hotel
Luncheon Meeting every Tuesday at 12:15 p.m. at Sagamore Hotel
Number of Members: 116

EXECUTIVE COMMITTEE

A. W. SCHUSTER, *Chairman*
S. C. STACY, *Vice-Chairman*
A. E. SCHELL, *Secretary-Treasurer*
M. L. BAXTER
W. J. BROWN
C. A. ELWOOD
H. L. MASON.
C. B. MCCATHRON

ROCK RIVER VALLEY

Organized: 1926
Territory: Thirty miles east and west of Madison, Wis., and extending southward through Rockford, Ill.
Meeting Places: Madison, Wis., Beloit, Wis., and Rockford, Ill.
Local Organization: Rock River Valley Engineering Council
Number of Members: 50

EXECUTIVE COMMITTEE

K. H. CASSON, *Chairman*
W. C. FISCHER, *Vice-Chairman*
T. G. LAUGHNAN, *Secretary-Treasurer*
BEN G. ELLIOTT
D. W. NELSON
JERVIS SWANNACK

ST. JOSEPH VALLEY

Organized: 1929
Territory: Counties of La Porte, Starke, Pulaski, St. Joseph, Marshall, Fulton, Elkhart, and Kosciusko in Indiana, and Cass and Berrien Counties in Michigan
Place of Meeting: South Bend, Ind.
Number of Members: 60

EXECUTIVE COMMITTEE

E. T. COBB, *Chairman*
O. E. E. ZAHN, *Secretary-Treasurer*
C. ROBERT EGRY
R. C. FITCH
ALLEN LOOMIS
G. R. MCNEILE
W. D. A. PEASLEE
L. E. WADDINGTON

ST. LOUIS

Organized: 1909
Territory: Radius of thirty miles from St. Louis, Mo.
Place of Meeting: Place varies
Local Organization: Engineers' Club of St. Louis
Number of Members: 225

EXECUTIVE COMMITTEE

R. M. BOYLES, *Chairman*
HERBERT KUENZEL, *Vice-Chairman*
H. E. FRECH, JR., *Secretary-Treasurer*
R. W. MERKLE
R. C. THUMSER
H. B. WELGE

SAN FRANCISCO

Organized: 1910
Territory: All territory north of the northern boundaries of the counties of San Luis Obispo, Kern, and San Bernardino
Place of Meeting: Engineers' Club, 206 Sansome St.
Luncheon Meetings, Tuesdays, California Hotel, Oakland; Thursdays, Engineers' Club, San Francisco
Local Organization: San Francisco Engineers' Club
Number of Members: 472

EXECUTIVE COMMITTEE

W. H. KASSEBOHM, *Chairman*
ALF HANSEN, *Vice-Chairman*
J. ALLAN CAMPBELL, *Secretary-Treasurer*
E. G. GOTHBERG
R. B. PLASS
MORRIS TAYLOR
GEO. N. SOMERVILLE, *Ex-Officio*

JUNIOR GROUP

TEMPLE VOORHEIS, *Chairman*
EDWARD E. POLOMIK, *Seminar Chairman*
M. P. WHITFIELD, *Secretary-Treasurer*

SAVANNAH

Organized: 1923
Territory: Radius of 125 miles from Savannah in Georgia
Place of Meeting: Savannah Hotel
Local Organization: Engineers' Council of Savannah Chamber of Commerce
Number of Members: 23

EXECUTIVE COMMITTEE

W. L. MINGLEDORFF, JR., *Chairman*
A. M. ORMOND, *Vice-Chairman*
B. J. SAMS, *Secretary-Treasurer*

SCHENECTADY

Organized: As a Branch, 1919; as a Section, 1927
Territory: Radius of thirty miles from Schenectady, N.Y.
Place of Meeting: Rice Hall
Number of Members: 276

EXECUTIVE COMMITTEE

L. A. GOBE, *Chairman*
D. C. BRECHT, F. R. FOWLER, E. L. THEARLE } *Vice-Chairmen*
J. B. NOLAN, *Secretary*
J. E. RYAN, *Treasurer*
H. E. BRUNELLE
D. R. EDWARDS
A. O. WHITE

SOUTHERN CALIFORNIA

Organized: 1915 as Los Angeles Section; reorganized 1941
Territory: South of southern boundaries of following counties: Monterey, Kings, Tulares, and Inyo, Calif.
Place of Meeting: Barker Bros. Store
Local Organization: Technical Societies of Los Angeles
Luncheon Meetings Thursdays at 12:00 noon at Engineers' Club
Number of Members: 620

EXECUTIVE COMMITTEE

R. G. ROSHONG, *Chairman*
D. K. COYLE, *Vice-Chairman*
B. N. PALM, *Secretary-Treasurer*
JAMES BEAN
J. CALVIN BROWN
M. L. CRATER
C. W. HUFFMAN
W. H. SHALLENBERG
EDWARD TIMBS
LLOYD YOST

JUNIOR GROUP

W. K. BOTTICHER, *Chairman*
F. R. ADLER, *Secretary*
WILBUR REASER

SOUTH TEXAS

Organized: 1919
Territory: South Texas and the northern part of the State not included in the North Texas Section territory
Place of Meeting: No fixed meeting place, but all meetings held in Houston
Number of Members: 179

SOUTH TEXAS
(Continued)

EXECUTIVE COMMITTEE

H. E. DEGLER, *Chairman*
W. T. ALLIGER, *Vice-Chairman*
J. B. T. DOWNS, *Secretary-Treasurer*
D. D. ALTON
JOHN DOGGETT, JR.
V. M. FAIRES
B. W. FARQUHAR
H. G. HIEBELER
M. H. KOTZEBUE
H. F. MOLLER
RALPH NEUHAUS
C. L. ORR
F. D. RAHM

SUSQUEHANNA

Organized: 1927
Territory: Counties of Cumberland, Dauphine, Lebanon, Adams, York, and Lancaster
Place of Meeting: Engineering Society of York, and at Lancaster twice a year
Local Organization: Engineering Society of York and Engineers' Society of Pennsylvania, Harrisburg, Pa.
Number of Members: 87

EXECUTIVE COMMITTEE

JACOB FISCH, *Chairman*
M. GERALD LEESON, *Vice-Chairman*
T. K. BREDA, *Secretary-Treasurer*
JOSEPH A. GALAZZI
E. W. GALLENHAMP
M. F. GANNETT
M. M. JONES
E. L. ROGERS

SYRACUSE

Organized: 1920
Territory: Radius of thirty miles from Syracuse, N.Y.
Place of meeting: Ball Room of the Onondaga Hotel
Local Organization: The Technology Club of Syracuse
Number of Members: 79

EXECUTIVE COMMITTEE

G. I. VINCENT, *Chairman*
J. A. KING, *Vice-Chairman*
L. EDWARD POTTER, *Secretary*
H. T. AVERY
C. F. DIETZ
W. E. HOPTON
J. W. LINFORD
M. B. MOYER
E. K. RHODES
D. V. SHETLAND
M. F. WILLIAMS

TOLEDO

Organized: 1920
Territory: Radius of thirty miles from Toledo, Ohio
Place of Meeting: University Club, Toledo, Ohio
Local Organization: Affiliated Technical Societies of Toledo
Number of Members: 58

EXECUTIVE COMMITTEE

R. J. MUGFOR, *Chairman*
SYDNEY BEVIN, *Vice-Chairman*
W. A. NELDEN, *Secretary-Treasurer*
RALPH FLOREK
T. L. HALLENBECK
R. F. HILL
B. H. KEYSEELING
H. O. KRANICH
R. C. LANGENDERFER
W. R. MORAN
D. M. PALMER
W. C. SCHROEDER
H. H. VOGEL
ERNEST W. WEAVER

TRI-CITIES

Organized: 1920
Territory: Radius of thirty miles from Moline, Ill.
Place of Meeting: Rock Island, Ill., Moline, Ill., and Davenport, Iowa.
Luncheon Meeting every Wednesday, Davenport Hotel, 12:00 noon
Number of Members: 83

EXECUTIVE COMMITTEE

K. R. HODGES, *Chairman*
P. E. ANDERSON, *Vice-Chairman*
C. A. CARLSON, *Secretary-Treasurer*
R. M. BARNES
R. A. CROSS
J. M. HARTMAN

UTAH

Organized: 1923
Territory: State of Utah
Place of Meeting: University Club, Salt Lake City
Local Organization: Utah Society of Professional Engineers
Number of Members: 42

EXECUTIVE COMMITTEE

H. L. ZETTERMAN, *Chairman*
R. D. BAKER, *Vice-Chairman*
R. E. KUNKEL, *Secretary-Treasurer*
G. W. CARTER
M. B. HOGAN
E. C. POLLARD

VIRGINIA

Organized: 1919
Territory: State of Virginia
Place of Meeting: Richmond, Norfolk, Blacksburg, Charlottesville, Roanoke, University, Petersburg
Local Organization: Central Virginia Engineers Club of Hampton Roads
Number of Members: 188

EXECUTIVE COMMITTEE

J. B. JONES, *Chairman*
D. A. ROGERS, *Vice-Chairman*
A. E. BOCK, *Secretary*
W. J. BARBER, *Treasurer*
G. T. ABERNATHY
E. W. BOWEN
O. N. HALL
G. E. HOPPE, JR.
EDWARD PRINGLE
ARTHUR ROBERTS, JR.

WASHINGTON, D.C.

Organized: 1919
Territory: District of Columbia
Place of Meeting: Auditorium, Potomac Electric Power Co., 10th & E Sts., Washington, D.C.
Number of Members: 481

EXECUTIVE COMMITTEE

C. E. MILLER, *Chairman*
M. A. MASON, *Vice-Chairman*
E. J. H. LANE, *Secretary-Treasurer*
C. E. BERBERICH
B. C. CRUICKSHANKS
RUDOLPH MICHEL
J. C. PHILLIPS

WATERBURY

Organized: 1917, as a Branch; reorganized as a Section, 1923
Territory: Litchfield County and a portion of New Haven County
Place of Meeting: Elton Hotel
Number of Members: 71

EXECUTIVE COMMITTEE

J. R. HICKS, *Chairman*
C. M. WARNER, *Vice-Chairman*
A. W. MINER, *Secretary-Treasurer*
A. L. ALVES
J. H. RAUB
R. S. SPERRY
R. S. STORRS

WESTERN MASSACHUSETTS

Organized: 1922
Territory: Includes counties of Berkshire, Franklin, Hampden, and Hampshire
Place of Meeting: Highland Hotel, Springfield, Mass.
Local Organization: Engineering Society of Western Massachusetts
Number of Members: 93

EXECUTIVE COMMITTEE

R. A. PACKARD, *Chairman*
J. F. MALCOLM, *Vice-Chairman*
D. A. BARTLETT, *Secretary-Treasurer*
LEO KRESSER
F. F. LANGE
E. WADSWORTH STONE

WESTERN WASHINGTON

Organized: 1919
Territory: State of Washington west of Columbia River with exception of territory included in 30-mile radius of Portland, Ore.
Place of Meeting: Engineers' Club, Seattle, Wash.
Local Organization: Seattle Engineers' Club
Luncheon Meetings daily at noon at Engineers' Club, Seattle
Number of Members: 203

EXECUTIVE COMMITTEE

B. T. MCMINN, *Chairman*
F. E. BLUMBERG, *Vice-Chairman*
L. B. COOPER, *Secretary-Treasurer*
G. C. MARTINSON
R. E. MESSER
N. J. SCHAAL

WEST VIRGINIA

Organized: 1925
Territory: State of West Virginia, South of Parallel 39
Place of Meeting: Charleston, W.Va.
Number of Members: 56

WEST VIRGINIA
(Continued)

EXECUTIVE COMMITTEE

H. B. HICKMAN, *Chairman*
M. C. BROOKE, *Vice-Chairman*
J. L. BARKER, JR., *Secretary-Treasurer*
L. B. MCQUAIDE, *Asst. Secretary-Treasurer*
A. H. CANNON
J. G. MILLER
M. C. MUMMA
F. L. SCHAEFER
R. D. WEBB

WORCESTER

Organized: 1915
Territory: Radius of thirty miles from Worcester, Mass.
Place of Meeting: Sanford Riley Hall, Worcester Poly. Inst.
Local Organization: Worcester Engineering Society
Number of Members: 126

EXECUTIVE COMMITTEE

L. J. HOOPER, *Chairman*
G. H. MCCULLOUGH, *Vice-Chairman*
W. F. BETH, *Secretary-Treasurer*
L. R. BALL
DAVID CHIRAS
F. W. MIERKE
E. H. SMITH
F. E. STRANDBERG

YOUNGSTOWN

Organized: 1928
Territory: Counties of Trumbull, Mahoning, and Columbiana in Ohio, and Mercer and Lawrence in Pennsylvania
Place of Meeting: Republic Rubber Co. Club Rooms, Albert St., Youngstown, Ohio
Number of Members: 63

EXECUTIVE COMMITTEE

H. W. SMITH, *Chairman*
L. A. KLINE, *Vice-Chairman*
C. W. FOARD, *Secretary-Treasurer*
F. J. BOWERS
C. H. LEGLER
W. J. LONGACHER
HANS E. MELIN

STUDENT BRANCHES

ARTICLE B6A, PAR. 20: The Standing Committee on Relations With Colleges shall, under the direction of the Council, have supervision of the Student Branches of the Society and of such work of the Society as aims to further the education of engineers through the colleges and schools of accepted standing.

STANDING COMMITTEE, RELATIONS WITH COLLEGES

H. E. DEGLER, *Chairman* (1944)
G. L. SULLIVAN (1945)
R. P. REECE (1946)
H. J. BROWN (1947)
HERBERT KUENZEL (1948)

M. M. BORING, A. D. HUGHES, R. H. PORTER, J. W. ZELLER — *Advisory Members* (1944)

J. M. SEXTON, *Junior Adviser* (1944)

RESEARCH COMMITTEES

ARTICLE B6A, PAR. 24: The Standing Committee on Research shall, under the direction of the Council, have supervision of the research activities of the Society.

The first Standing Committee on Research was organized in 1909.

STANDING COMMITTEE

HERMAN WEISBERG, *Chairman* (1944)
W. R. ELSEY (1945)
J. F. D. SMITH (1946)
D. L. LINDQUIST (1947)
G. A. HAWKINS (1948)

LUBRICATION

Appointed October, 1915, to investigate the fundamental problems of lubrication, to formulate results of investigations previously made, and to keep in touch with contemporary research in this field

(Reorganized May, 1936)

B. L. NEWKIRK, *Chairman*
S. J. NEEDS, *Secretary*
A. L. BEALL
OSCAR BRIDGEMAN
W. E. CAMPBELL
H. A. EVERETT
A. E. FLOWERS
J. C. GENIESSE
RAYMOND HASKELL
M. D. HERSEY
B. F. HUNTER
C. M. LARSON
F. C. LINN
G. L. NEELY
E. S. PEARCE
ERNEST WOOLER

FLUID METERS

Appointed 1916 to develop the theory of fluid meters of all kinds and to report on the best methods for their installation and use

(Reorganized July, 1926)

R. J. S. PIGOTT, *Chairman*
J. R. CARLTON, *Secretary*
H. S. BEAN
S. R. BEITLER
R. K. BLANCHARD
B. O. BUCKLAND
LOUIS GESS
E. W. JACOBSON
A. J. KERR
T. H. KERR
I. O. MINER
M. P. O'BRIEN
W. S. PARDOE
L. K. SPINK
R. E. SPRENKLE
T. R. WEYMOUTH
M. J. ZUCROW

STRENGTH OF GEAR TEETH

Appointed in December, 1921, to investigate factors affecting the strength and life of gear teeth

R. E. FLANDERS, *Chairman*
C. H. LOGUE, *Secretary*
EARLE BUCKINGHAM
A. M. GREENE, JR.
C. W. HAM
F. E. McMULLEN
E. W. MILLER
ERNEST WILDHABER

METAL CUTTING DATA AND BIBLIOGRAPHY

Appointed in September, 1923, to study the problems of metal cutting, including tool materials, tool design, speeds and feeds

(Reorganized December, 1943)

M. MARTELLOTTI, *Chairman*
O. W. BOSTON
W. C. DE GRAFF
F. M. FISHER
J. A. FRASER
T. F. GITHENS
M. F. JUDKINS
W. L. KENNICOTT
M. E. LANGE
F. W. LUCHT
F. J. OLIVER
C. J. WIBERG

CUTTING FLUIDS

Appointed in September, 1923, to study the problems of metal cutting, including lubrication and cooling

(Reorganized December, 1943)

O. W. BOSTON, *Chairman*
H. L. MOIR
W. H. OLDACRE

MECHANICAL SPRINGS

Appointed May, 1924, to determine the status of the mechanical-spring art, to promote and conduct necessary and adequate research, and to develop the art to the point of standardization

J. R. TOWNSEND, *Chairman*
C. T. EDGERTON, *Secretary*
R. W. COOK
W. T. DONKIN
RUPEN EKSERGIAN
G. E. HANSEN
BENJAMIN LIEBOWITZ
DAVID LOFTS
R. D. BRIZZOLARA (*Alternate*)
D. J. McADAM, JR.
L. C. PESKIN
R. E. PETERSON
J. W. ROCKEFELLER, JR.
B. W. ST. CLAIR
M. F. SAYRE
T. R. WEBER
KEITH WILLIAMS
J. K. WOOD
F. P. ZIMMERLI

ELEVATORS

Appointed June, 1924, to study the function and operation of elevator safeties and buffers and their associated mechanisms and to develop methods of test for the approval of elevator safety devices

(Reorganized August, 1940)

D. J. PURINTON, *Chairman*
D. L. LINDQUIST, *Vice-Chairman*
G. H. REPPERT (*Alternate*)
J. A. DICKINSON, *Secretary*
S. W. JONES, *Ex-Officio*
E. M. BOUTON
E. B. DAWSON (*Alternate*)
K. A. COLAHAN
G. P. KEOGH
F. PAVLICEK (*Alternate*)
J. J. MATSON
M. B. McLAUTHLIN
C. R. CALLAWAY (*Alternate*)
W. S. PAINE
J. L. KEANE (*Alternate*)
C. A. PETERS

EFFECT OF TEMPERATURE ON THE PROPERTIES OF METALS

Appointed December, 1924, as a Joint Research Committee of the A.S.T.M. and the A.S.M.E. to encourage the investigation and accumulation of data on the properties of metals used in the mechanic arts at extremely high and low temperatures

N. L. MOCHEL, *Chairman*
H. J. KERR, *Vice-Chairman*
J. W. BOLTON, *Secretary*
W. H. ARMACOST
A. B. BAGSAR
A. D. BAILEY
F. E. BASH
C. L. CLARK
E. S. DIXON
F. B. FOLEY
J. R. FREEMAN, JR.
H. J. FRENCH
H. W. GILLETT
A. J. HERZIG
G. F. JENKS
J. J. KANTER
C. E. MACQUIGG
R. F. MILLER
E. L. ROBINSON
J. H. ROMANN
A. E. WHITE
J. S. WORTH
Director, National Bureau of Standards, U.S. Department of Commerce
Representative of Bureau of Ships, U.S. Navy Department

BOILER FEEDWATER STUDIES

Appointed March, 1925, as a Joint Research Committee of the American Boiler Manufacturers Association, American Railway Engineering Association, American Water Works Association, Edison Electric Institute, the American Society for Testing Materials, and the A.S.M.E. to study methods of analysis and treatment of boiler feedwater for stationary and railroad practice

EXECUTIVE COMMITTEE (Total personnel 41)

C. H. FELLOWS, *Chairman*
R. C. BARDWELL, *Vice-Chairman*
J. B. ROMER, *Secretary*
A. G. CHRISTIE *
R. E. COUGHLAN
B. W. DE GEER

(*Continued*)

* Official A.S.M.E. representative serving on this committee.

BOILER FEEDWATER STUDIES

(Continued)

MAX HECHT
H. E. JORDAN
P. B. PLACE
S. T. POWELL
F. N. SPELLER
M. F. STACK
G. E. TATE
E. H. TENNEY
A. E. WHITE *

CONDENSER TUBES

Appointed May, 1925, to investigate and report on the causes of failure of tubes used in steam condensers and similar heat interchange apparatus

A. E. WHITE, *Chairman*
D. C. WEEKS, *Vice-Chairman*
P. A. BANCELL
R. A. BOWMAN
E. S. BUNN
D. K. CRAMPTON
C. A. CRAWFORD
H. M. CUSHING
R. E. DILLON
C. O. EVANS
J. R. FREEMAN, JR.
V. M. FROST
C. F. HARWOOD
G. C. HOLDER
W. C. HOLMES
W. B. PRICE
J. S. RODGERS
M. F. STACK
W. R. WEBSTER
Director, Bureau of Ships, U.S. Navy Department

WORM GEARS

Appointed May, 1927, to investigate certain problems in connection with the action of worm gear drives and to recommend improvements in their design, manufacture, and use

EARLE BUCKINGHAM, *Chairman*
G. H. ACKER
L. R. BUCKENDALE
D. L. LINDQUIST
A. A. ROSS
B. F. WATERMAN
Representative of Bureau of Ships, U.S. Navy Department

STRENGTH OF VESSELS UNDER EXTERNAL PRESSURE

Appointed June, 1929, to develop reliable design data on the strength of cylindrical and spherical surfaces under external pressure, particularly with reference to jacketed vessels

F. V. HARTMAN, *Chairman*
M. B. HIGGINS
E. C. KORTEN
A. W. LIMONT, JR.
H. E. SAUNDERS
E. E. SHANOR
R. G. STURM
D. B. WESSTROM
F. S. G. WILLIAMS
D. F. WINDENBURG
DANA YOUNG

WIRE ROPE

Appointed April, 1930, to investigate existing rope so that it may be better understood and more effectively used

W. H. FULWEILER, *Chairman*
H. LeR. BRINK
D. L. LINDQUIST
G. W. MARTIN
A. H. McDOUGALL
B. V. E. NORDBERG
W. S. PAINE
W. J. RYAN
GEORGE SIMPSON
L. E. YOUNG

CRITICAL PRESSURE STEAM BOILERS

Appointed June, 1931, to study the characteristics of high-pressure forced-circulation steam-generating units

H. L. SOLBERG, *Chairman*
W. H. ARMACOST
A. D. BAILEY
E. G. BAILEY
F. S. CLARK
C. H. FELLOWS
H. J. KERR
GEO. A. ORROK
E. C. PETRIE
E. L. ROBINSON
P. W. THOMPSON

PLASTIC FLOW OF METALS

Appointed October, 1938, to study plasticity in the particular field of rolling of steel

A. NADAI, *Chairman*
C. W. MacGREGOR, *Secretary*
E. C. BAIN
C. L. EKSERGIAN
LeVAN GRIFFIS
J. H. HITCHCOCK
W. P. ROOP
M. D. STONE
W. TRINKS

FURNACE PERFORMANCE FACTORS

Appointed in October, 1941, to collect and rationalize data on the performance of commercially important furnaces as an aid to design and operation

A. R. MUMFORD, *Chairman*
ALEX D. BAILEY
J. R. MICHEL (*Alternate*)
JOHN BLIZARD
S. P. BURKE
O. F. CAMPBELL
W. A. CARTER
B. J. CROSS
T. B. DREW
F. G. ELY
A. C. FIELDNER
W. C. SCHROEDER (*Alternate*)
J. H. HARLOW
H. C. HOTTEL
E. L. LINDSETH
W. H. McADAMS
A. J. NERAD
E. B. POWELL
A. A. RAYMOND
W. T. REID
R. A. SHERMAN
PHILIP SPORN
A. W. THORSON
HERMAN WEISBERG
W. J. WOHLENBERG

FORGING OF STEEL SHELLS

Appointed in October, 1941, to study methods of shell manufacture under modern conditions

M. D. STONE, *Chairman*
W. TRINKS, *Projects Director*
JOHN DIERBECK
D. W. FLETCHER
W. M. FRAME
W. N. HOWLEY
A. F. MACCONOCHIE
W. P. MUIR
A. NADAI
A. R. NETTENSTROM
GEORGE SACHS
A. E. VAN CLEVE
U.S. Army, Ordnance Department
U.S. Navy, Bureau of Ordnance

DEMOLITION BOMB BODIES

Appointed in October, 1943, to study methods of demolition bomb body manufacture under modern conditions

M. D. STONE, *Chairman*
W. O. CLINEDINST, *Secretary*
W. TRINKS, *Projects Director*
G. M. CROFT
F. C. FANTZ
W. M. FRAME
R. FURRER
H. B. LIGGETT
A. NADAI
GEORGE SACHS
U.S. Army Ordnance Department
U.S. Navy, Bureau of Ordnance

A.S.M.E. Representatives on Other Research Committees

See also A.S.M.E. Representatives on Other Activities, page RI-9

AMERICAN COORDINATING COMMITTEE ON CORROSION

STANDARDIZATION COMMITTEES

ARTICLE B6A, PAR. 23: The Standing Committee on Standardization shall advise the Council on the dimensional standardization work of the Society, including relations with the American Standards Association.

The first Standing Committee on Standardization was organized in April, 1911

STANDING COMMITTEE

T. E. FRENCH, *Chairman* (1944)
W. H. HILL (1945)
J. H. TAYLOR (1946)
E. J. BRYANT (1947)
D. S. ELLIS (1948)

STANDARDIZATION AND UNIFICATION OF SCREW THREADS (B1)

* *Joint sponsorship with the Society of Automotive Engineers. Sectional Committee originally organized in June, 1921. Reorganized in May, 1929*

A.S.M.E. Members (Total personnel, 34)

A. M. HOUSER, *Vice-Chairman* †
EARLE BUCKINGHAM, *Secretary*
E. J. BRYANT
G. S. CASE
T. G. CRAWFORD
H. C. E. MEYER
P. V. MILLER †
W. C. MUELLER
R. H. PERRY
G. T. TRUNDLE

SUBCOMMITTEE CHAIRMEN

Special Subcommittee on Revision of American Standard, P. V. MILLER
No. 1 on Scope, Arrangement and Editing of American National Standard (to be appointed)
No. 4 on Acme and Other Similar Threads, Except Gages, EARLE BUCKINGHAM
No. 5 on Screw Thread Gages and Inspection, G. S. CASE
No. 6 on Threading of General Purpose Nuts, J. S. DAVEY
No. 7 on Screw Threads for High Temperature Bolting, W. H. GOURLIE

PIPE THREADS (B2)

* *Joint sponsorship with the American Gas Association. Sectional Committee originally organized in 1913. Reorganized December, 1927*

A.S.M.E. Members (Total personnel, 40)

A. S. MILLER, *Chairman*
C. B. LEPAGE, *Acting Secretary*

TECHNICAL COMMITTEES

EXECUTIVE COMMITTEE

A.S.M.E. Members (Total personnel, 5)

W. C. MUELLER, *Chairman*
F. O. HOAGLAND, *Vice-Chairman*
H. E. HARRIS

No. 1 on T-Slots

A.S.M.E. Members (Total personnel, 7)

ERIK OBERG, *Chairman*
J. B. ARMITAGE
HARRY CADWALLADER, JR.
S. A. EINSTEIN
F. O. HOAGLAND

No. 2 on Tool-Posts and Tool Shanks

A.S.M.E. Members (Total personnel, 7)

O. W. BOSTON, *Chairman*
F. S. BLACKALL, JR.
GRANGER DAVENPORT
M. E. LANGE

No. 3 on Machine Tapers

A.S.M.E. Members (Total personnel, 20)

E. J. BRYANT, *Chairman*
C. B. LEPAGE, *Acting Secretary*
J. B. ARMITAGE
F. S. BLACKALL, JR.
EARLE BUCKINGHAM
F. H. COLVIN
B. P. GRAVES
E. E. GRIFFITHS
H. E. HARRIS
F. O. HOAGLAND
J. H. HORIGAN
L. F. NENNINGER

No. 4 on Spindle Noses and Collets for Machine Tools

A.S.M.E. Members (Total personnel, 26)

J. E. LOVELY, *Chairman*
L. F. NENNINGER, *Secretary*
J. B. ARMITAGE
H. W. FAUS
B. P. GRAVES
F. O. HOAGLAND
A. M. JOHNSON
M. E. LANGE
J. H. MANSFIELD
L. D. SPENCE

* Note: All of these standards committees for which the Society is sponsor or joint sponsor, or on which it has representation, are organized under the procedure of the American Standards Association.

† Official A.S.M.E. representative serving on this committee.

SMALL TOOLS AND MACHINE TOOL ELEMENTS (B5)

(Continued)

No. 5 on Milling Cutters

A.S.M.E. Members (Total personnel, 20)

J. B. Armitage
A. N. Goddard
E. E. Griffiths
J. H. Horigan
E. K. Morgan
Erik Oberg
E. D. Vancil

No. 6 on Designations and Working Ranges of Machine Tools

A.S.M.E. Members (Total personnel, 19)

John Haydock, *Chairman*
Earle Buckingham
T. H. Doan, Jr.
H. W. Faus
B. P. Graves
J. J. McBride
E. R. Smith

No. 7 on Twist Drill Sizes

A.S.M.E. Members (Total personnel, 7)

W. C. Mueller, *Chairman*
E. E. Griffiths
J. H. Horigan

No. 8 on Jig Bushings

A.S.M.E. Members (Total personnel, 9)

E. E. Griffiths
J. H. Horigan

No. 9 on Punch Press Tools

A.S.M.E. Members (Total personnel, 15)

D. H. Chason
E. W. Ernest
E. E. Griffiths
H. E. Harris
D. M. Palmer

No. 10 on Forming Tools and Holders

A.S.M.E. Members (Total personnel, 11)

W. C. Mueller, *Chairman*
W. E. Blank
E. E. Griffiths
L. D. Spence

No. 11 on Chucks and Chuck Jaws

A.S.M.E. Members (Total personnel, 8)

J. E. Lovely, *Chairman*

No. 12 on Cut and Ground Thread Taps

A.S.M.E. Member (Total personnel, 7)

J. E. Ennis

No. 13 on Splines and Splined Shafts

A.S.M.E. Members (Total personnel, 17)

J. B. Armitage
R. E. W. Harrison
F. O. Hoagland
J. E. Lovely

No. 17 on Nomenclature for Small Tools and Machine Tool Elements

A.S.M.E. Members (Total personnel, 12)

O. W. Boston, *Chairman and Secretary*
F. S. Blackall, Jr.
F. H. Colvin
H. E. Harris
F. O. Hoagland

No. 19 on Single-Point Cutting Tools

A.S.M.E. Members (Total personnel, 2)

F. H. Colvin, *Chairman*
O. W. Boston, *Secretary*

No. 20 on Reamers

A.S.M.E. Members (Total personnel, 16)

F. H. Colvin
T. F. Githens
E. E. Griffiths
J. H. Horigan
O. E. Koehler

No. 21 on Tool-Life Tests for Single-Point Tools

A.S.M.E. Members (Total personnel, 11)

O. W. Boston, *Chairman*
E. E. Griffiths
M. F. Judkins
H. L. Moir

No. 23 on Machine Pins

A.S.M.E. Members (Total personnel, 14)

E. E. Griffiths
J. J. McBride
R. H. Smith

GEARS (B6)

** Joint sponsorship with the American Gear Manufacturers Association. Sectional Committee organized June, 1921*

A.S.M.E. Members (Total personnel, 23)

U. S. Eberhardt, *Chairman*
Earle Buckingham, *Vice-Chairman* †
C. B. LePage, *Acting Secretary*
A. H. Candee †
G. H. Acker
L. H. Fry
C. B. Hamilton, Jr.
D. T. Hamilton
M. R. Hanna
O. A. Leutwiler

SUBCOMMITTEE CHAIRMEN

No. 3 on Nomenclature, D. T. Hamilton
No. 4 on Tooth Form (Spur Gears), W. P. Schmitter
No. 8 on Materials, E. J. Wellauer
No. 9 on Inspection, Granger Davenport

PIPE FLANGES AND FITTINGS (B16)

** Joint sponsorship with the Heating, Piping and Air Conditioning Contractors National Association, and the Manufacturers Standardization Society of the Valve and Fittings Industry. Sectional Committee organized November, 1921*

A.S.M.E. Members (Total personnel, 58)

C. P. Bliss, *Chairman* †
J. J. Harman, *Secretary*
A. L. Baker
L. W. Benoit †
A. L. Brown
Sabin Crocker
Ferdinand Fink
V. M. Frost
H. E. Haller
J. S. Hess
H. A. Hoffer †
A. M. Houser †
C. A. Kelting †
J. R. Kruse
(John Blizard, *Alternate*)
M. B. MacNeille
F. H. Morehead
L. S. Morse, Sr.
A. W. Oakley
Fred Ophuls
Ludwig Skog
J. E. Stark
J. R. Tanner †
J. H. Taylor
Rowland Tompkins
G. W. Watts
J. H. Williams
J. H. Zink

SUBCOMMITTEE CHAIRMEN

Executive Committee, C. P. Bliss
No. 1 on Cast Iron Flanges and Flanged Fittings, A. M. Houser
No. 2 on Screwed Fittings, F. H. Morehead
No. 3 on Steel Flanges and Flanged Fittings, C. P. Bliss
No. 4 on Materials and Stresses, A. M. Houser
No. 5 on Face to Face Dimensions of Ferrous Flanged Valves, J. R. Tanner
No. 6 on Malleable Iron or Steel Brass Seat Unions (to be appointed)
No. 7 on Rating of Pipe Fittings (to be appointed)
No. 8 on Marking of Pipe Fittings, F. H. Morehead

SHAFTING (B17)

** Sole sponsorship. Organized October, 1918*

A.S.M.E. Members (Total personnel, 13)

C. M. Chapman, *Chairman* †
C. B. LePage, *Secretary*
H. C. E. Meyer
L. C. Morrow
L. W. Williams †

BOLT, NUT, AND RIVET PROPORTIONS (B18)

** Joint sponsorship with the Society of Automotive Engineers. Sectional Committee organized March, 1922*

A.S.M.E. Members (Total personnel, 56)

W. R. Halliday, *Chairman* †
W. C. Stewart, *Secretary*
H. E. Aldrich
F. C. Billings
B. G. Braine
G. S. Case
T. G. Crawford
H. P. Frear
A. M. Houser †
Herman Koester †
W. C. Mueller
S. F. Newman
R. H. Perry
J. R. Tanner †
R. J. Whelan
E. M. Whiting
V. R. Willoughby
(J. J. McBride, *Alternate*)

SUBCOMMITTEE CHAIRMEN

No. 1 on Large and Small Rivets (to be appointed)
No. 2 on Wrench-Head Bolts and Nuts (to be appointed)
No. 3 on Slotted and Recessed Head Screws, F. P. Tisch
No. 4 on Track Bolts and Nuts (to be appointed)
No. 5 on Round Unslotted Head Bolts (Carriage Bolts) (to be appointed)
No. 6 on Plow Bolts (to be appointed)
No. 7 on Body Dimensions and Materials (to be appointed)
No. 8 on Nomenclature, G. S. Case
No. 9 on Socket Head Cap and Set Screws, Herman Koester

PLAIN AND LOCK WASHERS (B27)

** Joint sponsorship with the Society of Automotive Engineers. Sectional Committee organized March, 1926*

A.S.M.E. Members (Total personnel, 38)

EUGENE CALDWELL
T. G. CRAWFORD
B. S. LEWIS †
C. H. LOUTREL
J. J. MCBRIDE
H. C. E. MEYER
W. C. MUELLER †
E. M. WHITING †

SUBCOMMITTEE CHAIRMEN

No. 1 on Plain Washers, W. L. BARTH
No. 2 on Spring Washers, E. D. COWLIN

TRANSMISSION CHAINS AND SPROCKETS (B29)

** Joint sponsorship with the Society of Automotive Engineers, and the American Gear Manufacturers Association. Sectional Committee originally organized September, 1917. Reorganized December, 1926*

A.S.M.E. Members (Total personnel, 12)

W. J. BELCHER
J. M. BRYANT †
JOSEPH JOY
L. V. LUDY †
D. B. PERRY
C. R. WEISS

SUBCOMMITTEE CHAIRMEN

No. 1 on Roller Chain Standardization (to be appointed)
No. 2 on Silent Chain Standardization (to be appointed)

CODE FOR PRESSURE PIPING (B31)

** Sole sponsorship. Sectional Committee originally organized November, 1926. Reorganized December, 1937*

A.S.M.E. Members (Total personnel, 100)

E. B. RICKETTS, *Chairman*
H. C. COOPER
D. H. COREY
(T. W. GREENE, *Alternate*)
SABIN CROCKER
H. D. EDWARDS
E. R. FISH
CHARLES FITZGERALD
V. M. FROST
H. E. HALLER
W. D. HALSEY
J. S. HAUG
H. A. HOFFER
G. G. HOLLINS
E. L. HOPPING
A. M. HOUSER †
ALFRED IDDLES †
D. S. JACOBUS
T. M. JASPER
C. A. KELTING
E. H. KRIEG
G. SINDING-LARSEN
M. B. MACNEILLE
G. W. MARTIN
H. C. E. MEYER
J. W. MOORE
(J. D. CAPRON, *Alternate*)
F. H. MOREHEAD
(J. J. HARMAN, *Alternate*)
H. H. MORGAN
L. S. MORSE, SR.
R. M. NEE
E. W. NORRIS
C. W. OBERT
GEO. A. ORROK
A. L. PENNIMAN, JR.
C. S. ROBINSON †
J. H. ROMANN
D. B. ROSSHEIM
G. W. SAATHOFF
G. K. SAURWEIN
LUDWIG SKOG
H. S. SMITH
(H. H. MOSS, *Alternate*)
J. E. STARK
(L. H. CARR, *Alternate*)
J. R. TANNER
J. H. TAYLOR
J. H. VANCE
H. L. WHITTEMORE
J. H. WILLIAMS
T. F. WOLFE
J. H. ZINK

SUBCOMMITTEE CHAIRMEN

Subcommittee on Scope and Intent of Sectional Committee on Code for Pressure Piping, B31, SABIN CROCKER
No. 1 on Plan, Scope, and Editing, SABIN CROCKER
No. 2 on Power Piping, ALFRED IDDLES
No. 4 on Gas and Air Piping, J. S. HAUG
No. 5 on Refrigeration Piping, A. B. STICKNEY
No. 6 on Oil Piping, L. D. BURRITT
No. 7 on Piping Materials and Identification, F. H. MOREHEAD
No. 8 on Fabrication Details, LUDWIG SKOG
No. 9 on District Heating Piping, G. K. SAURWEIN
Special Committee on Pressures and Temperatures Above Those Covered by Code, E. R. FISH

WIRE AND SHEET METAL GAGES (B32)

** Joint sponsorship with the Society of Automotive Engineers. Sectional Committee originally organized November, 1928. Reorganized November, 1939*

A.S.M.E. Members (Total personnel, 36)

A. P. COTTLE
E. W. ERNEST
J. F. HOWE †
F. G. WILSON †

SUBCOMMITTEE CHAIRMAN

Wire and Sheet Metal Gages, J. R. TOWNSEND

SCREWS THREADS FOR HOSE COUPLINGS (B33)

** Sole sponsorship. Sectional Committee organized October, 1928*

A.S.M.E. Members (Total personnel, 27)

A. L. BROWN, *Secretary*
A. F. BREITENSTEIN †
J. J. CROTTY
W. L. CURTISS
W. E. DUNHAM †
J. J. HARMAN
(F. C. ERNST, *Alternate*)
H. C. E. MEYER
J. H. WILLIAMS

WROUGHT IRON AND WROUGHT STEEL PIPE AND TUBING (B36)

** Joint sponsorship with the American Society for Testing Materials. Sectional Committee organized May, 1928*

A.S.M.E. Members (Total personnel, 45)

H. H. MORGAN, *Chairman*
SABIN CROCKER, *Secretary*
J. S. ADELSON
H. E. ALDRICH
NEWELL HAMILTON
D. S. JACOBUS †
(F. S. CLARK, *Alternate*) †
J. J. KANTER
H. C. E. MEYER
F. H. MOREHEAD
H. B. OATLEY †
J. H. ROMANN
LUDWIG SKOG †
J. R. TANNER
A. E. WHITE

SUBCOMMITTEE CHAIRMEN

No. 1 on Plan, Scope, and Editing, H. H. MORGAN
No. 2 on Pipe and Tubing for Low Temperature Service, J. J. SHUMAN
No. 3 on Pipe and Tubing for High Temperature Service, J. R. TANNER
No. 4 on Materials, F. H. MOREHEAD

PRESSURE AND VACUUM GAGES (B40)

** Sole Sponsorship. Sectional Committee organized December, 1930*

A.S.M.E. Members (Total personnel, 43)

M. D. ENGLE, *Chairman*
A. W. LENDEROTH, *Secretary* †
E. J. BRYANT
J. P. CAVANAUGH †
PAUL DISERENS
C. H. GRAESSER
W. F. JONES
R. J. KEHL
J. C. MCCUNE †
A. H. MORGAN
H. B. REYNOLDS
W. C. SCHOENFELDT

SUBCOMMITTEE CHAIRMEN

No. 1 on Plan and Scope, M. D. ENGLE
No. 2 on Definitions, C. F. SCHWEP
No. 3 on Gage Sizes and Mounting Dimensions, H. B. REYNOLDS
No. 4 on Accuracy and Test Methods, O. J. HODGE

STOCK SIZES, SHAPES AND LENGTHS FOR HOT AND COLD FINISHED IRON AND STEEL BARS (B41)

** Sole sponsorship. Sectional Committee organized June, 1930*

A.S.M.E. Members (Total personnel, 25)

C. D. ALLEN
F. H. DECHANT
E. W. ERNEST
H. D. TANNER
L. W. WILLIAMS †

SUBCOMMITTEE CHAIRMEN

No. 1 on Hot Rolled Steel, HENRY WYSOR
No. 2 on Cold Finished Steels, L. E. CREIGHTON
No. 3 on Hot Rolled Iron (to be appointed)

SPECIFICATIONS FOR LEATHER BELTING (B42)

** Sole sponsorship. Sectional Committee organized May, 1931*

A S.M.E. Members (Total personnel, 24)

H. T. COATES
R. W. DRAKE †
KING HATHAWAY
P. G. RHOADS
G. A. SCHIEREN

SPECIFICATIONS FOR LEATHER BELTING (B42)

(Continued)

SUBCOMMITTEE CHAIRMEN

No. 1 on Standard Specifications (to be appointed)
No. 2 on Recommendations for Selection, Care and Installation, G. A. SCHIEREN

CLASSIFICATION AND DESIGNATION OF SURFACE QUALITIES (B46)

** Joint sponsorship with the Society of Automotive Engineers. Sectional Committee organized December, 1932*

A.S.M.E. Members (Total personnel, 66)

R. F. GAGG, *Chairman*
E. J. ABBOTT
E. J. BRYANT
T. G. CRAWFORD
R. C. DEALE †
U. S. EBERHARDT
S. A. EINSTEIN
W. W. GILBERT
J. J. HARMAN
R. E. W. HARRISON †
F. O. HOAGLAND
H. J. HOLTZCLAW
R. T. KENT
H. F. KURTZ
JOSEPH MANUELE
F. C. SPENCER
C. C. STEVENS
W. C. STEWART
J. S. TAWRESEY
C. H. WHITAKER
ERNEST WOOLER

SUBCOMMITTEE CHAIRMEN

Special Subcommittee on Revision and Editing, R. F. GAGG
No. 2 on Surfaces Produced by Molds, Dies, Rolls, or Any Other Means of Deforming Materials (to be appointed)
No. 3 on Coated Surfaces, G. B. HOGABOOM
No. 4 on Symbols for Indicating Surface Quality on Drawings, T. G. CRAWFORD
No. 5 on Ways, Means and Apparatus for Measuring Quality of Surface (to be appointed)
No. 7 on Standards for Appearance of Surfaces (to be appointed)

SHAFT COUPLINGS, INTEGRALLY FORGED FLANGE TYPE FOR HYDROELECTRIC UNITS (B49)

** Sole sponsorship. Sectional Committee organized October, 1943*

A.S.M.E. Members (Total personnel, 18)

R. E. B. SHARP, *Temporary Chairman* †
D. J. MCCORMACK, *Temporary Secretary* †
D. L. BARBOUR
L. F. HARZA
L. F. MOODY
G. R. RICH
E. B. STROWGER
R. V. TERRY

COMBUSTION SPACE FOR SOLID FUELS (B50)

** Sole sponsorship. Sectional Committee organized June, 1933*

A.S.M.E. Members (Total personnel, 21)

C. E. BRONSON, *Chairman*
W. G. CHRISTY
JOHN HUNTER
A. J. JOHNSON
V. G. LEACH †
J. P. MAGOS
J. F. MCINTIRE
F. L. MEYER
C. A. REED
JOHN VAN BRUNT †

SUBCOMMITTEE CHAIRMEN

No. 1 on Purpose and Scope, C. E. BRONSON
No. 2 on Combustion and Design, B. M. GUTHRIE
No. 3 on Warm Air Furnaces, J. H. MANNY
No. 4 on Steel Heating Boilers, W. B. RUSSELL
No. 5 on Cast Iron Boilers, J. F. MCINTIRE

SCHEME FOR IDENTIFICATION OF PIPING SYSTEMS (A13)

** Joint sponsorship with the National Safety Council. Sectional Committee organized June, 1922*

A.S.M.E. Members (Total personnel, 35)

E. E. ASHLEY
W. L. BUNKER
CROSBY FIELD
H. L. MINER
H. S. SMITH
FRANK THORNTON, JR.
ROWLAND TOMPKINS
FRANK UMBEHOCKER †

SUBCOMMITTEE CHAIRMEN

Executive Committee, A. S. HEBBLE
Identification by Colors (to be appointed)
Classification, CROSBY FIELD
Identification Markings Other Than Color (to be appointed)
Editing Subcommittee, A. S. HEBBLE

MINIMUM REQUIREMENTS FOR PLUMBING AND STANDARDIZATION OF PLUMBING EQUIPMENT (A40)

** Joint sponsorship with The American Public Health Association. Sectional Committee organized November, 1928*

A.S.M.E. Members (Total personnel, 53)

C. B. LEPAGE, *Acting Secretary*
J. F. CARNEY, *Alternate*
J. J. CROTTY
A. M. HOUSER †
G. W. MARTIN
(A. H. MORGAN, *Alternate*)
W. K. MCAFEE
W. R. WEBSTER †

SUBCOMMITTEE CHAIRMEN

Research Committee on Plumbing (to be appointed)
No. 1 on Minimum Requirements for Plumbing, T. I. COE
No. 2 on Staple Vitreous China Plumbing Fixtures, H. R. VAN SCIVER
No. 3 on Staple Porcelain (All Clay) Plumbing Equipment, H. R. VAN SCIVER
No. 4 on Enameled Sanitary Ware, A. H. CLINE, JR.
No. 5 on Traps (to be appointed)
No. 6 on Brass Plumbing Products (to be appointed)
No. 7 on Brass Fittings for Flared Copper Tubes, F. L. RIGGIN
No. 8 on Cast Iron Soil Pipe and Fittings (to be appointed)
No. 9 on Gasoline, Oil and Grease Separators (to be appointed)
Joint Committee on Threaded Cast Iron Pipe, F. H. MOREHEAD
No. 11 on Soldered Fittings for Tubing, A. M. HOUSER
No. 12 on Minimum Air Gaps in Plumbing Systems, W. K. MCAFEE

ROLLED THREADS FOR SCREW SHELLS OF ELECTRIC SOCKETS AND LAMP BASES (C44)

** Joint sponsorship with the National Electrical Manufacturers Association. Sectional Committee organized June, 1929*

A.S.M.E. Members (Total personnel, 15)

E. J. BRYANT †
EARLE BUCKINGHAM †
A. B. MORGAN, *Alternate*

LETTER SYMBOLS AND ABBREVIATIONS FOR SCIENCE AND ENGINEERING (Z10)

** Joint sponsorship with the American Association for the Advancement of Science, American Institute of Electrical Engineers, American Society of Civil Engineers, and the Society for the Promotion of Engineering Education. Sectional Committee originally organized January, 1926. Reorganized October, 1935*

A.S.M.E. Members (Total personnel, 44)

S. A. MOSS, *Vice-Chairman* †
K. H. CONDIT
L. C. LICHTY
R. E. PETERSON †
(S. R. BEITLER, *Alternate*) †
G. A. STETSON
FRANK THORNTON, JR.

SUBCOMMITTEE CHAIRMEN

Executive Committee, H. M. TURNER
Steering Committee, H. M. TURNER
No. 1 on Letter Symbols and Signs for Mathematics, A. A. BENNETT
No. 2 on Symbols for Hydraulics, J. C. STEVENS
No. 3 on Symbols for Mechanics, R. E. PETERSON
No. 4 on Symbols for Structural Analysis, ALBERT HAERTLEIN
No. 5 on Symbols for Heat and Thermodynamics, S. A. Moss
No. 6 on Symbols for Photometry, A. E. PARKER
No. 7 on Aeronautical Symbols, G. W. LEWIS
No. 8 on Symbols for Electrical Quantities, EDWARD BENNETT
No. 9 on Symbols for Radio, H. M. TURNER
No. 10 on Symbols for Physics, H. K. HUGHES
No. 11 on Abbreviations for Scientific and Engineering Terms, G. A. STETSON
No. 12 on Symbols for Unit Operations in Chemical Engineering, J. H. PERRY

STANDARDS FOR DRAWINGS AND DRAFTING ROOM PRACTICE (Z14)

** Joint sponsorship with the Society for the Promotion of Engineering Education. Sectional Committee organized September, 1926*

A.S.M.E. Members (Total personnel, 46)

T. E. FRENCH, *Chairman*
H. P. FREAR
J. J. HARMAN
A. C. HARPER
E. R. HILL
SAMUEL KETCHUM †
C. W. KEUFFEL
F. R. LANEY
H. B. LANGILLE
RUDOLPH MICHEL, *Alternate*
F. W. MING
W. C. MUELLER
E. B. NEIL
J. W. OWENS
F. C. PANUSKA
ED S. SMITH †
ROWLAND TOMPKINS

SUBCOMMITTEE CHAIRMAN

Subcommittee on Revision, F. G. HIGBEE

GRAPHIC PRESENTATION (Z15)

** Sole sponsorship. Sectional Committee organized December, 1926*

A.S.M.E. Members (Total personnel, 31)

G. E. HAGEMANN, *Secretary* †
C. M. BIGELOW
WALLACE CLARK
T. E. FRENCH
D. B. PORTER †

SUBCOMMITTEE CHAIRMEN

No. 1 on Plan and Scope (to be appointed)
No. 2 on Terminology (to be appointed)
No. 3 on Preferred Practice for Time Series Charts, A. H. RICHARDSON
No. 4 on Engineering and Scientific Graphs, W. A. SHEWHART

GRAPHICAL SYMBOLS AND ABBREVIATIONS FOR USE ON DRAWINGS (Z32)

** Joint sponsorship with American Institute of Electrical Engineers. Sectional Committee organized June, 1936*

A.S.M.E. Members (Total personnel, 48)

E. E. ASHLEY
J. M. BARNES
T. E. FRENCH †
G. F. HABACH
D. T. HAMILTON
J. J. HARMAN
W. C. MUELLER
L. L. MUNIER
F. C. PANUSKA †
W. C. STEWART
T. R. THOMAS

SUBCOMMITTEE CHAIRMEN

No. 1 on Symbols for Use in Mechanical Engineering, T. E. FRENCH
No. 2 on Symbols for Use in Electrical Engineering, H. W. SAMSON
No. 3 on Abbreviations for Use on Drawings, T. E. FRENCH

DEVELOPMENT OF STATISTICAL APPLICATIONS IN ENGINEERING AND MANUFACTURING

Joint sponsorship with the American Mathematical Society, American Society for Testing Materials, American Statistical Association, and Institute of Mathematical Statistics. Appointed in December, 1929

A.S.M.E. Members (Total personnel, 9)

A. G. ASHCROFT
W. H. FULWEILER
L. K. SILLCOX †
J. S. TAWRESEY †

A.S.M.E. Representatives on Miscellaneous Standardization Committees

See also A.S.M.E. Representatives on Other Activities, page RI-9

ACOUSTICAL MEASUREMENTS AND TERMINOLOGY (Z24)

** Sponsor body: Acoustical Society of America*

F. H. LEWIS

AERONAUTICS (D9)

** Sponsor body: Society of Automotive Engineers*

E. A. SPERRY, JR.

BUILDING CODE REQUIREMENTS FOR LIGHT AND VENTILATION (A53)

** Sponsor bodies: Federal Housing Administration, and U.S. Public Health Service*

F. R. SCHERER

CAST IRON AT ELEVATED TEMPERATURES

Subcommittee of American Society for Testing Materials Committee A-3 on Cast Iron

D. B. ROSSHEIM

COAL AND COKE (D5)

Committee of American Society for Testing Materials

R. M. HARDGROVE

DEFINITIONS OF ELECTRICAL TERMS (C42)

** Sponsor body: American Institute of Electrical Engineers*

F. O. ELLENWOOD

DRAINAGE OF COAL MINES (M6)

** Sponsor body: American Mining Congress*

O. M. PRUITT

ELECTRIC WELDING APPARATUS (C52)

** Sponsor bodies: American Welding Society*

R. E. KINKEAD

FOREST FIRE PROTECTION

Committee of National Fire Protection Association

C. B. WHITE

JOINT CONFERENCE COMMITTEE ON PIPING CODES AND STANDARDS

C. A. KELTING, *Chairman*
SABIN CROCKER
V. M. FROST
E. D. GRIMISON
A. M. HOUSER
ALFRED IDDLES
J. R. KRUSE
F. H. MOREHEAD
D. B. ROSSHEIM
J. H. ZINK

LOADING PLATFORMS AT FREIGHT TERMINALS AND WAREHOUSES (E12)

** Sponsor body: American Trucking Association, Inc.*

M. C. MAXWELL

MANHOLE FRAMES AND COVERS (A35)

** Sponsor bodies: ASA Telephone Group, and American Society of Civil Engineers*

ANTON HANSEN

ASA MECHANICAL STANDARDS COMMITTEE

ALFRED IDDLES, *Chairman* †
(A. L. BAKER, *Alternate*) †

POWER TEST CODES COMMITTEES

ARTICLE B6A, PAR. 27: The Standing Committee on Power Test Codes shall, under the direction of the Council, have supervision of all the activities of the Society in connection with the A.S.M.E. Power Test Codes, including the interpretation of such codes.

The first Standing Committee on Power Test Codes was organized in December, 1918, to revise and extend the Power Test Codes which had been formulated by various technical committees appointed to develop particular codes. This work began in 1884.

THE WOMAN'S AUXILIARY TO THE A.S.M.E.

The Woman's Auxiliary to the A.S.M.E. was organized on May 10, 1923, and its Constitution and By-Laws was approved by the Council of the A.S.M.E. on October 27, 1924. The objects of the Auxiliary are to render service to all that pertains to the interest of the profession of mechanical engineering; to cooperate with any committees of the A.S.M.E.; and to assist the sons and daughters of the members of the Society or worthy students of mechanical engineering in obtaining scholarships; and to promote any other objects consistent with the aims or objects of the A.S.M.E.

NATIONAL OFFICERS

President, MRS. R. F. GAGG
First Vice-President, MRS. COLLINS P. BLISS
Second Vice-President, MRS. G. W. FARNY
Third Vice-President, MRS. R. M. GATES
Fourth Vice-President, MRS. JUSTIN J. MCCARTHY
Fifth Vice-President, MRS. S. F. DUNCAN
Recording Secretary, MRS. MATTHEW S. CUMNER
Corresponding Secretary, MRS. CROSBY FIELD
Treasurer, MRS. CHARLES E. GUS

STANDING COMMITTEE CHAIRMEN

Student Loan, MRS. F. M. GIBSON
Membership, MRS. G. E. HAGEMANN
Calvin W. Rice Scholarship, MRS. J. NOBLE LANDIS

COUNCIL REPRESENTATIVES

HAROLD V. COES
WARREN H. MCBRYDE

OFFICERS OF LOCAL SECTIONS

CLEVELAND

Chairman, MRS. EUGENE R. MCCARTHY

LOS ANGELES

Chairman, MRS. BURNIE M. CRAIG

METROPOLITAN

Chairman, MRS. EARL B. SMITH
First Vice-Chairman, MRS. WALDO MCC. MCKEE
Second Vice-Chairman, MRS. G. J. NICASTRO
Third Vice-Chairman, MRS. C. HIGBIE YOUNG
Recording Secretary, MRS. ERIK OBERG
Corresponding Secretary, MRS. C. F. KAYAN
Treasurer, MRS. A. W. ANDERSON

PHILADELPHIA

Chairman, MRS. JOHN A. FRANSEMA

AWARDS

The following paragraphs deal with the medals, awards, scholarships, and loan funds which come within the jurisdiction of the A.S.M.E. Other awards available to Student-members are listed in *Mechanical Engineering*, February, 1938, page 183. The Society also participates with other engineering societies in a number of joint awards. Further details concerning all the awards may be obtained from the headquarters of the Society.

Honorary Membership, to which persons of acknowledged professional eminence are elected by unanimous vote of Council under the provisions of the By-Laws and Rules. A list of honorary members is given on page RI-43.

Life Membership, which may be conferred by the Council for distinguished service to the Society; or secured by a member by payment for an annuity in accordance with the provisions of the By-Laws.

A.S.M.E. Medal, established by the Society in 1920 to be presented, together with an engraved certificate, for distinguished service in engineering and science. May be awarded for general service in science having possible application in engineering.

Holley Medal, instituted and endowed in 1924 by George I. Rockwood, Past Vice-President of the Society, to be bestowed, together with an engraved certificate, for some great and unique act of genius of engineering nature that has accomplished a great and timely public benefit.

Worcester Reed Warner Medal, established in 1930, provision for which was made in the will of Worcester Reed Warner, Honorary Member of the Society, is a gold medal to be bestowed, together with an engraved certificate, for an outstanding contribution to permanent engineering literature.

Melville Medal, established in 1914 by the bequest of Rear-Admiral George W. Melville, Honorary Member and Past-President of the Society, to be presented, together with an engraved certificate, for an original paper or thesis of exceptional merit, presented to the Society by a member for discussion and publication, to encourage excellence in papers. Only papers of single authorship are eligible. The medal may be presented annually.

Spirit of St. Louis Medal, established by an endowment fund created in 1929 by citizens of St. Louis, Mo., to be awarded for meritorious service in the advancement of aeronautics. This medal will be awarded at the discretion of the Council of the Society at approximately three-year periods upon the recommendation of its Board of Honors and Awards.

Spirit of St. Louis Junior Award, established in 1938 by an endowment fund created by the General Committee for the 1935 Aeronautic Meeting in St. Louis; a cash award of $50, made every three years, for the best paper on an aeronautic subject presented at any A.S.M.E. meeting during the three-year period either personally by the author (a Junior Member of the Society under thirty years of age) or by a Junior Member designated by him, and submitted to the Committee on Medals within a reasonable period (to be determined by the Committee) after its initial presentation.

Pi Tau Sigma Medal Award, established in 1938, endowed by Pi Tau Sigma, the national honorary mechanical engineering fraternity, to be presented annually, together with an engraved certificate, to a young mechanical engineer for outstanding achievement in his profession within the ten years after graduation from a regular four-year mechanical engineering course of a recognized American college or university. Any mechanical engineering graduate, not more than thirty-five years of age, whose achievement has been all or in part in any field including industrial, educational, political, research, civic, etc., is eligible.

Junior Award, annual cash award of $50, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with an engraved certificate, for the best paper or thesis submitted by a Junior Member. Only papers of single authorship are eligible.

Charles T. Main Award, annual cash award of $150, established in 1919 from a fund created by Charles T. Main, Past-President of the Society, to be awarded, together with an engraved certificate, to a Student-member of the Society, for the best paper within the general subject of the influence of the profession upon public life. The exact subject is assigned by the Board of Honors and Awards, subject to the approval of the Council, and is announced each year through the Honorary Chairmen of the Student Branches.

Student Awards, two annual cash awards of $25 each, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with engraved certificates, for the best papers or theses submitted by Student-members. The awards for 1932 and subsequent years have been given, one for undergraduate and the other for postgraduate work.

SCHOLARSHIPS AND LOAN FUNDS

Max Toltz: Loan Fund of $15,000 established by Major Max Toltz, former member of the Council of the Society, the income to be used for assistance to Student-members.

John R. Freeman: Fund of $25,000 established in 1926 by John R. Freeman, Past-President of the Society, the income to be used for travel scholarships and research.

Woman's Auxiliary: Educational Loan Fund offered by the Woman's Auxiliary to the Society to assist sons and daughters of members or worthy students of mechanical engineering. Calvin W Rice Memorial Scholarship Fund for students in mechanical engineering from South America.

RECIPIENTS OF AWARDS

The names of the recipients of the different awards to date are given in the following lists, together with the dates of presentation, and the services or papers for which the awards were made. There were no awards for the years not listed.

A.S.M.E. Medal

1921 Hjalmar Gotfried Carlson, in recognition of the services rendered the Government because of his invention and part in the production of 20,000,000 Mark III drawn steel booster casings used principally as a component of 75-mm high explosive shells, but also used extensively in gas shells and bombs

1922 Frederick Arthur Halsey, for his paper describing the premium system of wage payments presented before the Society at the Providence Meeting in 1891, as the adoption of the methods there proposed has had a profound effect toward harmonizing the relations of worker and employer

1923 John Ripley Freeman, for his eminent service in engineering and manufacturing by his meritorious work in fire prevention and the preservation of property

1926 R. A. Millikan, in recognition of his contributions to science and engineering

1927 Wilfred Lewis, for his contributions to the design and construction of gear teeth

1928 Julian Kennedy, for his services and contributions to the iron and steel industry

1929 William LeRoy Emmet, for his contributions in the development of the steam turbine, electric propulsion of ships, and other power-generating apparatus

1931 Albert Kingsbury, for his research and development work in the field of lubrication

1933 Ambrose Swasey, for his contributions to the advancement of the engineering profession and for his part in the development of the turret lathe and the astronomical telescope

1934 Willis H. Carrier, in recognition of his research and development work in air-conditioning

1935 Charles T. Main, for distinguished achievements in the textile and other industries, in engineering education, and for eminent service to the engineering profession

1936 Edward Bausch, for meritorious mechanical developments in the field of optics

1937 Edward P. Bullard, for outstanding leadership in the development of station-type machine tools

1938 Stephen J. Pigott, for outstanding leadership in marine propulsion and construction

1939 James E. Gleason, for service to the cause of safer and better transportation

1940 Charles F. Kettering, for outstanding inventions and research

1941 Theodor von Kármán, for his brilliance as a teacher, his researches in elasticity and many fields of physics and mechanics, and his distinguished leadership in the fields of aerodynamics and aircraft design

1942 E. G. BAILEY, for achievement and leadership in steam and combustion engineering
1943 LEWIS K. SILLCOX, pre-eminent learned technologist—lover of wisdom—inspirer of men.

HOLLEY MEDAL

1924 HJALMAR GOTFRIED CARLSON, for his inventions and processes which made possible the timely production of drawn steel booster casings for artillery ammunition, thereby aiding victory in World War I (diploma in recognition of achievements presented in 1921)
1927 ELMER AMBROSE SPERRY, for achievements and inventions that have advanced the naval arts, including the gyroscope that has freed navigation from the dangers of the fluctuating magnetic compass
1929 BARON CHUZABURO SHIBA, for his contributions to knowledge through fundamental research, including the field of aerodynamics, by the development of ultra-rapid kinematographic methods
1934 IRVING LANGMUIR, for his contributions to science and engineering, including the development of gas-filled incandescent lamps, thoriated filament for thermionic emission, atomic hydrogen welding, phase control operation of the thyratron tube, and fundamental research in oil films
1936 HENRY FORD, for revolutionary influence through invention and practice on transportation and on mass production methods in manufacturing
1937 FREDERICK G. COTTRELL, for preeminent public service—the invention of electric precipitation—advancement of the science of gas liquefaction—gifts for engineering research
1938 FRANCIS HODGKINSON, for meritorious services in the development of the steam turbine
1939 CARL E. JOHANSSON, in recognition of his pioneer work in the development of basic measuring gages
1940 EDWIN HOWARD ARMSTRONG, for his leadership in the field of radio communication
1941 JOHN C. GARAND, for the invention and development of the semi-automatic rifle, which has been adopted by the U.S. Army as the U.S. Rifle, Caliber .30, M1, an outstanding contribution to our national defense
1942 ERNEST O. LAWRENCE, for originating the cyclotron, a unique invention for producing high-speed electrified particles, and for adapting it to research in physics, chemistry, medicine, and the properties of engineering materials
1943 VANNEVAR BUSH, for machines used in easing applied mathematics from computational barriers.

WORCESTER REED WARNER MEDAL

1933 DEXTER S. KIMBALL, for his contributions to efficiency in management as exemplified by his recently revised "Principles of Industrial Organization" and by his many articles, engineering society papers, and public addresses
1934 RALPH E. FLANDERS, for his contributions to a better understanding of the relationship of the engineer to economic problems and social trends as exemplified by the many papers which he has presented
1935 STEPHEN TIMOSHENKO, for his contributions to the theory of the design of elastic structures and the treatment of dynamics of moving machinery
1936 CHARLES M. ALLEN, for his early and continued hydraulic laboratory work and for the permanent value of the papers on his development of methods of testing large hydraulic turbine installations
1937 CLARENCE F. HIRSHFELD, for his research and contributions to the theory and practice of heat-power engineering as exemplified by books and papers
1938 LAWFORD H. FRY, for contributions relating to improved locomotive boiler design and utilization of better materials in railway equipment
1939 RUPEN EKSERGIAN, for influential papers of permanent value in A.S.M.E. Transactions
1940 WILLIAM BENJAMIN GREGORY, for distinguished work in hydraulic engineering, which has been the basis for many engineering papers
1941 RICHARD VYNNE SOUTHWELL, for his many distinguished services to engineering and science through papers and publications in many fields, including aeronautics, theory of structures, elasticity, and hydrodynamics
1942 FRED H. COLVIN, for his contributions to both technical advancement and improvement in management in the metal-working industries, as influenced by more than fifty years of articles and books—particularly American Machinists' Handbook
1943 IGOR I. SIKORSKY, for contributions inspiring creative engineering, especially in aeronautics.

MELVILLE MEDAL

1927 LEON P. ALFORD, "Laws of Manufacturing Management"
1929 JOSEPH W. ROE, "Principles of Jig and Fixture Practice"
1930 HERMAN DIEDERICHS and WILLIAM D. POMEROY, "The Occurrence and Elimination of Surge or Oscillating Pressure in Discharge Lines From Reciprocating Pumps"
1931 ARTHUR E. GRUNERT, "Comparative Performance of a Pulverized-Coal-Fired Boiler Using Bin System and Unit System of Firing"
1932 ALEXEY J. STEPANOFF, "Leakage Loss and Axial Thrust in Centrifugal Pumps"
1933 WILLIAM E. CALDWELL, "Characteristics of Large Hell Gate Direct-Fired Boiler Units"
1935 OSCAR R. WIKANDER, "Draft-Gear Action in Long Trains"
1936 H. A. STEVENS HOWARTH, "The Loading and Friction of Thrust and Journal Bearings With Perfect Lubrication"
1937 ALFRED J. BÜCHI, "Supercharging of Internal-Combustion Engines With Blowers Driven by Exhaust-Gas Turbines"
1938 ALPHONSE I. LIPETZ, "Air Resistance of Railroad Equipment"
1939 LESTER M. GOLDSMITH, "High-Pressure High-Temperature Turbine-Electric Steamship *J. W. Van Dyke*"
1940 CARL A. W. BRANDT, "The Locomotive Boiler"
1941 ROGER V. TERRY, "Development of the Automatic Adjustable-Blade-Type Propeller Turbine"
1942 J. KENNETH SALISBURY, "The Steam-Turbine Regenerative Cycle—An Analytical Approach."

SPIRIT OF SAINT LOUIS MEDAL

1929 DANIEL GUGGENHEIM, founder of the Guggenheim Fund for the Promotion of Aeronautics
1932 PAUL LITCHFIELD, for his work in encouraging and sponsoring airship design and construction in this country
1935 WILL ROGERS, for his splendid, constructive, and unselfish work in the achievement of aviation, and the building up of public confidence in aviation through his articles in the press, over the radio, and from the speaker's platform
1938 JAMES H. DOOLITTLE, for meritorious service in the advancement of aeronautics
1941 JOHN E. YOUNGER, for notable contributions to the science of airplane design, particularly in the conception, analysis, and supervision of the development of the fundamental design principles, requirements, and criteria which first assured the success of the pressure-cabin type of high-altitude airplane.

SPIRIT OF SAINT LOUIS JUNIOR AWARD

1941 WILBUR W. REASER, for his paper, "Calculation of the Heat Loss from an Airplane Cabin."

PI TAU SIGMA MEDAL

1938 WILFRID E. JOHNSON, for his development work in the field of refrigeration
1939 JOHN I. YELLOTT, JR., in recognition of significant achievements in steam-flow research and engineering education; also contributions on "Supersaturated Steam" and "Condensation of Flowing Steam in Diverging Nozzles"
1940 GEORGE A. HAWKINS, for significant achievements in high-pressure steam research and engineering education
1941 R. HOSMER NORRIS, for outstanding achievement in mechanical engineering, particularly in the heat-transfer field
1942 JOHN T. RETTALIATA, for outstanding achievement in mechanical engineering.

JUNIOR AWARD

1915 ERNEST O. HICKSTEIN, "Flow of Air Through Thin Plate Orifices"
1916 L. M. MCMILLAN, "The Heat Insulating Properties of Commercial Steam-Pipe Coverings"
1919 E. D. WHALEN, "Properties of Airplane Fabrics"
1921 S. LOGAN KERR, "Moody Ejector Turbine"

1922 R. H. HEILMAN, "Heat Losses From Bare and Covered Wrought-Iron Pipe at Temperatures up to 800 Degrees Fahrenheit"
F. L. KALLAM, "Preliminary Report on the Investigation of the Thermal Conductivity of Liquids"
1923 S. S. SANFORD and SABIN CROCKER, "The Elasticity of Pipe Bends"
1924 R. H. HEILMAN, "Heat Losses Through Insulating Material"
1925 GILBERT S. SCHALLER, "An Investigation of Seattle as a Location for a Synthetic Foundry Industry"
1927 WILLIAM M. FRAME, "Stresses Occurring in the Walls of an Elliptical Tank Subjected to Low Internal Pressure"
1928 M. D. AISENSTEIN, "A New Method of Separating the Hydraulic Losses in a Centrifugal Pump"
1929 ARTHUR M. WAHL, "Stresses in Heavy, Closely Coiled Helical Springs"
1930 ED SINCLAIR SMITH, "Quantity-Rate Fluid Meters"
1931 M. K. DREWRY, "Radiant-Superheater Developments"
1932 EDMOND M. WAGNER, "Frictional Resistance of a Cylinder Rotating in a Viscous Fluid Within a Coaxial Cylinder"
1933 TOWNSEND TINKER, "Surface Condenser Design and Operating Characteristics"
1934 JOHN I. YELLOTT, JR., "Supersaturated Steam"
1935 STANLEY J. MIKINA, "Effect of Skewing and Pole Spacing on Magnetic Noise in Electrical Machinery"
1936 HARWOOD F. MULLIKAN, JR., "Evaluation of Effective Radiant Heating Surface and Application of the Stefan-Boltzman Law to Heat Absorption in Boiler Furnaces"
1937 LESLIE J. HOOPER, "American Hydraulic-Laboratory Practice"
1938 ARTHUR C. STERN, "Separation and Emission of Cinders and Fly Ash"
1940 ROBERT E. NEWTON, "A Photoelastic Study of Stresses in Rotary Disks"
1941 JOHN T. RETTALIATA, "The Combustion Gas Turbine"
1942 WINSTON M. DUDLEY, "Analysis of Longitudinal Motions in Trains of Several Cars"
1943 TROELS WARMING, "Power Pulsation Between Synchronous Generators."

CHARLES T. MAIN AWARD

1925 CLEMENT R. BROWN, Catholic University of America. Subject: "The Influence of the Locomotive on the Unity of the United States"
1926 W. C. SAYLOR, Johns Hopkins University. Subject: "The Effect of the Cotton Gin Upon the History of the United States During Its First Seventy Years"
1927 No Award. Subject: "Scientific Management and Its Effect Upon the Industries"
1928 ROBERT M. MEYER, Newark College of Engineering. Subject: "Scientific Management and Its Effect Upon Manufacturing"
1929 No Award. Subject: "The Influence of Engineering on Farm Production"
1930 JULES PODNOSSOFF, Polytechnic Institute of Brooklyn. Subject: "The Value of the Safety Movement in the Industries"
1931 ROBERT E. KLISE, University of Michigan. Subject: "Interchangeability—Its Development and Significance in Industry"
1932 MARSHALL ANDERSON, University of Michigan. Subject: "Apprenticeship and Vocational Training"
1933 GEORGE D. WILKINSON, JR., Newark College of Engineering. Subject: "Progress in the Prevention of Smoke and Atmospheric Pollution"
1934 PHILIP P. SELF, Colorado State College. Subject: "Air Conditioning—Its Practicability and Relation to Public Welfare"
1935 G. LOWELL WILLIAMS, Lafayette College. Subject: "Coordinated Transportation—An Economic Comparison of Railroad, Bus, Truck, Water, and Air Transportation for Long and Short Haul"
1936 No Award. Subject: "Development in the Generation and Distribution of Power and Their Effect Upon the Consumer"
1937 ALLAN P. STERN, Case School of Applied Science. Subject: "The Influence of the Introduction of Labor Saving Machinery Upon Employment in the United States"
1938 EDWARD W. CONNOLLY, University of Detroit. Subject: "Economic Limitations in Engineering Design, With Concrete Examples"
1939 JAMES R. BRIGHT, Lehigh University. Subject: "The Economics of Investment in New Manufacturing Equipment—With Concrete Cases"
1940 FRANK DE POULD, Case School of Applied Science. Subject: "What Has Been the Effect of Technological Advance on Employment?"
1941 JOHN J. BALUN, University of Detroit. Subject: "The Need and Possibilities of Participation by Engineers in Public Affairs"
1942 BERNARD J. ISABELLA, Case School of Applied Science. Subject: "The Engineer and Preparation for the Coming Peace"
1943 MITCHELL C. KAZEN, University of Detroit. Subject: "Government as Affected by Engineering."

STUDENT AWARD

1916 BOYNTON M. GREEN, Stanford University, "Bearing Lubrication"
HOWARD E. STEVENS, Rensselaer Polytechnic Institute, "An Investigation of the Dynamic Pressure on Submerged Flat Plates"
M. ADAM, Louisiana State University, "The Adaptability of the Internal Combustion Engine to Sugar Factories and Estates"
1917 H. R. HAMMOND and C. W. HOLMBERG, The Pennsylvania State College, "Study of Surface Resistance With Glass as the Transmission Medium"
1919 C. F. LEH and F. G. HAMPTON, Stanford University, "An Experimental Investigation of Steel Belting"
W. E. HELMICK, Stanford University, "An Experimental Investigation of Steel Belting"
1920 HOWARD G. ALLEN, Cornell University, "Wire Stitching Through Paper"
1921 KARL H. WHITE, University of Kansas, "Forces in Rotary Motors"
RICHARD H. MORRIS and ALBERT J. R. HOUSTON, University of California, "A Report Upon an Investigation of the Herschel Type of Improved Weir"
1923 CHARLES F. OLMSTEAD, University of Minnesota, "Oil Burning for Domestic Heating"
H. E. DOOLITTLE, University of California, "The Integrating Gate: A. Device for Gaging in Open Channels"
1924 GEORGE STUART CLARK, Stanford University, "Two Methods Used for the Determination of the Gasoline Content of Absorption Oils in Absorption Plants"
L. J. FRANKLIN and CHARLES H. SMITH, Stanford University, "The Effect of Inaccuracy of Spacing on the Strength of Gear Teeth"
1925 HARRY PEASE COX, JR., Rensselaer Polytechnic Institute, "A Study of the Effect of End Shape on the Towing Resistance of a Barge Model"
W. S. MONTGOMERY, JR., and E. RAY ENDERS, JR., Pennsylvania State College, "Some Attempts to Measure the Drawing Properties of Metals"
1926 R. E. PETERSON, University of Illinois, "An Investigation of Stress Concentration by Means of Plaster of Paris Specimens"
CECIL G. HEARD, University of Toronto, "Pressure Distribution Over U.S.A. 27 Aerofoil With Square Wing Tips—Model Tests"
1927 ALFRED H. MARSHALL, Princeton University, "Evaporative Cooling"
ROGER IRWIN EBY, University of Washington, "Measurement of the Angular Displacement of Flywheels"
1928 CLARENCE C. FRANCK, Johns Hopkins University, "Condition Curves and Reheat Factors for Steam Turbines"
1929 FRANK VERNON BISTROM, University of Washington, "An Investigation of a Rotary Pump"
WILLIAM WALLACE WHITE, University of Washington, "An Investigation of a Rotary Pump"
1930 GERARD EDEN CLAUSSEN, Polytechnic Institute of Brooklyn, "High-Temperature Oxidation of Steel"
HAROLD L. ADAMS and RICHARD L. STITH, University of Washington, "A Wind Tunnel for Undergraduate Laboratory Experiments"
1931 JULES PODNOSSOFF, Polytechnic Institute of Brooklyn, "Pressure and Energy Distribution in Multi-Stage Steam Turbines Operating Under Varying Conditions"
1932 H. E. FOSTER, JR., University of Tennessee, "Factors Affecting Spray Pond Design" (Undergraduate Award)
WILLIAM A. MASON, Stanford University, "An Experi-

mental Investigation of the Flame Propagation in Internal-Combustion Engines" (Postgraduate Award)

1933 HUGO V. CORDIANO, Polytechnic Institute of Brooklyn, "Thermal Analysis of Lithium-Magnesium System of Alloys" (Undergraduate Award)
JAMES A. OSTRAND, JR., Princeton University, "Sudden Enlargement in the Open Channel" (Postgraduate Award)

1934 H. REYNOLDS HUDSON, Georgia School of Technology, "Dynamic Balance and Functional Utility Applied to Automotive Design" (Undergraduate Award)

1935 CHARLES P. BACHA, Rutgers University, "The Behavior of Metals Subjected to Combined Stress" (Postgraduate Award)
ROBERT W. BEAL, Oregon State College, "Do Lubricating Oils Wear Out?" (Undergraduate Award)

1936 LEON B. STINSON, Oklahoma Agricultural and Mechanical College, "Polymerized Motor Fuels; Their Economic Significance" (Undergraduate Award)
DEWITT D. BARLOW, JR., Princeton University, "The Critical Speeds of Lateral Vibrations of Shafts with Gyroscopic Effects" (Postgraduate Award)

1937 GINO J. MARINELLI, Rensselaer Polytechnic Institute, "Investigation of the Towing Resistance of a Model Submarine Hull" (Undergraduate Award)

1938 MARSHALL C. LONG, Princeton University, "An Investigation Into the Angular Characteristics of an Adjustable Blade Current Meter" (Postgraduate Award)
DONALD C. MCSORLEY, Michigan State College, "Humidity Insulation" (Undergraduate Award)

1939 DAVID T. JAMES, Michigan State College, "Bells—Concerning Their Tones" (Undergraduate Award)

1940 GEORGE W. SHEPHERD, JR., Princeton University, "An Automatic Mechanical Control for Synchronizing Prime Movers" (Postgraduate Award)
EDWARD D. ROWAN, Oregon State College, "Powder Metallurgy" (Undergraduate Award)

1941 G. WALKER GILMER, III, University of Florida, "Center of Pressure Characteristics of a Marconi Yacht Sail" (Undergraduate Award)

1942 ARTHUR W. MCCLURE, Princeton University, "A Specific Speed Analysis of Turbosuperchargers for Aircraft" (Postgraduate Award)
J. PACKARD LAIRD, Princeton University, "An Analysis of Motorcycle Behavior" (Undergraduate Award)

1943 WILLIAM L. HUTTON, Princeton University, "The Aerodynamic Development of the Star Sail" (Undergraduate Award).

FREEMAN TRAVEL SCHOLARSHIP

1927	HERBERT N. EATON	1933	H. J. CASEY
1928	BLAKE R. VAN LEER	1934	
1929	ROBERT T. KNAPP	1935	VICTOR L. STREETER
1931	REGINALD WHITAKER	1936	
1932	G. ROSS LORD		

HONORARY MEMBERS

HONORARY MEMBERS IN PERPETUITY

ALEXANDER LYMAN HOLLEY, Founder of the Society. Died 1882.

JOHN EDSON SWEET, Founder of the Society. Died 1916.

HENRY ROSSITER WORTHINGTON, Founder of the Society. Died 1880.

DECEASED HONORARY MEMBERS

	ELECTED	DIED
LEON PRATT ALFORD	1941	1942
HORATIO ALLEN	1880	1889
LORENZO ALLIEVI	1937	1941
SIR WILLIAM ARROL	1905	1913
SIR JOHN AUDLEY FREDERICK ASPINALL	1911	1937
WILLIAM WALLACE ATTERBURY	1925	1935
SIR BENJAMIN BAKER	1886	1907
JOHANN BAUSCHINGER	1884	1893
SIR HENRY BESSEMER	1891	1898
SIR FREDERICK JOSEPH BRAMWELL	1884	1903
JOHN ALFRED BRASHEAR	1908	1920
GUSTAVE CANET	1900	1908
ANDREW CARNEGIE	1907	1919
DANIEL KINNEAR CLARK	1882	1896
RUDOLPH JULIUS EMMANUEL CLAUSIUS	1882	1888
HUTCHINSON I. CONE	1936	1941
SIR JOHN CODE	1889	1892
PETER COOPER	1882	1883
CHARLES DE FRÉMINVILLE	1919	1936
CARL GUSTAF PATRICK DE LAVAL	1912	1913
RUDOLPH DIESEL	1912	1913
ALEX DOW	1936	1942
JAMES DREDGE	1886	1906
VICTOR DWELSHAUVERS-DERY	1886	1913
THOMAS ALVA EDISON	1904	1931
ALEXANDRE GUSTAVE EIFFEL	1889	1923
MARSHAL FERDINAND FOCH	1921	1929
SIR CHARLES DOUGLAS FOX	1900	1921
JOHN RIPLEY FREEMAN	1932	1932
JOHN FRITZ	1900	1913
MAJOR-GENERAL GEORGE WASHINGTON GOETHALS	1917	1928
FRANZ GRASHOF	1884	1893
REAR-ADMIRAL ROBERT STANISLAU GRIFFIN	1920	1933
OTTO HALLAUER	1882	1883
CHARLES HAYNES HASWELL	1905	1907
NATHANAEL GREENE HERRESHOFF	1921	1938
FRIEDRICH GUSTAV HERRMANN	1884	1907
GUSTAV ADOLPH HIRN	1882	1890
JOSEPH HIRSCH	1889	1901
IRA N. HOLLIS	1928	1930
ROBERT WOOLSTON HUNT	1920	1923
BENJAMIN FRANKLIN ISHERWOOD	1894	1915
ALBERT KINGSBURY	1940	1943
HENRI LÉAUTÉ	1891	1916
ERASMUS DARWIN LEAVITT	1915	1916
HENRI LE CHATELIER	1927	1936
CHARLES THOMAS MAIN	1939	1943
ANATOLE MALLET	1912	1919
CHARLES H. MANNING	1913	1919
REAR-ADMIRAL GEORGE WALLACE MELVILLE	1910	1912
THE HONORABLE SIR CHARLES ALGERNON PARSONS	1920	1931
CHARLES TALBOT PORTER	1890	1910
EDWIN JAY PRINDLE	1939	1942
AUGUSTE C. E. RATEAU	1919	1930
SIR EDWARD J. REED	1882	1906
FRANZ REULEAUX	1882	1905
CALVIN WINSOR RICE	1931	1934
PALMER C. RICKETTS	1931	1934
HENRI ADOLPHE-EUGENE SCHNEIDER	1882	1898
CHARLES M. SCHWAB	1918	1939
JAMES A. SEYMOUR	1940	1943
C. WILLIAM SIEMANS	1882	1883
VISCOUNT EI-ICHI SHIBUSAWA	1929	1931
AUREL STODOLA	1941	1942
AMBROSE SWASEY	1916	1937
ELIHU THOMSON	1930	1937
HENRY ROBINSON TOWNE	1921	1924
HENRI TRESCA	1882	1885
WILLIAM CAWTHORNE UNWIN	1898	1933
SAMUEL MATTHEWS VAUCLAIN	1920	1940

GEANDE UFFICIALE ING. PIO PERRONE	1920
HARRY R. RICARDO	1942
REAR ADMIRAL SAMUEL MURRAY ROBINSON	1941
EDWARD N. TRUMP	1943
MAJOR GENERAL WILLIAM H. TSCHAPPAT	1938
RIGHT HONORABLE LORD WEIR	1920
MAJOR GENERAL CHARLES MACON WESSON	1941
ORVILLE WRIGHT	1918
ROY V. WRIGHT	1943

PAST-PRESIDENTS

Dates in parentheses denote year of death.

ALEXANDER LYMAN HOLLEY, *Chairman of the Preliminary Meeting for Organization of The American Society of Mechanical Engineers* (1882)

1880–1882	ROBERT HENRY THURSTON (1903)
1883	ERASMUS DARWIN LEAVITT (1916)
1884	JOHN EDSON SWEET (1916)
1885	JOSEPHUS FLAVIUS HOLLOWAY (1896)
1886	COLEMAN SELLERS (1907)
1887	GEORGE H. BABCOCK (1893)
1888	HORACE SEE (1909)
1889	HENRY ROBINSON TOWNE (1924)
1890	OBERLIN SMITH (1926)
1891	ROBERT WOOLSTON HUNT (1923)
1892	CHARLES HARDING LORING (1907)
1893–1894	ECKLEY BRINTON COXE (1895)
1895	EDWARD F. C. DAVIS (1895)
1895	CHARLES ETHAN BILLINGS (1920)
1896	JOHN FRITZ (1913)
1897	WORCESTER REED WARNER (1929)
1898	CHARLES WALLACE HUNT (1911)
1899	GEORGE WALLACE MELVILLE (1912)
1900	CHARLES HILL MORGAN (1911)
1901	SAMUEL T. WELLMAN (1919)
1902	EDWIN REYNOLDS (1909)
1903	JAMES MAPES DODGE (1915)
1904	AMBROSE SWASEY (1937)
1905	JOHN RIPLEY FREEMAN (1932)
1906	FREDERICK WINSLOW TAYLOR (1915)
1907	FREDERICK REMSEN HUTTON (1918)
1908	MINARD LAFEVER HOLMAN (1925)
1909	JESSE MERRICK SMITH (1927)
1910	GEORGE WESTINGHOUSE (1914)
1911	EDWARD DANIEL MEIER (1914)
1912	ALEXANDER CROMBIE HUMPHREYS (1927)
1913	WILLIAM FREEMAN MYRICK GOSS (1928)
1914	JAMES HARTNESS (1934)
1915	JOHN ALFRED BRASHEAR (1920)
1916	DAVID SCHENCK JACOBUS
1917	IRA NELSON HOLLIS (1930)
1918	CHARLES THOMAS MAIN (1943)
1919	MORTIMER ELWYN COOLEY
1920	FRED J. MILLER (1939)
1921	EDWIN S. CARMAN
1922	DEXTER SIMPSON KIMBALL
1923	JOHN LYLE HARRINGTON (1942)
1924	FREDERICK ROLLINS LOW (1936)
1925	WILLIAM FREDERICK DURAND
1926	WILLIAM LAMONT ABBOTT
1927	CHARLES M. SCHWAB (1939)
1928	ALEX DOW (1942)
1929	ELMER AMBROSE SPERRY (1930)
1930	CHARLES PIEZ (1933)
1931	ROY V. WRIGHT
1932	CONRAD N. LAUER (1943)
1933	A. A. POTTER
1934	PAUL DOTY (1938)
1935	RALPH E. FLANDERS
1936	WILLIAM L. BATT
1937	JAMES H. HERRON
1938	HARVEY N. DAVIS
1939	ALEXANDER G. CHRISTIE
1940	WARREN H. MCBRYDE
1941	WILLIAM A. HANLEY
1942	JAMES W. PARKER
1943	HAROLD V. COES

TREASURERS

Apr. 1880—Dec. 1881	LYCURGUS B. MOORE *
Dec. 1881—Nov. 1884	CHARLES W. COPELAND (1895)
1894—1925	WILLIAM H. WILEY (1925)
1925—1935	ERIK OBERG
1935—date	WILLIAM D. ENNIS

SECRETARIES

Organization Meeting, 1880	SAMUEL S. WEBBER, JR. (1921)
Acting Secretary, Apr.-Nov. 1880	LYCURGUS B. MOORE *
Nov. 1880—Mar. 1883	THOS. WHITESIDE RAE (1895)
1883—1906	FREDERICK R. HUTTON (1918)
1906—1934	CALVIN W. RICE (1934)
1934—date	CLARENCE E. DAVIES

* Deceased. Year not known.

Index to Society Records, Part 1

The page numbers in this section are preceded by the letters "RI," which are omitted in the following index.

Abbreviations and Symbols, Graphical, Comm.. 31
Abbreviations and Symbols, Letter, Comm.... 30
Abrasive Wheels, Rep. on Safety Comm..... 35
Acoustical Measurements, Rep. on Comm..... 31

Transactions

of The American Society of Mechanical Engineers

Published on the tenth of every month, except March, June, September, and December

OFFICERS OF THE SOCIETY:

ALEX D. BAILEY, *President*

K. W. JAPPE, *Treasurer* C. E. DAVIES, *Secretary*

COMMITTEE ON PUBLICATIONS:

E. J. KATES, *Chairman*

L. N. ROWLEY, JR. H. L. DRYDEN

W. A. CARTER J. M. JURAN

GEORGE A. STETSON, *Editor* K. W. CLENDINNING, *Managing Editor*

ADVISORY MEMBERS OF THE COMMITTEE ON PUBLICATIONS:

N. C. EBAUGH, GAINESVILLE, FLA. O. B. SCHIER, 2ND, NEW YORK, N. Y.

Junior Member

RICHARD S. BIDDLE, NEW YORK, N. Y.

Published monthly by The American Society of Mechanical Engineers. Publication office at 20th and Northampton Streets, Easton, Pa. The editorial department is located at the headquarters of the Society, 29 West Thirty-Ninth Street, New York 18, N. Y. Cable address, "Dynamic," New York. Price $1.50 a copy, $12.00 a year; to members and affiliates, $1.00 a copy, $7.50 a year. Changes of address must be received at Society headquarters two weeks before they are to be effective on the mailing list. Please send old as well as new address. . . . By-Law: The Society shall not be responsible for statements or opinions advanced in papers or . . . printed in its publications (B13, Par. 4) . . . . Entered as second-class matter March 2, 1928, at the Post Office at Easton, Pa., under the Act of August 24, 1912. . . .

Copyrighted, 1945, by The American Society of Mechanical Engineers. Reprints from this publication may be made on condition that full credit be given the Transactions of the A.S.M.E. and the author, and that date of publication be stated.

Depositories for A.S.M.E. Transactions in the United States, Including Territories and Dependencies

BOUND copies of the complete Transactions of The American Society of Mechanical Engineers will be found in the libraries in the United States and other countries which are listed on the following pages.

Alabama

Auburn.....Engineering Library, Alabama Poly. Inst.
Birmingham.....Public Library
University.....Library, University of Alabama

Arizona

Tucson.....Library, University of Arizona

Indexes to A.S.M.E. Papers and Publications

THIS and the following pages will serve as a guide to the current publications of the A.S.M.E.

Regular Society Publications, 1944

Mechanical Engineering, monthly (see index on page RI-55)
A.S.M.E. Transactions, monthly including the *Journal of Applied Mechanics* (see index on page RI-63)
A.S.M.E. Mechanical Catalog and Directory, 1945 edition.

Publications Issued in 1944

Bibliography of Aircraft Plywood
Design Data on Strength of Materials
Design Data on Mechanics
1942 Automotive and Oil Engine Power Cost Reports

American Standards

1944 Supplement to Socket Set Screws
Cast Iron Pipe Flanges and Flanged Fittings, Class 250

API-ASME Code for Unfired Pressure Vessels

1944 Supplement

Boiler Construction Code

1944 Addenda to:
- Locomotive Boiler Code
- Low-Pressure Heating Boiler Code
- Power Boiler Code
- Unfired Pressure Vessel Code
- Specifications for Materials
- Welding Qualifications

Power Test Codes

Coal Pulverizers
Gaseous Fuels

How to Find Papers Presented at 1944 A.S.M.E. Meetings

THE technical programs of the meetings of the Society and of its Professional Divisions have been published in *Mechanical Engineering* and may be located by consulting the index on pages RI-55–RI-62. A majority of these papers were published, or will be published, in *Mechanical Engineering* or the Transactions (including the *Journal of Applied Mechanics*) and may be located by reference to the indexes of these publications. Several additional papers and reports included in these 1944 programs were not published during the year in Transactions or *Mechanical Engineering* but were issued in mimeographed or photo-offset form.

Complete sets of these are on file for reference purposes at the office of the Society and the Engineering Societies Library, under the title of "Miscellaneous Papers Presented at A.S.M.E. Meetings, 1944." Photostat copies of any of the papers may be secured from the Library at twenty-five cents a page to members, or thirty cents a page to nonmembers.

Publications Developed by the Technical Committees

THE Society's technical committees, the first of which was organized many years ago and all of which have been continuously at work on codes, standards, research, and other special reports, have developed a series of publications of permanent value to the membership. The following list is presented here for record and for ready reference. This list covers the entire group of publications of these committees completed to date which are now available.

To assist members in securing copies of these publications the sale price is also given. A discount of 20 per cent is allowed to A.S.M.E. members on all publications except where otherwise noted.

A.S.M.E. AMERICAN STANDARDS

Bolt, Nut, and Rivet Proportions

Large Rivets (B18.4—1937), $0.65
Plow Bolts (B18f—1928), $0.35
Round Unslotted-Head Bolts (B18.5—1939), $0.50
Slotted-Head Proportions: Machine Screws, Cap Screws, and Wood Screws (B18c—1930), $0.45
Small Rivets (B18a—1927), $0.30
Socket Set Screws and Socket-Head Cap Screws (B18.3—1943), $0.40
Supplement to Socket Set Screws (B18.30—1944), $0.10
Tinners', Coopers', and Belt Rivets (B18g—1929), with 1942 Addendum, $0.35
Track Bolts and Nuts (B18d—1930), $0.40
Wrench-Head Bolts and Nuts and Wrench Openings (B18.2—1941), $0.65

Piping and Pipe Fittings

Air Gaps and Backflow Preventers in Plumbing Systems (A40.4—1942 and A40.6—1943), $0.45
Brass Fittings for Flared Copper Tubes (A40.2—1936), $0.35
Cast-Iron Pipe Flanges and Flanged Fittings for 25 Lb Maximum Saturated Steam Pressure (B16b2—1931), $0.40
Cast-Iron Pipe Flanges and Flanged Fittings Class 125 (B16a—1939), $0.60
Cast-Iron Pipe Flanges and Flanged Fittings Class 250 (B16b—1944), $0.45
Cast-Iron Pipe Flanges and Flanged Fittings for 800 Lb Maximum Hydraulic Pressure (B16b1—1931), $0.35
Cast-Iron Soil Pipe and Fittings (A40.1—1935), $0.65
Cast-Iron Long Turn Sprinkler Fittings for 150 and 250 Lb Maximum Saturated Steam Pressure (B16g—1929) and Addendum (B16g1—1937), $0.50
Cast-Iron Screwed Fittings for 125 and 250 Lb Maximum Saturated Steam Pressure (B16d—1941), $0.40
Cast-Iron Screwed Drainage Fittings (B16.12—1942), $0.45
Code for Pressure Piping (B31.1—1942), $2.00
Face-to-Face Dimensions of Ferrous Flanged and Welding End Valves (B16.10—1939), $0.55
Ferrous Plugs, Bushings, Lock Nuts, and Caps (B16.14—1943), $0.40
Malleable-Iron Screwed Fittings for 150 Lb Maximum Saturated Steam Pressure (B16c—1939), $0.50
Pipe Plugs (B16e2—1936), $0.35
Pipe Threads (B2.1—1942), $0.75
Scheme for the Identification of Piping Systems (A13—1928), $0.50
Steel Pipe Flanges and Flanged Fittings for 150 to 2500 Lb Maximum Steam Service Pressure (B16e—1939), $1.25
Soldered-Joint Fittings (A40.3—1941), $0.45
Steel Butt-Welding Fittings (B16.9—1940), $0.40
Threaded Cast-Iron Pipe for Drainage, Vent, and Waste Services (A40.5—1943), $0.25
Wrought-Iron and Wrought-Steel Pipe (B36.10-1939), $0.50

Letter and Graphical Symbols and Charts

Abbreviations for Scientific and Engineering Terms (Z10.1—1941), $0.35
Drawings and Drafting-Room Practice (Z14.1—1935), $0.50
Engineering and Scientific Charts for Lantern Slides (Z15.1—1932), $0.50
Engineering and Scientific Graphs for Publications (Z15.3—1943), $0.75
Graphical Symbols for Use on Drawings in Mechanical Engineering (Z32.2—1941), $0.50
Letter Symbols for Gear Engineering (B6.5—1943), $0.25
Letter Symbols for Hydraulics (Z10.2—1942), $0.35
Letter Symbols for Mechanics of Solid Bodies (Z10.3—1942), $0.25
Letter Symbols for Heat and Thermodynamics (Z10c—1943), $0.35
Time Series Charts (Z15.2—1938), $1.25

MISCELLANY

Fire-Hose Coupling Screw Threads (B26—1925), $0.25
Gear Materials and Blanks (B6.2—1933), $0.50
Hose Coupling Screw Threads (B33.1—1935), $0.25
Indicating Pressure and Vacuum Gages (B40—1939), $0.40
Preferred Thickness for Uncoated Thin Flat Metals (B32.1—1941), $0.25
Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases (C44—1931), $0.35
Shaft Couplings (B49—1932), $0.35
Spur Gear Tooth Form (B6.1—1932) $0.45

Small Tools and Machine Tool Elements

Machine Tapers (B5.10—1943), $0.60
Milling Cutters (B5c—1930), $0.75
Reamers (B5.14—1941), $0.75
Taps—Cut and Ground Threads (B5.4—1939), $1.25
Terminology and Definitions for Single-Point Cutting Tools (B5.13—1939), $0.40
Adjustable Adapters (B5.11—1937), $0.50
Chucks and Chuck Jaws (B5.8—1936), $0.45
Circular and Dovetailed Forming Tool Blanks and Holding Elements (B5.7—1943), $0.50
Shafting and Stock Keys (B17.1—1943), $0.45
Markings for Grinding Wheels (B5.17—1943), $0.25
Involute Splines, Side Bearings (B5.15—1939), $0.65
Jig Bushings (B5.6—1941), $0.35
Lathe Spindle Noses (B5.9—1936), $0.50
Spindle Noses and Arbors (B5.18—1943), $0.25
Rotating Air Cylinders and Adapters (B5.5—1932), $0.35
Tool Holder Shanks Tool Post Openings (B5.2—1943), $0.35
T-Slots, Their Bolts, Nuts, Tongues, and Cutters (B5a—1941), $0.35
Twist Drills (B5.12—1940), $0.55
Code for Design of Transmission Shafting (B17c—1927), $0.75
Shafting and Stock Keys (B17.1—1934), $0.45
Screw Threads for Bolts, Nuts, Machine Screws, and Threaded Parts (B1.1—1935), $0.60
Screw Thread Gages and Gaging (B1.2—1941), $0.60
Acme and Other Translating Threads (B1.3—1941), $0.45
Tolerances, Allowances, and Gages for Metal Fits (B4a—1925), $0.50
Woodruff Keys, Keyslots, and Cutters (B17f—1930), $0.35

BOILER CONSTRUCTION CODE

1943 Editions: with 1944 Addenda
- Locomotive Boiler Code, $0.75
- Low-Pressure Heating Boiler Code, $0.75
- Miniature Boiler Code, $0.50
- Power Boiler Code, $2.25
- Specifications for Materials, $3.00
- Suggested Rules for Power Boilers, $1.00
- Unfired Pressure Vessel Code, $1.50
- Welding Qualifications, $0.65

Boiler Code Interpretation Service, $5.00 annually
API-ASME Code for Unfired Pressure Vessels
1943 Edition, with 1944 Supplement, $1.25

POWER TEST CODES AND AUXILIARY SECTIONS

Test Codes for

Atmospheric Water-Cooling Equipment (1930), $0.45
Coal Pulverizers (1944), $0.70
Displacement Compressors, Vacuum Pumps, and Blowers (1939), $0.75
Dust Separating Apparatus (1941), $0.90
Evaporating Apparatus (1941), $0.50
Feedwater Heaters (1927), $0.35
Gaseous Fuels (1944), $0.75
Gas Producers (1928), $0.55
Hydraulic Prime Movers (1938 with 1942 Addenda), $0.60
Internal-Combustion Engines (1930), $0.55
Reciprocating Steam-Driven Displacement Pumps (1927), $0.65
Reciprocating Steam Engines (1935), $0.65
Refrigerating Systems (1927), $0.55
Solid Fuels (1931), $0.55
Speed-Responsive Governors (1927), $0.45
Steam Condensing Apparatus (1938), $0.65
Steam Locomotives (1941), $0.55
Steam Turbines (1941), $2.50
Appendix to Test Code for Steam Turbines (1943), $1.50

Auxiliary Sections

General Instructions (1929), $0.35
Definitions and Values (1931), $0.40
Part 1 — General Considerations (1935), $0.35
Part 2 — Pressure Measurement
- Chapter 1, Barometers; Chapter 6, Tables, Multipliers, and Standards (1941), $0.60
- Chapter 4, Bourdon, Bellows, Diaphragm, and Deadweight Gages (1938), $0.65
- Chapter 5, Liquid Column Gages (1942), $0.75

Part 3 — Temperature Measurement
- Chapter 1, General; Chapter 5, Pyrometric Cones; Chapter 6, Liquid-in-Glass Thermometers; and Chapter 7, Bourdon-Tube Thermometers (1931), $0.75
- Chapter 2, Radiation Pyrometers (1936), $0.55
- Chapter 3, Thermocouple Thermometers or Pyrometers (1940), $0.65
- Chapter 8, Optical Pyrometers (1940), $0.35

Part 4 — Head Measuring Apparatus (1933), $0.35
Part 5 — Chapter 4, Flow Measurement by Means of Standardized Nozzles and Orifice Plates (1940), $2.75
Part 6—Electrical Measurements (1934), $1.25
Part 8—Measurement of Indicated Horsepower (1941), $0.75
Part 9—Heat of Combustion (1943), $0.40
Part 11—Determination of Quality of Steam (1940), $0.45
Part 12—Measurement of Time (1942), $0.40
Part 13—Speed Measurements (1939), $0.45
Part 14—Linear Measurements (1936), $0.55
Part 15—Measurement of Surface Areas (1937), $0.75
Part 16—Density Determinations (1931), $0.30
Part 17—Determination of the Viscosity of Liquids (1931), $0.45
Part 18—Humidity Determinations (1932), $0.50
Part 20—Smoke-Density Determinations (1936), $0.65
Part 21—Leakage Measurements (1942), $0.60

RESEARCH

Fluid Meters:
- Part 1—Theory and Application (1937), $3.00
- Part 2—Description of Meters (1931), $1.75
- Part 3—Selection and Installation (1933), $1.50

Report of the A.G.A.-A.S.M.E. Committee on Orifice Coefficients (1935), $2.75
Tests on Electrical Equipment for Drilling Rotary Drilled Oil Wells (1933), $0.85
Tests on Steam Equipment for Drilling Rotary Drilled Oil Wells (1932), $0.85
Bibliography on Aircraft Plywood (1944), $1.00
Bibliography on Deterioration of Condensing Equipment (1845–1930), $1.25
Bibliography on Management Literature and Supplement (1903–1935), $2.75
Bibliography on Marketing Research (1935), $1.00
Bibliography on Woods of the World (1928), $1.25

SAFETY CODES

Safety Code for Cranes, Derricks, and Hoists (B30.2—1943), $1.50
Safety Code for Elevators (A17.1—1937 with 1942 Supplement), $1.00
Elevator Inspectors' Manual (A17.2—1937), $0.75
Safety Code for Jacks (B30.1—1943), $0.30
Safety Code for Mechanical Power-Transmission Apparatus (B15—1927), $0.35
Compressed-Air Machinery and Equipment (B19—1938), $0.30

Biographies

BIOGRAPHIES issued under the sponsorship of the A.S.M.E. Biography Committee are as follows:

Autobiography of John A. Brashear (1924), $5.00
Autobiography of an Engineer, by W. LeR. Emmet (1940), $3.50
Autobiography of John Fritz (1940), $3.25
Biography of James Hartness, by Joseph W. Roe (1937), $4.00
Biography of Fred J. Miller (1941), $1.00
Biography of John Stevens, by Archibald Douglas Turnbull (1928), $5.00
Biography of John Edson Sweet, by A. W. Smith (1925), $4.50
Biography of Robert Henry Thurston, by William F. Durand (1929), $5.00
Life of Henry Laurence Gantt, by L. P. Alford (1934), $5.00

Books on Special Subjects

Reflections on the Motive Power of Heat (1943), $2.75
Corrosion-Resistant Metals (1936), $1.25
Design Data on Strength of Materials, Book 1 (1944), $1.50
Design Data on Mechanics (1944), $1.50
Engineering's Part in the Development of Civilization (1939), $1.50
Flow of Water in Pipes and Pipe Fittings (1941), $8.00
General Discussion on Lubrication (1938) (no discount), $6.50
Hydraulic Laboratory Practice (1929), $10.00
Hydraulic Structures (1937), $18.00
I.S.A. Tolerance System (1942), $2.50
Manual on Cutting of Metals (1939), $5.00
Manual of Consulting Practice (1939), $0.40
Oil Engine Power Cost Report (1942), $1.25
1942 Automotive Diesel Engine Cost and Performance Data (1944), $0.25
Sixty Year Index to A.S.M.E. Technical Papers (1941), $3.75
Surface Finish (1942) (no discount), $3.25
Theoretical Steam Rate Tables (1937), $1.25

Regular Society Publications

*Mechanical Engineering**—Annual Subscription rate in United States $6.00; to Canada $6.75; elsewhere, $7.50
A.S.M.E. Transactions,* including *Journal of Applied Mechanics*, Annual subscription rate in United States, $12.00, elsewhere, $12.75
1945 A.S.M.E. Mechanical Catalog and Directory, $3.00 (sent gratis to members upon request)

---

*Subscription price included in A.S.M.E. membership dues.
